While EAN is a purely T cell-mediated process, the situation in AIDP may be more complex. It has been established that plasmapheresis exerts a beneficial effect on the course of the human illness. Since plasmapheresis removes circulating immunoglobulin, among other plasma components, the possibility that circulating antibody may have a role in the pathogenesis of the Guillain-Barré syndrome is attractive. Complement-fixing myelin-specific IgM antibodies (most cases) and IgG antibodies that bind to GM1 ganglioside (20% of cases) have been reported in the serum in AIDP, particularly early in the course of the illness, a finding which lends credence to this suggestion. Demonstration of the terminal attack complex of complement both in the blood and the spinal fluid in AIDP cases reinforces the contention that antibody has a role in the pathogenesis of AIDP. At the same time the process is unlikely to be purely and simply antibody-mediated since this will not account for the inflammatory cellular infiltrates that are the pathologic hallmark of the disease. A synergism between an antibody-mediated process and a T cell-mediated one is distinctly possible. The blood-nerve barrier is ordinarily impervious to immunoglobulin but access into the nerves may be provided when a cellular immune response opens the blood-nerve barrier. EAN can be adoptively transferred with T cells, but the disease is more severe if recipients are also given myelin-specific antibody.

The clinical diagnosis of AIDP usually presents little difficulty. Onset of symptoms is subacute – evolution is complete after 2 weeks in 50% of cases, after 3 weeks in over 80%, and after 4 weeks in over 90%. A stable period, which is usually brief, is followed by a recovery period that proceeds to completion within a period of weeks to a few months. Fifteen per cent of cases are left with a permanent handicap. In most instances the disease is monophasic; about 5% of cases have one or more recurrences.

The major complaint is of weakness, which covers a wide spectrum from mild ataxia to total paralysis of every motor and cranial nerve. In most instances, weakness begins in the legs, more commonly distally at first and then proximally, but the arms may be involved before the legs and proximal involvement may precede distal. The process is characterized by relative but seldom absolute symmetry. Facial weak-

ness, usually bilateral, is noted in half the cases. In 20% of cases weakness becomes so profound that respiratory assistance is required. Tendon reflexes are generally abolished. Ataxia may be prominent early in the disease and can cause confusion as to the diagnosis. Sensory symptoms are in general less prominent than motor ones, although almost all patients complain of subjective tingling or numbness, usually in a distal symmetric glove- and stocking-like distribution. Objectively demonstrable sensory loss is less extensive than the subjective complaints would lead one to anticipate. Significant muscular or neuropathic pain occurs in 30% of cases. Autonomic function is frequently abnormal and may cause wide fluctuations in blood pressure, pulse, abnormalities of sweating, and gastric atony.

The cerebrospinal fluid (CSF) protein is normal during the first few days of the illness, but then rises, reaching sometimes very high values after 3–4 weeks. Cells in the CSF are not prominent, but a few cases may show 20–30 cells mm⁻³ and in those cases associated with HIV infection a pleocytosis is the norm rather than the exception. Conduction of nerve impulses through areas of segmental demyelination is severely compromised. Conduction velocity is characteristically slowed, though not invariably so, and prolonged distal latencies are frequent. Nerve conduction studies, if carefully performed, reveal abnormalities in 90% of cases.

In severe cases, the major effort in terms of clinical management must be devoted to the prevention of complications. Seriously ill patients are best cared for in intensive care or respirator units. A course of vigorous plasmapheresis treatment has been shown to lessen time of hospital confinement, and in severe cases, to lessen time spent on a respirator. Response to intravenous immunoglobulin is sometimes seen. Immunosuppressive and glucocorticoid treatments are not recommended.

Acute motor axonal neuropathy (AMAN) This is the commonest form of the Guillain-Barré syndrome in China and Mexico. Most cases follow *Campylobacter jejuni* infection. AMAN is primarily a disease of children and young adults from rural areas. Incidence peaks in the summer whereas AIDP occurs throughout the year. The clinical presentation is purely motor, often with total paralysis. Electrical studies indicate axonal damage rather than demyelination. Pathologic study of fatal cases has revealed axonal interruption confined to motor roots in some cases but no axonal interruption in others. The absence of axonal interruption in some cases is not surprising since recovery is usually rapid, at a tempo in keeping with axonal functional compromise

but inconsonant with frank axonal interruption. Immunoglobulin and complement are deposited on axons at nodes of Ranvier. Macrophages are found interdigitated between axons and overlying intact myelin, a location totally different from that seen in AIDP. T Cells are absent. Many cases have had antibodies to GM1 ganglioside. The disease is thought to be antibody-mediated. From 5 to 20% of Guillain-Barré cases in the United States and Europe have this form of the disease. Response to intravenous immunoglobulin treatment has been reported.

Acute sensori-motor axonal neuropathy (ASMAN) This form of the Guillain-Barré syndrome has the same pathologic features as AMAN except that both motor and sensory roots are involved. The process is purely axonal and likely to be severe. Recovery is delayed relative to AMAN, pointing to more extensive axonal interruption. ASMAN is relatively rare in the USA and Europe.

The Miller Fisher syndrome (MFS) This form of the Guillain-Barré syndrome constitutes not more than 5% of cases. The clinical picture is one of ophthalmoplegia, ataxia and areflexia. Most cases follow *Campylobacter jejuni* infection. The process is usually self-limited and response to plasmapheresis is often gratifying. Almost all MFS cases have antibody to GQb1 ganglioside, a minor ganglioside of peripheral nerves but one that is enriched at nodes of Ranvier of the extraocular nerves and in dorsal root ganglia. The former location is relevant to the ophthalmoplegia and the latter to the ataxia and areflexia. It seems likely that the antibody to GQb1 ganglioside causes the disease.

Chronic inflammatory demyelinating polyneuropathy

This illness is generally viewed as a variant of AIDP. The process is indolently progressive, however, rather than explosive in onset. A history of an antecedent infection is uncommon. The clinical presentation is one of weakness with absence of deep tendon reflexes and distal sensory loss. Nerve conduction studies reveal slowing, a finding that points to a demyelinating process. The pathologic hallmark is T cell and macrophage infiltrates with accompanying demyelination, though the inflammatory infiltrates are less florid than in AIDP. Some cases have responded to plasmapheresis treatment or intravenous immunoglobulin and a favorable clinical response to glucocorticoids is sometimes observed.

Dorsal root ganglion neuronitis

This is a rare disease. Most cases have had an associated neoplasm, most commonly small cell carcinoma of the lung, though sporadic cases are encountered. The pathologic feature is one of a lymphocytic and macrophagic infiltrate of dorsal root ganglia with destruction of dorsal root neurons. The clinical presentation is one of progressive sensory loss and areflexia with preservation of muscle strength. The sensory loss may advance to the point that the patient becomes bedridden. Antibodies to a protein called Hu, found in dorsal root and other neurons, can be detected in most cases associated with lung cancer. Hu-specific antibodies recognize a family of 35–37 kDa RNA-binding proteins that are encoded by at least three discrete genes. Hu proteins bind AU-rich regions of mRNAs that regulate cell proliferation. The disease is thought to be autoimmune, but formal proof for this contention is lacking. A similar neuropathy with like pathology sometimes complicates Sjögren's syndrome.

Acute pandysautonomia

Fewer than 50 cases of this illness have been described. The disease is characterized by an acute loss of sympathetic and parasympathetic function with severe orthostatic hypotension, anhidrosis, dry eyes and mouth, disturbed bladder and bowel function, fixed heart rate, and fixed pupils. A few cases have had an associated small cell cancer of the lung but most have been sporadic. The illness is monophasic and sometimes remits, but most cases are left with at least some residual disability.

Demyelinating neuropathy associated with antimyelin-associated glycoprotein (MAG) antibodies

This illness presents as a slowly progressive, symmetric mixed (motor and sensory) neuropathy with slowed nerve conduction. Most often it has been associated with an IgMκ gammopathy and the IgMκ binds to a 100 kDa myelin protein known as myelin-associated glycoprotein (MAG), to carbohydrate moieties on several other myelin-associated glycoproteins of lower molecular weight, and to acidic sulfoglucuronyl glycolipids of myelin. IgMκ and complement deposits along myelin sheaths in nerve can be detected and by electron microscopy a widening of myelin lamellae at the minor dense line can be shown. There are no inflammatory cells. Injection of the monoclonal antibody into experimental animals reproduces the disease. Some cases have responded to plasmapheresis or to treatment of their underlying gammopathy with cytotoxic drugs.

Multifocal motor neuropathy with conduction block

This entity is characterized by weakness that is asymmetric, usually distal, and affecting the arms more than the legs. There may be wasting, fasciculations and cramps. Reflexes are paradoxically preserved. The clinical features may mimic those of amyotrophic lateral sclerosis. Electrical study reveals denervation and motor nerve conduction block. These patients have a monoclonal IgM antibody that binds to GM1 and GD_{1b} gangliosides as well as to motor end-plates at the neuromuscular junction. Experimental animals immunized with GM1 ganglioside develop a similar disease and injection of patient antibody into animals reproduces it. It seems likely, therefore, that the monoclonal antibody causes the disease. Some patients have improved when antibody titer was lowered or in response to cytotoxic agents.

Neuropathy of sclerosing myeloma

Most myelomas are osteolytic but from 1 to 3% cause bone sclerosis. Fifty per cent of sclerosing myelomas are associated with a neuropathy that is slowly progressive but nonetheless invariably fatal unless the sclerosing myeloma is discovered and treated. Pathologically, the process is characterized by destruction of both myelin and axons. Sclerosing myelomas produce monoclonal IgM or IgA, but the quantity may be small and a spike may not be detected in the blood. Monoclonal IgG or IgA is not deposited in the damaged peripheral nerves. In addition to the neuropathy there may ultimately be widespread failure of other organs plus bony overgrowth at a distance from the myeloma as, for example, in lumbar vertebrae. The condition is often called the POEMS syndrome because of associated features including polyneuropathy, organomegaly, endocrinology, an M-spot, and skin changes.

The cause of this neuropathy is not known, but it is likely that products other than immunoglobulin that are toxic to peripheral nerves are released in excess by sclerosing myelomas or by macrophages, induced to do so by some product released by the myeloma cells. Candidates include calcitonin, interleukin 1, interleukin 6, tumor necrosis factor α , vascular endothelial growth factor or some combination of them. All of the above are found in increased amount in the circulation of patients with this neuropathy. Radiation of an isolated myeloma can be followed by remission. When disease is more widespread, response to chemotherapy is sometimes obtained.

Central nervous system

Postinfectious and postrabies vaccination encephalomyelitis

This is an acute monophasic illness in which the brain and spinal cord are peppered with innumerable minute perivenular foci of demyelination. T Lymphocytes and macrophages, the final vectors of myelin destruction, are found at sites of myelin destruction. T Cells from patients proliferate *in vitro* when exposed to a protein of central nervous system myelin known as myelin basic protein (MBP). Antibodies to MBP are also detectable in most instances. In former times the majority of cases came on within a few days of the development of a measles rash. Such cases are now rare except in those less developed countries where measles remains endemic. An identical syndrome is seen as a complication of rabies vaccination with vaccines prepared from brain tissue. Animals immunized with MBP develop the same disease. The animal model, which is mediated by a delayed-type hypersensitivity response, is called experimental autoimmune encephalomyelitis (EAE).

Clinically postinfectious encephalomyelitis begins abruptly with symptoms and signs that point to damage chiefly of the white matter of the brain and spinal cord. Headache and delirium at onset may give way to lethargy and coma. Seizures at onset are frequent. There may be neck stiffness and fever. Focal signs may be superimposed, spinal cord involvement with limb paralysis being the most frequent. The spinal fluid shows an increased protein content and sometimes a lymphocytic pleocytosis. Mortality is 20%, and half the survivors have residual deficits. The illness does not recur. Administration of high doses of glucocorticoids every 4–6 h is the treatment of choice.

Multiple sclerosis

Multiple sclerosis (MS) is characterized by areas of myelin destruction in the central nervous system known as plaques. Central nervous system myelin is made by oligodendrocytes and as the illness progresses oligodendrocytes come to be lost. In addition, axons coursing through areas of demyelination may be destroyed, particularly in the later stages of the disease.

MS usually begins in early adult life though some patients do not manifest clinical symptoms until the 5th or 6th decades. Two-thirds of cases are in women. MS is characterized by attacks which last for days to weeks followed by remissions which may last from months to years. Recovery from early attacks may be complete or incomplete, but as one attack follows another residual disability

accumulates. A proportion of patients present with a slowly but nonetheless inexorably progressive illness rather than with the more frequent pattern of attacks followed by remissions. Others may, after a time, sometimes many years, switch from a relapsing–remitting course to a progressive one. The basis for the switch from flaring–remitting to progressive disease is not known.

The clinical features of the disease are protean. This reflects the fact that any site within the CNS white matter can be attacked by invading inflammatory cells. Nonetheless, there are certain sites of predilection. These include the optic nerves, the periventricular and deep white matter of the cortex, cerebellar inflow and outflow tracts, and the spinal cord. As a consequence visual loss, spasticity, weakness, incoordination, diplopia, and sensory loss, particularly of vibration and joint sense, are frequent features.

Multiple sclerosis is an inflammatory disease. B cells, macrophages, and CD4⁺ and CD8⁺ T cells are found within and at the margins of active plaques. All these cell types are activated; the B cells synthesize IgG which exhibits oligoclonal restrictions, the macrophages release interleukin 1 (IL-1), tumor necrosis factor α (TNF α), and IL-6. The CD4⁺ T cells are chiefly of the T_H1 cell subset. They secrete IL-2, IFN γ and lymphotoxin (LT), all of which are found in active MS plaques.

MS is most commonly viewed as an autoimmune disease, but no antigen against which the immune response is thought to be directed has been identified. Periodically, interest in a viral causation for MS resurfaces, but to the present no virus has been identified that links to the disease despite diligent search. Nonetheless, there is reason to believe that an MS-relevant antigen does exist.

Propensity to develop MS is at least in part genetically determined. Concordance for MS between siblings is 3%, a value some 25 times that for the population at large. For identical twins, concordance is 20%, based on clinical features, but if paraclinical features (abnormal MRI scan or spinal fluid) are taken into account concordance rises to 40%. Inheritance of susceptibility is surely polygenic since the steep drop in concordance from monozygotic twins, who share all their genes, to siblings who share half their genes cannot be explained by any single gene model.

Genes alone do not determine who will get MS since even in identical twins concordance is only 40%. This observation indicates that some environmental factor is also in play. Identical twins, both with MS, can have disease of quite different severity so that disease course is determined by something

other than genetic endowment. One gene marker has been identified that is overrepresented in MS populations though it is not necessarily present in any individual MS patient. This is the class II histocompatibility allele HLA-DR2/DQW1 on chromosome 6.

Most attacks of MS occur without any obvious triggering event. It is known, however, that viral infections in MS patients are commonly followed within a few weeks by an MS attack at a frequency 3–5 times background. Administration of IFN γ also triggers attacks. Since IFN γ is one of the products of activated T_H1-type T cells and since infectious illness activates these same cells it is possible that both triggering events are in fact the same. Many MS patients relate a period of stress as an antecedent to their attack. Their contention may have merit but must be viewed as conjectural at this time. Pregnancy protects in MS; attack frequency falls well below baseline levels during the second and third trimesters.

Several abnormalities have been detected in the blood at the onset of and during MS attacks. IL-2 and IFN γ levels rise, whereas release by macrophages of prostaglandin, an inhibitor of immune responses, falls at onset of attacks. An increased proportion of activated CD4⁺ T cells has also been noted. Non-specific suppressor function is reduced during MS attacks and recovers with remission. The defect in suppressor function lies primarily in CD8⁺ T cells.

Considerable effort has gone into a search for agents that will correct these abnormalities with the hope that such agents once identified will prove efficacious therapeutically. IFN β corrects deficient non-specific suppressor function and lowers IFN γ production by activated T_H1-type T cells. Interleukin 10 is an inhibitory cytokine for T_H1-type T cells. IFN β increases IL-10 production. IFN β lessens MS attack frequency and is widely used to treat the disease.

B cells in MS plaques make immunoglobulin but whether any of this is directed against an MS-relevant antigen is not known. What is known is that antibodies to numerous viruses as well as to epitopes that clearly have nothing to do with MS, for example tetanus toxoid, are synthesized within the CNS. It is thus evident that some of the antibodies being made are irrelevant antibodies insofar as the pathogenesis of MS is concerned. Possibly all are irrelevant antibodies.

TNF α is synthesized by activated macrophages and microglia. TNF α causes oligodendrocytes to retract their processes and to close their K⁺ channels, at least *in vitro*. When TNF α is added to organotypic cultures demyelination ensues and death of oligodendrocytes has also been reported. The notion that TNF α may be a major vector of myelin destruction in MS is attractive since IFN γ , a product of activated

T_H1 -type T cells, is known to induce both $TNF\alpha$ synthesis and secretion by macrophages and as mentioned $IFN\gamma$ provokes attacks of MS. Activated T_H1 -type T cells release lymphotoxin ($TNF\beta$) in addition to $IFN\gamma$. Lymphotoxin binds to the same cell receptors as $TNF\alpha$ and duplicates many of its actions. Accordingly, a delayed-type hypersensitivity response mediated by T_H1 -type T cells acting in conjunction with macrophages is thought to have a major role in the genesis of MS lesions. $TNF\alpha$ and LT have totally different effects on astrocytes than on oligodendrocytes. $TNF\alpha$ and LT promote astrogliosis as does IL-1, another product of activated macrophages. It should be noted that astrogliosis is a characteristic feature of established MS lesions.

$CD8^+$ T cells are also present in MS plaques. $CD8^+$ T cells have two established functions. The first is cytolysis mediated by perforin and other molecules secreted by killer cells once they have made contact with antigen presented within the epitope-bearing cleft on the class I major histocompatibility complex (MHC) molecules of the target cell. Perforins are capable of damaging oligodendrocytes, and though oligodendrocytes in health do not express class I MHC, they can be induced to do so by $IFN\gamma$. Thus the anatomical substratum for cytolysis exists within the brain but whether $CD8^+$ T cell-mediated cytolysis occurs in fact is not known.

The second major role for $CD8^+$ cells is suppression. In most strains of rats or mice, experimental autoimmune encephalomyelitis (EAE) is a monophasic disease; animals that have recovered from an EAE attack rarely relapse. $CD8$ knockout mice lack $CD8$ cells. In them, EAE is a relapsing disease. The data suggest a role for $CD8$ suppressor cells as a preventor of relapses. The loss of $CD8$ suppressor cell function observed at the time of MS attacks may be relevant in this regard. $CD8$ knockout mice recover from their first attack at the same tempo as controls. Relapses are also self-limited. Though $CD8$ cells are found in the brain in MS it is by no means clear that they have any role in the ending of an attack.

Secondarily, progressive MS poses a problem. The reason why the disease should change its course is not understood. Progressive MS patients are almost invariably spastic. It has been proposed that a strategic hit of the disease itself interferes with normal communications between the nervous and immune systems and that this unfavorably alters immune homeostasis. There is increasing evidence that the nervous system does exert some control over the immune system. Pituitary hormones may either up- or downregulate the immune system. Prolactin, for example, is stimulatory to the immune system

whereas corticotropin is inhibitory. The lymphoid organs also receive a substantial intraparenchymal sympathetic innervation. Ablation of the sympathetic nerves in experimental animals is followed by augmented immune responses. The severity of EAE, for example, is augmented in sympathetic nervous system (SNS)-ablated rats whereas treatment with the β -adrenergic agonist drug isoproterenol lessens the severity of EAE. Lymphocytes carry β_2 -adrenergic receptors and the number of these receptors rises following SNS ablation.

In progressive MS patients it is often possible to show that SNS function is defective, presumably because MS lesions have interrupted the normal flow of signals down the spinal cord to the neurons in the lateral columns that relay to the sympathetic ganglia and to the adrenal medulla. β -Adrenergic receptor density on $CD8^+$ T cells is 2–3-fold upregulated in progressive MS, suggesting that the progressive MS patient may be a mimic, albeit an imperfect one, for the SNS-ablated rat. Alternatively increased β_2 -adrenergic receptor on $CD8^+$ T cells may simply reflect immune system activation.

The mainstay of treatment of multiple sclerosis attacks is glucocorticoid therapy. One popular treatment regimen is intravenous solumedrol at a dose of 250 mg every 6 h for from 3 to 5 days.

Necrotizing myelopathy

In this rare disease the central core of the spinal cord is destroyed. Macrophages are prominent in areas of necrosis; lymphocytes are rare. Spinal cord destruction begins most often in the thoracic region and extends rostrally and caudally over time. The illness occurs sporadically but is also seen on a background of systemic lupus erythematosus or of pulmonary tuberculosis, in heroin addicts and as a remote effect of cancer particularly small cell carcinoma of the lung and lymphoma. There is some evidence to suggest that the process is antibody-mediated.

Acute necrotizing hemorrhagic leukoencephalitis

This devastating affliction comes on with brutal suddenness, usually after an ill-defined upper respiratory illness. It resembles postinfectious encephalomyelitis in the sense that perivenular inflammatory foci are found but in addition there is fibrinoid necrosis of blood vessels, multiple foci of petechial hemorrhage and frank necrosis of brain substance. A model for it has been developed by superimposing a Sanarelli–Shwartzman reaction on to the standard immunization protocol for induction of EAE.

Paraneoplastic cerebellar degeneration (PCD)

This is the most frequently encountered paraneoplastic syndrome affecting the CNS. PCD occurs on a background of one of the following tumors: 1) small cell cancer of the lung, 2) Hodgkin's disease, 3) breast cancer, 4) ovarian cancer, and 5) cancer of the female genital tract. The neurologic syndrome may antedate detection of the underlying tumor by months or even years. Onset is subacute with escalating difficulties in coordination of the limbs and trunk, disturbed speech and chaotic eye movements. Ultimately the patient may be rendered bedfast. The spinal fluid protein often shows a mild elevation of protein and a modest lymphocytic pleocytosis. Magnetic resonance imaging is usually normal early in the course but after a time diffuse cerebellar atrophy may become apparent. Pathologically there is selective loss of cerebellar Purkinje cells and of the neurons of the deep cerebellar nuclei. Perivascular mononuclear cell cuffing in the cerebellum, brainstem and leptomeninges may or may not be present.

In cases with breast cancer, ovarian cancer or cancer of the female genital tract, antibodies that react with the cytoplasm of Purkinje cells, so-called Yo-specific antibodies, can be demonstrated. Yo-specific antibodies react against two Purkinje cell proteins. The first has a molecular weight of 34 kDa and a remarkable structure with inexact tandem repeats of a six amino acid unit extending over 90% of its sequence. No function for this protein is known. The second protein has a molecular weight of 62 kDa and is a leucine zipper RNA-binding protein. Both proteins are found in the tumors of patients with subacute cerebellar degeneration and in 20% of tumors of the same organs from other patients. Yo-specific antibodies are found in the spinal fluid; they are synthesized locally within the CNS. Cases of PCD on a background of small cell lung cancer frequently have Hu-specific antibodies. Some cases occur in the absence of an underlying tumor.

The role that antibody against Purkinje cell cytoplasm plays in the disease is uncertain. Most patients with Hodgkin's disease and subacute cerebellar degeneration do not have antibodies to neuronal components, yet their clinical picture is indistinguishable from those who do.

Response to glucocorticoids and plasma exchange has been disappointing.

Paraneoplastic encephalomyelitis

A small proportion of patients with small cell cancer of the lung have circulating Hu-specific antibodies that react with the nuclei of all neurons of the human brain, spinal cord and dorsal root ganglia in a diffuse

homogeneous pattern with sparing of the nucleoli. Hu antigens are found in all small cell cancers. Antibodies to Hu antigens are present in the spinal fluid; much of this antibody is synthesized intrathecally.

Patients with Hu-specific antibodies may develop 'encephalomyelitis'. The clinical picture has varied widely. Cases have been described showing: 1) relatively selective involvement of the cerebellum as described above; 2) brainstem encephalitis; 3) anterior horn cell degeneration; 4) necrotizing myelopathy; 5) dorsal root ganglion neuronitis; 6) the Lambert-Eaton syndrome (which clearly is not caused by Hu-specific antibodies); and 7) various combinations of the above. These various entities have already been discussed. In addition, some cases with antibodies against Hu have presented with limbic encephalitis, an entity in which the mesial portions of the temporal lobes are selectively destroyed. Profound memory loss is the predominant clinical feature of limbic encephalitis. Partial complex seizures are frequent as well. It is unclear why individuals with Hu-specific antibodies should develop such varied clinical manifestations. What is clear is that when a paraneoplastic syndrome is suspected, the presence of anti-Hu provides a marker for the presence of an underlying small cell cancer. A finding of Hu-specific antibodies is important since the tumor is likely to be occult and/or resectable.

Stiff man syndrome

This rare disease is characterized by axial and limb rigidity and painful spasms. More cases occur in men than in women. Stiff man syndrome occurs both sporadically and as a remote effect of cancer. Most sporadic cases, but not all, have high titer circulating antibodies to glutamic acid decarboxylase (GAD). The enzyme catalyzes the formation of gamma amino butyric acid (GABA) from glutamic acid. GABA is a major inhibitory neurotransmitter and GABA agonists ameliorate the symptoms of stiff man syndrome. Ten per cent of cases have epilepsy. GABA agonists are antiepileptic. Antibodies to GAD are a marker for insulin-dependent diabetes mellitus though the titers are much lower than in stiff man syndrome. One-third of cases of stiff man syndrome have diabetes. There is a high incidence of autoimmune diseases in sporadic cases. It seems likely that GAD-specific antibodies cause the disease.

Stiff man syndrome also occurs on a background of breast cancer and very rarely other tumors. Breast cancer patients do not have antibodies to GAD. Rather, they have antibodies to amphiphysin, a 128 kDa nonmembrane protein but one that is concentrated at presynaptic vesicles. The topography of amphiphysin largely overlaps that of GAD. Its func-

tion is unknown but a role in neurotransmitter exocytosis seems likely. Response to immunotherapy has been seen in some cases.

Rasmussen's encephalitis

This is a rare disease of childhood. The clinical features are intractable seizures, progressive hemiparesis, and intellectual deterioration. The pathologic features are progressive unilateral cortical atrophy with lymphocytic infiltrates in the involved hemisphere. Several cases have had circulating antibodies to the GluR3 glutamate receptor.

Anti-phospholipid antibodies, strokes, epilepsy and migraine

Antibodies to phospholipid are seen in 25% of systemic lupus erythematosus cases. They also occur sporadically. Phospholipid-specific antibodies bind to and activate platelets. This leads to vascular thromboses which, when they occur in the CNS, cause strokes. Areas of infarction provide a nidus for focal seizures. Platelets are activated during migraine, and platelet activation by phospholipid-specific antibodies is one cause, albeit rare, of migrainous symptomatology.

Opsoclonus-myoclonus

Opsoclonus is characterized by erratic, rapid eye movements. Myoclonus is characterized by jerking involuntary movements of other muscles. Two per cent of children with neuroblastoma develop opsoclonus-myoclonus. The condition also occurs in the absence of tumor, often as a sequelum of an infectious illness.

Opsoclonus also occurs as a remote effect of breast cancer. Such patients have a circulating antibody, designated anti-Ri, that binds to proteins of molecular weights of 55 and 80 kDa. The Ri antigen is found in the nuclei of CNS neurons and in the tumor.

Both childhood and breast cancer-associated cases may wax and wane spontaneously and both respond to glucocorticoid treatment. The cause is unknown, but an antibody-mediated process is plausible.

Infections of the central nervous system (CNS) occur in two fundamentally different tissue compartments: the leptomeninges (meningitis) and the brain parenchyma (encephalitis). While the blood–brain barrier (BBB) ordinarily deters the invasion of microorganisms into both sites, it also excludes most circulating leukocytes and antibodies, thus making the CNS uniquely susceptible to infection when invasion does occur. Intrinsic cells of the CNS have tightly regulated immunological function, and substances present normally within the brain can have immunomodulatory effects. In general, successful immune responses to neurological infections must overcome these structural and functional restrictions without causing damage to the nonrenewable cells of the CNS.

Unique anatomical features of the CNS

The structures that comprise the BBB prevent the entry of infectious pathogens, inflammatory cells and circulating proteins such as antibodies and cytokines into the CNS. Cerebrovascular endothelial cells maintain tight intercellular junctions and very low rates of vesicular transport that differentiate them from other endothelium. A dense basement membrane ensheaths these cells which is then surrounded by a network of pericytes and astrocytic foot processes that actively maintains the integrity of the BBB (Figure 1). In only a few specific locations within the CNS is the BBB ‘fenestrated’ and easier to cross.

The Virchow–Robin spaces immediately surrounding blood vessels that penetrate the surface of the brain are actually extensions of the subpial space (Figure 2). These spaces contain macrophage-like cells with phagocytic and antigen-presenting capacities beyond those found within the brain parenchyma itself. Foreign antigens and lymphocytes pass through these spaces into the lymphatic channels of the head and neck. As a result, the Virchow–Robin spaces form well-defined sites, distinct from the brain itself, where important immunological reactions can take place. They typically become engorged with inflammatory cells during a variety of neurological infections (Figure 3).

The cerebrospinal fluid (CSF) is produced by cells of the choroid plexus which is contained within the ventricles of the brain. Its protein content, including antibodies and complement, are derived from the

Figure 1 Ultrastructural features of the blood–brain barrier. Within the CNS, capillary endothelial cells contain many fewer pinocytotic vesicles, greatly increased numbers of mitochondria, and have intercellular tight junctions. This is surrounded by a dense basement membrane, pericytes, and astrocytic foot processes. In contrast, general capillaries have intercellular clefts, fenestrae, and prominent pinocytotic vesicles (not shown).

Figure 2 The Virchow–Robin space. This extension of the subpial space contains perivascular macrophages and can serve as a conduit through which foreign antigens and other leukocytes leave the CNS. (Adapted with permission from Esiri and Gay (1990) *Journal of the Neurological Sciences* 100: 3–8.)

blood and are normally present at less than 1% of circulating levels. Conversely, the CSF contains abundant nutrients (glucose, amino acids, etc.) that many infectious pathogens can utilize. Furthermore, recirculation of the CSF throughout the subarachnoid space may disseminate microorganisms throughout the neuraxis. During a variety of infections within the leptomeninges or the brain parenchyma, the CSF contains inflammatory cells, antibodies and immunoregulatory cytokines.

Immune capabilities of intrinsic cells of the CNS

In general, cells of the CNS lack expression of class I and class II major histocompatibility complex

Figure 3 Perivascular inflammation within the Virchow–Robin space. Infection within the CNS recruits many types of circulating leukocytes across the blood–brain barrier into the Virchow–Robin space. These cells can often extend into the brain parenchyma itself; this allows for direct interactions with infectious organisms and infected neural cells. (Adapted with permission from Esiri and Gay (1990) *Journal of the Neurological Sciences* 100: 3–8.)

(MHC) antigens. While glial cells such as astrocytes can be induced to express these antigens *in vitro*, only microglia and perivascular macrophages reliably express MHC antigens during CNS infections *in vivo*. Neither of these cells appear to have the antigen-presenting capacity of dendritic cells that are found in other tissues.

In a murine model of viral encephalitis, many different cytokines are induced in the brain before inflammation develops, suggesting that intrinsic cells of the CNS produce these immunological mediators *in vivo*. Likewise, proinflammatory cytokines can be identified within microglial cells by immunocytochemistry using brain tissue specimens from autopsy cases of both acute and chronic human neurological infections. Despite often being the target of infection, neurons have not been reliably shown to express MHC antigens or release cytokines.

Entry of circulating inflammatory cells into the CNS

At baseline, cerebrovascular endothelial cells express few adhesion molecules and nonactivated lymphocytes and monocyte/macrophages do not enter the CNS with any efficiency. With infection, however, a variety of adhesion molecules including ICAM-1 and VCAM-1 are upregulated on endothelial cell surfaces. Activated lymphocytes and monocytes can then extravasate across the BBB without regard to their antigenic specificity. The entry of T cells in particular is dependent on the expression of LFA-1. Lymphocytes that identify their antigen are selectively retained within the CNS while the remaining cells depart. Although multiple cell types within the CNS can probably present antigen to activated T cells, it is controversial whether any serve as primary activators of naive T cells.

Regulation of lymphocyte function within the CNS during infection

Once T cells have entered the brain, they produce cytokines but there is little evidence that they proliferate locally in response to antigenic stimulation. The pattern of cytokines produced depends on the type of infection and on the genetic background of the host. Nevertheless, data from several systems suggest that skewing of T cell responses towards the production of type 2 cytokines is more likely in the CNS than in other organs. Both the lack of proliferation and the preferential release of interleukin 4 (IL-4) and IL-10 may be due to the effects that brain-derived gangliosides exert on T cells.

Features of the immune response to specific types of pathogens within the CNS

Viruses

Viruses invade the CNS through hematogenous dissemination or by retrograde transport up neurons that have processes extending into sites of infection in the periphery. As intracellular pathogens, their tropism for different neural cells and effect on host cell function determine the severity of disease. The paucity of MHC antigen expression within the CNS can make the cytotoxic T lymphocyte (CTL)-mediated clearance of viruses difficult and may predispose to chronic or relapsing infections. Their capacity to establish latency also allows viruses to avoid detection by the immune system. In other circumstances, antiviral antibodies can shut off virus production by infected neurons in a noncytolytic manner and promote recovery from disease. During chronic CNS infection caused by human immunodeficiency virus (HIV), the long-term production of

inflammatory mediators such as tumor necrosis factor α (TNF α) may promote the development of neurological symptoms.

Bacteria

Bacteria require specific virulence factors to allow invasion of the CNS and production of disease. Organisms that cause acute meningitis are usually encapsulated; this inhibits phagocytosis and activation of complement through the classical pathway. As a result, these bacteria survive in the bloodstream longer and are more likely to invade the CNS. Once in the subarachnoid space, favorable conditions (i.e. limited intrinsic host defense, abundant nutrients) allow for rapid bacterial multiplication. Cytokines, particularly IL-1 and TNF α , are secreted in response to bacterial products and induce endothelial expression of adhesion molecules important for neutrophil egress. The production of other chemotactic stimuli including IL-8 also recruits neutrophils, but low levels of opsonins, antibody and complement in the CSF limit bacterial phagocytosis by these infiltrating cells. These responses combine to produce BBB dysfunction, leakage of protein and cerebral edema. Slow-growing bacteria adapted to survive inside macrophages, such as mycobacteria, induce mononuclear inflammatory responses and cause sub-acute or chronic disease.

Fungi

Fungi are generally avirulent pathogens; most individuals with fungal infections of the CNS have some underlying immune deficiency. The greater frequency of these disorders in patients with impaired cell-mediated rather than humoral immunity implies that the former is the primary means of host defense against fungal pathogens that invade the CNS. In the setting of deficient cellular immunity, fungi can grow unchecked in the CSF without eliciting an inflammatory response. As a result, these infections are difficult to eradicate from the CNS completely and require long-term antifungal therapy. Mortality in general is high.

Parasites

Only a few parasites frequently invade the nervous system. Free-living amoebae that cause acute meningitis enter the CNS by crossing the olfactory mucosa. All other parasites are assumed to enter from the bloodstream. Intracellular pathogens such as *Toxoplasma* may establish latent infections which reactivate in the face of acquired deficiencies of cellular immunity. The cysticercus of *Tania solium* induces an intense inflammatory reaction which may induce

seizures. The organisms are eventually killed, leaving behind calcified nodules. Malaria, on the other hand, induces a toxic encephalopathy associated with ICAM-1-mediated adhesion of parasitized erythrocytes to cerebral capillary endothelial cells and induction of local cytokine production.

NEUROMUSCULAR JUNCTION AUTOIMMUNITY

John Newsom-Davis and **Angela Vincent**, Neurosciences Group, Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK

There are three antibody-mediated disorders of the neuromuscular junction. In myasthenia gravis (MG) antibodies cause loss of the muscle acetylcholine receptor (AChR). It meets in full Witebsky's criteria for antibody-mediated autoimmune disease: 1) the presence of antibodies against a defined antigen (AChR); 2) transfer of the disorder to naive experimental animals by injection of MG immunoglobulins; 3) induction of the disorder in experimental animals by specific immunization against AChR; and 4) transfer of disease from immunized to naive animals by their lymphocytes. The Lambert-Eaton myasthenic syndrome (LEMS) is an antibody-mediated presynaptic disorder where the target is the nerve terminal voltage-gated calcium channel, and in which the first two of the above criteria are met. It is of additional interest as the best example currently available of an autoantibody-mediated paraneoplastic neurological disease. Acquired neuromyotonia (Isaacs' syndrome) has recently been shown to be due to autoantibodies to voltage-gated potassium channels in peripheral motor nerves, leading to their increased excitability and consequent continuous muscle fibre activity. This disorder also meets the first two criteria listed above.

Myasthenia gravis

The dominant clinical feature is fatiguable weakness of skeletal muscle, typically affecting the ocular muscles early in the disease, and bulbar, limb, trunk

and respiratory muscles in severe cases. MG appears to affect all races, the prevalence in the Western world being about 5-9 per 100 000 with an annual incidence of about 4 per million. It may occur from early childhood to extreme old age. Other autoimmune diseases occur at increased frequency, especially thyroid disease, and other autoantibodies are common. About 8% of babies born to myasthenic mothers have a transient neonatal myasthenia due to placental transfer of AChR-specific antibody, and in a small proportion there may be limitation of intrauterine movement with development of arthrogryposis multiplex congenita.

Weakness in MG is due to loss of the number and function of AChRs that are transmembrane proteins (mol. wt 250 kDa) located on the peaks of the postsynaptic folds at the neuromuscular junction, and consist of five subunits (α_2 , β , γ/ϵ , δ) grouped around a central ion channel. The α subunits bind acetylcholine and also a snake toxin, α -bungarotoxin. Loss of AChRs in MG, as shown by reduced [125 I] α -bungarotoxin (BuTx) binding to the neuromuscular junction, results in a decrease in the acetylcholine sensitivity of the postsynaptic membrane. Thus the electrical potentials that result from release of acetylcholine from the motor nerve terminal are reduced, resulting in decreased probability of triggering a muscle action potential and of muscle contraction.

Loss of functional AChRs is due to AChR autoantibodies that are detectable in 85% of patients with generalized MG and in 50-60% of patients

with restricted ocular MG. In the 15% of patients with generalized weakness who are 'seronegative' for anti-AChR there are thought to be antibodies to other determinants at the neuromuscular junction. As in anti-AChR positive MG, the role of antibodies in seronegative MG is clearly demonstrated by the response to plasma exchange and immunosuppressive drug treatment, the occurrence of neonatal MG and the passive transfer of experimental disease to animals.

Antibodies against AChR are measured by a radioimmunoassay using AChRs obtained from human amputated leg muscle (cross-reactivity with other species of AChR is incomplete), labeled with [125 I] α -BuTx. Antibodies (absent in controls) are detected in some patients who are clinically in remission, and very occasionally in those with autoimmune predisposition without signs of MG. In general the titer correlates only weakly with disease severity between individuals. However, within an individual the titer shows an inverse correlation with muscle strength.

Antibodies against AChR are heterogeneous and all subclasses are usually represented. Most antibodies appear to be directed to the conformational epitopes on the extracellular domain of the AChR; some of these are to the 'main immunogenic region' on the α subunits, to which the sequence α 67-76 makes an important contribution. In some patients a proportion of antibodies are directed to the γ (fetal) AChR, but in others antibodies bind preferentially to the ϵ (adult) AChR. There is no substantial idiotypic sharing.

Several antibody-mediated mechanisms contribute to loss of functional AChRs. These include complement-mediated lysis of the postsynaptic membrane, downregulation of AChRs secondary to cross-linking and, less frequently, blockade of AChR function. There may be marked simplification of the postsynaptic folds in severe cases, and immunoglobulin G (IgG) and complement components (C3 and C9) are found both on the membrane itself and on debris in the synaptic cleft.

Clinical, immunological and immunogenetic characteristics allow at least three subgroups of patients to be identified in the AChR antibody-positive Caucasian MG population. The largest group is predominantly female, of young onset (<40 years) with high AChR antibody titers, medullary hyperplasia of the thymus, and a strong association with HLA-B8 (80%) and HLA-DR3 (70%). The older-onset group (>40 years) is more often male with relatively low anti-AChR titers and thymic atrophy, and associated weakly with HLA-B7 and HLA-DR2; it is further distinguished from the young onset

group by a strong association with Ig heavy chain loci, as shown by restriction fragment length polymorphism (RFLP) typing using a probe for the C μ switch region. The third group comprises those with thymoma; mean anti-AChR titers are intermediate and no HLA association has been consistently identified in Caucasians. In Oriental patients, young-onset, low anti-AChR titer cases predominate and the late-onset group is not evident. Different immunogenic associations also occur, notably with HLA-DR9 and Gm1,2,21.

The thymus is implicated in many MG cases. It is a site of specific antibody production, especially in those showing changes of medullary hyperplasia, i.e. lymphoid follicles with germinal centers. Other sites of antibody synthesis include lymph node, peripheral blood and bone marrow. Rates of AChR antibody production by thymic cells in culture correlate with the serum antibody titer; and antibody fine specificities, defined by competition with monoclonal antibodies to the AChR, in culture supernatants and in serum are closely matched. The thymus in MG is also enriched for AChR-reactive T cells, and AChR has been demonstrated *in situ* in thymic myoid cells by staining with monoclonal antibodies against the AChR. Myoid cells are found, in both MG patients and in controls, mainly in the medullary epithelium and septal regions and appear to be HLA class II negative. However, rare nonmyoid cells that are both AChR positive and HLA class II positive can be identified in MG thymus and may be antigen-presenting cells.

In the case of thymoma, few or no antibodies to the AChR are synthesized in culture by the thymoma-derived lymphocytes, but the adjacent thymus may show change of hyperplasia and some anti-AChR production. Immunohistochemical studies indicate that thymomas are epithelial tumors of unusual phenotype. They may arise from rare cells in the cortex that express markers for both cortical epithelium and subcapsular/medullary epithelium. They do not appear to express AChR, but nevertheless contain a 155 kDa protein that cross-reacts with a cytoplasmic AChR epitope. The role of this epitope and other related neuronal or muscle antigens in inducing MG in thymoma cases is unclear.

Class II-restricted T cell epitopes have been identified in MG patients (and also in controls) using *Torpedo* (electric fish) AChR α subunit, mouse α subunit fusion proteins, and synthetic peptides or recombinant polypeptides of the human AChR. The epitopes and restricting class II haplotypes appear to be diverse. Some T cells recognize synthetic peptide epitopes on the extracellular domain of the AChR sub-

units, but their functional significance is not yet clear.

Anticholinesterase medication provides some symptomatic improvement. Thymectomy is usually recommended for those with thymoma and in young-onset patients with generalized symptoms. In those with restricted ocular disease, low-dose alternate-day prednisolone treatment is often effective. Late-onset generalized cases and those who fail to respond to thymectomy often respond to treatment with prednisolone and/or azathioprine. Combined treatment is more effective and better tolerated than prednisolone alone. Severe disease can be temporarily controlled by plasmapheresis or intravenous immunoglobulin.

Experimental autoimmune myasthenia gravis

The discovery by Patrick and Lindstrom that rabbits immunized with AChR, purified from the electric organ of electric eel *Electrophorus*, developed a myasthenia-like illness (experimental autoimmune myasthenia gravis, EAMG) provided an animal model for the human disease. The clinical features of EAMG bear a striking resemblance to MG, especially when induced in primates, and include fatigue, flaccid limb paralysis, drooping of eyelids, paralysis of eye movements and respiratory muscle weakness.

EAMG is classically induced by repeated immunization with xenogeneic or syngeneic native AChR in Freund's complete adjuvant. It can also be induced without adjuvant, however, or by immunizing with particular synthetic peptides of the α subunit. Additionally, it can be passively transferred to recipients by immunoglobulins or purified IgG from immunized animals, or by experimentally raised AChR-specific monoclonal antibodies.

As in the human disease, AChRs are decreased in number and miniature end-plate potentials are small. In mice immunized with AChR, Freund's adjuvant and additional *Pertussis*, the end-plates show a prominent mononuclear cell infiltration typically 7–10 days after a single immunization. If the animal survives, this acute phase, which has no known counterpart in MG, is followed by a chronic phase in which there is simplification of the postsynaptic folds and loss of AChR. Complement-depleted (cobra venom-treated) rats are resistant to EAMG induced either by active immunization or passive transfer. Modulation of AChR numbers by antibody cross-linking also contributes to AChR loss, but blocking antibodies are not prominent.

Murine susceptibility to EAMG is linked to particular H-2 haplotypes that control the T cell response to the AChR, and to particular Ig heavy chain genes. However, the correlation between AChR antibody levels and clinical disease in mice is poor, and other

strain-specific factors may play a part. In rabbits there is a better correlation between AChR antibody titers, clinical weakness and electrophysiological abnormalities. Antibodies are of the IgG class, and many are directed against the main immunogenic region on the immunizing AChR and cross-react with autologous AChR (see above).

Antibodies to the AChR are T cell dependent. The T cell *in vitro* proliferation response to AChR correlates with the level of anti-AChR, and also with disease severity as judged by the muscle AChR content. A number of T cell epitopes on the α subunit have been identified in the Lewis rat, and CD4⁺ AChR-specific T cell clones can help anti-AChR production by AChR primed B cells.

Several different preimmunization treatment regimens have been shown to interfere with the development of EAMG, including corticosteroids, azathioprine, cyclosporine and oral treatment with AChR (oral tolerance). High-dose cyclophosphamide with or without irradiation followed by bone marrow transplantation diminishes the autoimmune response in established EAMG, and cyclosporine partially inhibits the response to secondary immunization. Anti-idiotypic antibodies can alter the induction of EAMG passively induced by monoclonal antibodies to the AChR, but have variable effects on the actively immunized disease. Anti-I-A monoclonal antibody therapy can be protective.

Lambert-Eaton myasthenic syndrome

This disorder is much less common than myasthenia gravis. It is characterized by proximal muscle weakness, depressed tendon reflexes, post-tetanic potentiation and autonomic changes, including dry mouth and constipation. Onset can be in adolescence, but is usually after 40 years of age. Other autoimmune diseases may associate, notably thyroid disease and vitiligo, and other autoantibodies occur at increased frequency.

About 60% of cases have associated small cell lung cancer (SCLC). The neurological disorder typically precedes radiological evidence of the tumor by up to 2 years, and exceptionally 4–5 years. Many of the remainder have been followed for 10 years or more, making an underlying tumor very unlikely.

The physiological abnormality is presynaptic, in contrast to myasthenia gravis. Quantal release of acetylcholine by the nerve impulse depends on the opening of voltage-gated Ca^{2+} channels (VGCCs) and the consequent local influx of Ca^{2+} into the nerve terminal; in LEMS, the calcium-dependent release of transmitter is greatly reduced, and freeze-fracture electron microscopy shows loss of active

zone particles that are thought to represent VGCCs. Postsynaptic AChRs are normal.

The disorder is caused by IgG autoantibodies that bind to VGCCs (or to structures closely associated with them). There are at least four subtypes of neuronal VGCCs (T-, L-, N-, P/Q-). Antibodies to P/Q-type VGCCs dominate the immune response, and can be detected by radioimmunoprecipitation assay using a cone snail neurotoxin ($[^{125}\text{I}]\omega$ -conotoxin MVIIC) to label the VGCCs. Serum titers broadly correlate with disease severity in individual patients. LEMS IgG injected into mice transfers the physiological changes, i.e. reduced quantal release of acetylcholine and morphological changes such as clustering and reduction in the number of active zone particles. These effects appear to be dependent on antibody divalency, as Fab fragments are without effect, suggesting that loss of VGCCs may be brought about by cross-linking. Recent passive transfer studies to mice have shown that the autonomic changes may similarly be mediated by autoantibodies to P/Q-type and occasionally N-type VGCCs.

HLA-B8 and (less strongly) HLA-DR3 and Ig heavy chain markers associate with LEMS, both in its SCLC-associated and noncancer forms. SCLC patients without LEMS do not show these associations, implying that susceptibility to LEMS in SCLC cases is partly conferred by immune response genes.

SCLC is thought to be of neural crest origin. SCLC cell lines express VGCCs, as shown by depolarization-induced $^{45}\text{Ca}^{2+}$ influx. LEMS IgG, both from SCLC and non-SCLC cases, causes a highly significant reduction of K^{+} -stimulated $^{45}\text{Ca}^{2+}$ flux into these cells compared with control IgG, and inhibition of flux correlates with an electromyographic measure of disease severity. These results suggest that the antibodies against VGCCs in SCLC cases are triggered by tumor VGCCs, and that the cross-reactivity with nerve terminal VGCCs leads to the neurological disorder. The immune response in these patients may be generated within the tumors as macrophage infiltration in LEMS-associated SCLC is greatly increased compared with non-LEMS cases.

Thus, in its cancer-associated form, LEMS provides the first clear evidence that a paraneoplastic neurological syndrome can be caused by an antibody-mediated autoimmune process. Consistent with this, treatment of the neoplasm by surgery, chemotherapy or deep X-ray is usually followed by improvement or remission of the neurological syndrome in those who survive the effects of the tumor. Many of the noncancer cases respond to immunosuppressive treatment (prednisolone and azathioprine), and short-term improvement may follow plasmapheresis or intravenous immunoglobulin.

Acquired neuromyotonia (Isaacs' syndrome)

Acquired neuromyotonia is a rare disorder characterized by widespread muscle twitching (myokymia) and cramps, sometimes associated with muscle hypertrophy, stiffness, weakness, increased sweating and central effects. Onset can be from adolescence to old age. There is an association with thymoma, with myasthenia gravis, and probably also with lung cancer.

The physiological abnormality is an increased excitability of peripheral motor nerves that can discharge spontaneously or fail to shut off after voluntary activation. The abnormal activity is principally generated at motor nerve terminals (i.e. it continues distal to local anesthetic block), and it continues during sleep and general anesthesia. The abnormality is consistent with a decrease in the number of functional voltage-gated potassium channels (VGKCs) that normally control nerve excitability.

The disorder appears to be due to IgG antibodies against VGKCs. The neuromyotonic discharges decrease following plasma exchange, and patients' IgG injected into mice produces changes consistent with the downregulation of VGKCs. Antibodies to VGKCs can be detected by immunoprecipitation assays using $[^{125}\text{I}]\alpha$ -dendrotoxin that labels some (but not all) VGKCs, and in a majority of patients by a molecular immunohistochemical assay in which the relevant human VGKC is expressed in *Xenopus* oocytes.

Neuromyotonia can be controlled in some patients by carbamazepine or phenytoin (which both reduce nerve excitability), and in others by immunosuppressive drugs, as used in MG.

NEUTRALIZATION OF BIOLOGICAL REACTIONS BY ANTIBODIES

John P Hearn and **Georgina E Webley**, Reproductive Health Research Programme (HRP), World Health Organisation, Geneva, Switzerland

The immunological manipulation of endocrine and allied reproductive regulatory systems provides us with an example of how both our basic knowledge and its applied dimensions have progressed through the interdisciplinary catalysis of immunology and reproductive biology. Over the first 70 years of the twentieth century, the complex feedback interactions between gonadotropins and steroids were described, resulting, for example, in new approaches to infertility (gonadotropin releasing hormone, GnRH), fertility control (the contraceptive pill) and the management of domesticated farm stock (progesterone sponges, prostaglandins). By the early 1970s, pure preparations of most of the generic hormones were available and their mechanisms of action had been tested through immunological neutralization. The discovery by Canfield and Pierce in 1971 of the sub-unit structures of the gonadotropins explained why previous attempts to immunize against the entire hormones – luteinizing hormone (LH), follicle-stimulating hormone (FSH), chorionic gonadotropin (CG) – resulted in cross-reactions between these and thyroid-stimulating hormone. It also allowed progression from crude immunizations to the development of specific epitope, anti-idiotypic and sequenced subfraction antibodies, now progressing to the sequencing of the key genes and prohormones. The discovery that potential ‘vaccines’ against self antigens could be achieved, through conjugation with nonself antigens, such as tetanus toxoid, opened new avenues for the development of immunological

fertility regulation. In addition, a range of new immunological probes to study gamete maturation, receptor function, sperm and egg surface antigens, embryonic cell signal transduction, trophoblast and placental antigens, and the embryo–maternal dialog at implantation have become available, together with some advances in adjuvant technology that reduce the trauma of immunization with Freund’s adjuvant. Species differences in the sequences and antigenicity of gonadotropins, or the differing emphasis in biological actions between related groups of progestagens, androgens or estrogens in various species, still hinders the easy extrapolation of results between species. However, similarities between the endocrine and immunological characteristics of the fetal allograft with those of certain carcinomas has allowed some shared approaches to diagnosis and monitoring, for example with CG in pregnancy, choriocarcinoma or teratocarcinoma.

Rationale

An immunological approach to reproductive physiology, asking fundamental questions, is paying off at the basic, strategic, and applied levels. Perturbation of the closely interrelated feedback systems, shown in **Figure 1** and **Table 1**, is giving us a better understanding of the efficacy, specificity, and practicality of intervention, together with the priorities, benefits, and risks of the sites now available. In theory, active or passive neutralization has many advantages, as a

Table 1 Neutralization effects with antibodies

	Hormone neutralized	Effect
<i>Female</i>		
Hypothalamus	GnRH	Reproductive shutdown
Pituitary	LH/FSH	Prevents ovulation, disrupts feedback
Ovary	Progesterone/estradiol 17-β	Broad effects on LH increase
	Estradiol	FSH increase and behavior
	Inhibin	FSH increase
	Estrone/androstenedione	Raises ovulation rate
Ovum	Zona pellucida	Blocks fertilization
Embryo	Platelet activating factor	Inhibit fertility; unconfirmed
	Early pregnancy factor	
	Chorionic gonadotropin	Prevents implantation
<i>Male</i>		
Sperm	LDH-CD4 isoenzyme	Reduces fertility
	Sperm surface antigens	Reduce fertility

controlled response can be short or long term, potentially reversible, relatively noninvasive, and well targeted either to a system or to a specific site. In practice, caveats remain concerning species specificity, induced autoimmunity or its consequences when continually secreted antigens are inhibited, or unpredictable side-effects through the neutralization of as yet poorly understood genes, proteins, enzymes or steroids that may have multiple roles or feedback links.

Consequently, neutralization with antibodies may be utilized to: 1) advance understanding of the mechanisms of action of factors affecting reproductive processes; 2) suppress fertility in the management of human and animal reproduction; 3) enhance fertility

in certain cases; 4) understand the etiology of disorders such as precocious puberty, polycystic ovarian disease and premature menopause; or 5) develop generic methodologies such as those of radioimmunoassay, ELISA and other immunoassays that have transformed the field.

Experimental manipulation

The endocrine and developmental processes regulating reproduction at the molecular, cellular and systemic levels are open to immunological perturbation by neutralization of hormones, enzymes or cell surface antigens. From the mid-1970s, Fraser, Jeffcoate and others immunized rodents, sheep and

primates against GnRH, producing a shutdown of the reproductive system through a deprivation of gonadotropins. This physiological castration, while with some potential for management of domesticated farm stock, pets or pest species, has little general applicability to the human. Similarly immunization against LH or FSH produced general suppression of the reproductive endocrine system, although Moudgal reported more specific effects with heterologous FSH preparations and Baird, DeKretser, Knight and others pursued the inhibin-FSH relationship. The enigmatic role of prolactin in seasonal breeding and in lactation was studied by McNeilly, while the relationships of oxytocin from pituitary and ovarian sources were explored in parturition and in the support of the corpus luteum.

The potential of chorionic gonadotropins, as a specific signal in early primate pregnancy, to yield a long-term, reversible contraceptive for the human is being investigated by several groups. Active or passive immunization against the whole β subunit, or the C-terminal specific peptide which differs from LH, conjugated with heterologous ovine LH α subunit in one case, was shown by Hearn, Stevens, Talwar, Thau and their groups to be effective in suppressing primate pregnancy and is now being tested in phase II clinical trials on humans by Jones, Stevens, Talwar and others. The Talwar heterospecies dimer comprising human CG β subunit and ovine LH α subunit has successfully completed phase II efficacy trials. Canfield and colleagues, Nial and Tregear and others are exposing the structural-physiological function relationships of this hormone, together with its effects on embryo-maternal signaling at the start of pregnancy. Allen has profitably explored the interspecies regulation of pregnancy in equids by equine CG, using embryo transfer techniques.

Neutralization of reproductive steroids has also provided a great deal of information on sites of action, feedback mechanisms, endocrine regulation of puberty, and of sexual behavior, but the widespread effects of steroids throughout the body precludes any permanent, nontherapeutic intervention in humans. An interesting agricultural dimension is Scaramuzzi's work in increasing the ovulation rate and productivity in sheep or cattle by immunizing against androstenedione, testosterone and estrone, while the role of prostaglandins in corpus luteum function and in early pregnancy is being studied in many laboratories. In addition, Heap, Wang and others are examining the requirements for progesterone in early pregnancy using monoclonals, idiotypes and anti-idiotypes to probe embryo and endometrial interactions.

Looking to more local interactions, cell surface antigens have been studied as markers to sperm maturation and as possible targets for immunological neutralization. Alexander, Anderson, Moore, Voisin and others are testing a range of potential antigens. The vast numbers of sperm produced make an immunocontraceptive approach questionable, but the significance of naturally circulating sperm antibodies, or those produced as a consequence of vasectomy, is being clarified. The LDH-C₄ sperm-specific isoenzyme, now characterized, partially sequenced, and shown by Goldberg to be immunogenic and to suppress fertility in a variety of species, may have practical applications in immunocontraception. Potentially more specific targets are zona pellucida antigens and perhaps sperm receptor molecules that might inhibit fertilization. Aitken, Dunbar and others have identified a range of potential candidates.

A great deal of effort is being expended in defining the roles of the multiplicity of trophoblast antigens, where Beer, Billingham, Johnson and others are making progress in this difficult field, while Redman is exploring the importance of fetal alloantigenic signaling in the human and its relationship with recurrent abortion or pre-eclampsia. There appears to be a greater incidence of such disorders in partners with similar HLA allotypes.

Although only a few examples are provided here, it is clear that the interface of immunology and reproductive biology is advancing our fundamental and strategic knowledge in virtually all of the areas open to study. The greater availability of carefully cloned genes, specific immunological probes, defined reagents for immunocytochemistry, polymerase chain reaction (PCR) and *in situ* hybridization should allow us to define, far more precisely, the ontogeny of expression, mechanisms of action and complex interrelationships of reproductive events in the future.

NEUTROPHILS

Dirk Roos, Central Laboratory of the Netherlands Red Cross Blood Transfusion Service and Laboratory for Experimental and Clinical Immunology, Amsterdam, The Netherlands

Neutrophils, the major type of polymorphonuclear leukocytes, are mobile cells that can ingest and kill invading microorganisms. For this purpose, neutrophils use both newly generated, highly reactive oxygen compounds, and microbicidal or microbistatic proteins stored in their granule compartments. The biological significance of this line of defense is well illustrated by the overwhelming infections in patients with severe neutropenia or neutrophil dysfunctions. However, neutrophils may also cause serious tissue injury, for instance during persistent infections or chronic inflammation. Therapeutic intervention is then indicated.

Neutrophils are often called 'granulocytes'. Strictly speaking, however, 'granulocytes' is a collective noun for the polymorphonuclear leukocytes, which include neutrophilic granulocytes (neutrophils), eosinophilic granulocytes (eosinophils) and basophilic granulocytes (basophils).

Neutrophil maturation and morphology

Neutrophils mature in the bone marrow in about 2 weeks. In the first half of this period, the neutrophil precursor cells undergo six divisions and differentiate from myeloblasts through promyelocytes to neutrophil myelocytes (**Figure 1**). Myeloblasts are cells with a large nucleus relative to the surrounding cytoplasm, which contains no or few granules. In the promyelocyte stage, the azurophil granules (black dots in **Figure 1**) are formed, whereas the specific granules (open organelles in **Figure 1**) are formed in the myelocytic stage. Because cell divisions still occur after azurophil granule formation has stopped, these granules are distributed over the daughter cells and are complemented with specific granules actively formed during this stage. The final ratio of azurophil to specific granules in human neutrophils is about 1:2. Later stages of neutrophil differentiation comprise metamyelocytes, band forms and segmented cells. As the names indicate, these stages are characterized by

the typical appearance of the neutrophil nucleus. Divisions do not take place during this period.

About 60% of all nucleated cells in the bone marrow belong to the myeloid series. Indeed, the bone marrow comprises a reserve pool of mature neutrophils that contains about 20 times the number of neutrophils in the circulation. Under normal conditions these cells are released into the blood 2 days after (apparent) completion of their maturation. During infections these cells are released sooner, together with band forms (up to 10^{12} per day in adults instead of the usual 10^{11} per day). The appearance of immature neutrophils in the blood is reflected by a decreased chemotactic responsiveness of these cells. In the circulation about half of the neutrophils are in a margined pool of cells sequestered in postcapillary venules. This pool is released when epinephrine is generated by exercise or injected intravenously. Neutrophils circulate for only 6–10 h; thereafter, they move to the tissues, where they remain active for 2–6 days. The site of neutrophil apoptosis and destruction by tissue macrophages is not known.

Neutrophil movement

Egress of neutrophils from the bone marrow to the circulation, and diapedesis from the circulation to the tissues, involves squeezing of the neutrophils through the blood vessel wall, in between the endothelial cells and through the basement membrane. For this purpose, neutrophils create gaps between endothelial cells of about $1\ \mu\text{m}$, without disturbing the endothelial cell layer. Thanks to its lobulated nucleus the neutrophil is very flexible, which greatly facilitates its passage through these pores (a rounded neutrophil has a diameter of $12\text{--}15\ \mu\text{m}$). It is not known which humoral factors cause egress from the bone marrow in healthy individuals.

Adherence of neutrophils to endothelial cells in postcapillary venules is facilitated by passive move-

Figure 1 Neutrophil life span and stages of maturation. The ordinate shows the flux through each compartment and the abscissa shows the time in each compartment. The area of each of the compartments gives the number of cells in each compartment. The stepwise increase in cell numbers through the first three compartments represents serial divisions of the cells in these compartments. Note that no divisions occur after the myelocyte stage. Amsterdam: Elsevier/North-Holland.)

ment of the neutrophils to the vessel wall, which causes reversible interaction with selectin molecules on the endothelial cells, influenced by the fluid flow (neutrophil rolling). This is followed by a more stable interaction with accessory molecules, such as ICAM-1 (neutrophil spreading), which leads to diapedesis and movement into the tissues. During inflammation these processes are strongly increased as a result of the formation of chemotactic agents in the inflamed area, such as the complement fragment C5a, the tripeptide formyl-Met-Leu-Phe (fMLP), interleukin 8 (IL-8) and leukotriene B₄. These agents increase the surface expression of certain adhesion molecules on the neutrophils, such as the CD18 integrin β_2 family, and also activate these molecules for enhanced binding to endothelial cell structures, probably by changing their configuration. Moreover, these chemotactic agents also induce the neutrophils to move to areas of higher concentration of these agents. This is the process of chemotaxis, which directs the cells toward the infected or inflamed area. On the other hand, endotoxin, released by microorganisms, induces macrophages to generate IL-1

and tumor necrosis factor (TNF). These agents, including endotoxin, affect the endothelial cells by upregulating the adhesion proteins ICAM-1, VCAM-1 and E-selectin, thus promoting neutrophil adherence. Finally, endothelial cells also generate platelet-activating factor and IL-8 under these conditions, which promotes neutrophil migration.

The biological significance of adherence and migration is clearly demonstrated by the clinical symptoms of patients with leukocyte adhesion deficiency, i.e. severe, recurrent bacterial infections, impaired wound healing, persistent leukocytosis and severe deficiency in mounting an inflammatory response. Neutrophils from these patients lack all three CD18 adherence proteins, are strongly depressed in their ability to adhere to endothelial cells or other neutrophils (aggregation) and are chemotactically inactive.

Phagocytosis and bacterial killing

Neutrophils are specialized in ingestion and intracellular killing of a large array of different bacteria,

yeasts, fungi, mycoplasmas, and perhaps also viruses. Most microorganisms can only be phagocytosed after opsonization with specific antibodies and/or complement fragments. The neutrophil carries specific receptors on its surface for immunoglobulin G (IgG) (Fc γ receptors, Fc γ R) and for the complement components C3b (complement receptor type 1, CR1) and iC3b (CR3). Within certain size limitations, any material covered by these opsonins will be ingested – not only microorganisms but also simple immune complexes containing only one particular antigen.

Binding of opsonized material to neutrophil surface receptors leads to concentration of such receptors around the area of contact. Subsequently, the cell extends pseudopods that engulf the opsonized particle (Figure 2). By consecutive receptor binding, these pseudopods fit tightly around the particle and finally fuse with each other to form a closed membrane vesicle (phagosome) around the particle, within the neutrophil. Neutrophils may 'overeat' themselves in infected areas, i.e. they rupture. Macroscopically, this is manifested as pus formation.

Receptor binding also starts two other processes, i.e. the generation of reactive oxygen compounds and the release of granule contents (degranulation). Both reactions are localized events in that they are restricted to the release of microbicidal products into the phagosome (Figure 2); however, the secretion of these products begins before the phagosome is closed, and some of the oxygen compounds and granule enzymes may thus escape into the extracellular environment of the neutrophils. Moreover, neutrophils adhering to opsonized material that is too large to be ingested (e.g. immune complexes deposited along basement membranes) may secrete these products in large quantities into the extracellular space.

Generation of reactive oxygen products is initiated

by the activation of NADPH oxidase. This enzyme is located in the plasma membrane of neutrophils (and eosinophils, monocytes and macrophages), and thus also in the phagosomal membrane (Figure 2). It accepts electrons from NADPH on the cytosolic side of the membrane and transmits these electrons to oxygen on the other side of the membrane (in the phagosome or in the extracellular space). This reaction yields superoxide ($O_2^{\cdot -}$), a univalently reduced oxygen radical. NADPH oxidase is a complicated enzyme. It consists of at least five different proteins, two of which are incorporated in the plasma membrane and three that are, in resting cells, located in the cytosol. In this configuration the enzyme is not active. Upon neutrophil activation (e.g. by binding of opsonized microorganisms to cell surface receptors), the three cytosolic NADPH oxidase components are translocated from the cytosol to the plasma membrane and then form an active enzyme complex with the two membrane components of the oxidase. In this configuration the enzyme generates superoxide.

Superoxide spontaneously dismutates into hydrogen peroxide (H_2O_2), which may then react with chloride ions to form hypochlorous acid (HOCl), in a reaction catalyzed by myeloperoxidase. This enzyme is an abundant constituent of neutrophil azurophilic granules, and is released upon cell activation into the phagosome and into the extracellular space. HOCl is very toxic for a broad range of microorganisms but is rather short lived. However, it can react with primary and secondary amines, and thus give rise to *N*-chloramines, some of which are very stable, microbicidal agents. Under normal, phagocytosing conditions, neutrophils convert more than 75% of their superoxide into hypochlorous acid and *N*-chloramines, and thus create a highly toxic environment within the phagosomes and in the cell surroundings.

Figure 2 Neutrophil activation. Contact of opsonized microorganisms with neutrophil surface receptors (IgG-Fc and complement receptors) starts phagocytosis, NADPH oxidase activation and degranulation. Within the phagosome, oxidative products may interact with granule proteins for effective killing of ingested microorganisms. MPO, myeloperoxidase. (Reproduced with permission from Roos D (1991) The respiratory burst of phagocytic leucocytes. *Drug Investigations* 3: 48–53.)

Speculation as to the formation by neutrophils of oxygen radicals other than superoxide lack experimental evidence. For the formation of hydroxyl radical ($\text{OH}^\bullet$), iron is needed as a catalyst, and this is not available in the proper configuration within neutrophils. In fact neutrophils prevent $\text{OH}^\bullet$ formation by binding iron to lactoferrin, a protein stored in the specific granules and released upon activation. Only within target cells (e.g. within ingested bacteria) may iron be available in a form that catalyzes $\text{OH}^\bullet$ formation, and this may help in the destruction of these targets. Also, singlet oxygen, an energetically activated type of oxygen, is not generated by neutrophils.

Degranulation does not occur in resting neutrophils. During phagocytosis or adherence of neutrophils to large substrates, changes in the cytosolic free Ca^{2+} concentration, in addition to other signals, induce the fusion of granules with the plasma membrane. Neutrophils contain at least two different types of granule (Table 1). The azurophil granules resemble the lysosomes in other cell types in that they contain acid hydrolases, with a low pH optimum. Moreover, these granules also contain the aforementioned myeloperoxidase, as well as a number of serine proteinases. Further, the azurophil granules also contain large amounts of defensins, small peptides with a broad range of bactericidal activity, and bactericidal permeability-increasing protein (BPI), a very potent antibiotic against gram-negative bacteria. Lysozyme, an enzyme that hydrolyzes certain peptidoglycans of gram-positive bacteria, is present in

the azurophil as well as in the specific granules of neutrophils. Other proteins found in the specific granules are lactoferrin, an iron-binding and therefore bacteriostatic protein, and vitamin B_{12} -binding protein. The metalloproteinases collagenase and gelatinase are also present in the specific granules. Finally, neutrophils also contain so-called secretory vesicles, which actively exchange their membrane-bound receptors and enzymes with the plasma membrane. The distinction between the different types of granule is sometimes difficult. Myeloperoxidase and lactoferrin are considered good markers for azurophil and specific granules, respectively. However, granules without either marker do exist, possibly due to 'immaturity' of these granules.

The release of oxygen products and granule contents is not a simple all-or-nothing phenomenon. Both reactions can be potentiated by so-called priming agents, which by themselves do not induce secretion but only enhance the reactions initiated by activating agents. Physiological priming agents include TNF, platelet-activating factor and endotoxin. Thus, the same agents that cause upregulation and activation of surface receptors, and chemotaxis, also prime the neutrophils for enhanced microbicidal activity. However, neutrophils adhering to a surface, i.e. with ligands bound to their β_2 integrins, degranulate in response to these otherwise priming agents.

The biological significance of the neutrophil's microbicidal activity is illustrated by patients lacking either NADPH oxidase activity or proper granule contents. Patients with chronic granulomatous disease (CGD), unable to generate superoxide, suffer early in life from serious infections of the lungs, skin, soft tissues, lymph nodes, bones and liver with catalase-positive bacteria (catalase-negative bacteria secrete some hydrogen peroxide, which aids in killing these organisms in the phagosomes of CGD neutrophils). Patients with specific-granule deficiency (a rare disorder) suffer from recurrent infections with bacteria, without increased susceptibility to a particular pathogen. Patients with Chédiak-Higashi syndrome are characterized by partial oculocutaneous albinism, neutropenia and recurrent pyogenic infections. The neutrophils (and many other cells) of these patients contain giant granules composed (in the neutrophils) of aggregated azurophil granules. As a result, these neutrophils are less mobile and do not release azurophil granule contents upon phagocytosis.

Involvement in inflammatory reactions

Neutrophils play an important role in inflammatory reactions, both in the removal of microorganisms

and aged and damaged cells, as well as in the generation of inflammatory agents (chemotactic peptides, cytokines, leukotrienes and other lipid mediators). Moreover, neutrophils also mediate tissue injury. This last reaction is a necessary evil, meant to remove alien material from the tissues. Under normal conditions, when the causative agent has been removed and chemotactic factors are no longer produced, neutrophil (and macrophage) invasion stops and tissue repair commences; however, when neutrophil infiltration does not stop, as in chronically inflamed areas, the tissues may be permanently damaged.

Plasma and tissue fluids contain large amounts of a series of proteinase inhibitors, such as serine proteinase inhibitors (serpins, e.g. α_1 -proteinase inhibitor, α_1 -antichymotrypsin, plasminogen-activator inhibitor) and α_2 -macroglobulin. These inhibitors are very efficient in blocking serine proteinase activity. However, during neutrophil activation, reactive oxygen compounds are released and inactivate these inhibitors. Additionally, elastase, if not blocked by α_1 -proteinase inhibitor, is able to inactivate many of these tissue-protecting inhibitors. Moreover, the metalloproteinases collagenase and gelatinase, which are secreted by neutrophils as inactive precursors, are activated by the reactive oxygen compounds from these cells.

Thus, the following situation exists. Oxidative products of neutrophils are either short lived (HOCl) or – even more importantly – they act very non-specifically by oxidizing methionine residues in all proteins; therefore, these oxidative agents will quickly be scavenged by albumin or other abundant proteins surrounding the neutrophil. On the other hand, the proteinases released by neutrophils are also harmless because they are either secreted as inactive precursors (metalloproteinases) or will be quickly inactivated by serpins in the extracellular fluid. In combination, however, the neutrophil products act synergistically and become highly toxic for the surrounding tissues.

Well-known noninfectious conditions accompanied by neutrophil infiltrations are gout, rheumatoid arthritis, autoimmune vasculitis and some forms of glomerulonephritis. Tissue injury in these inflammatory conditions is at least in part due to products from neutrophils. Neutrophils are also involved in some inflammatory reactions in the lung. Adult respiratory distress syndrome (ARDS) may develop in combination with, or as a consequence of,

pulmonary aspiration, diffuse intravascular coagulation, severe pneumonia, hypertransfusion or sepsis. Inflammatory mediators generated under these conditions may cause intravascular aggregation of neutrophils, leading to obstruction of pulmonary capillaries and localized release of toxic mediators from these cells. The effects of TNF on lung cells may also play a role in ARDS and endotoxin shock. Lung emphysema is supposed to be caused at least in part by elastase released from neutrophils. Also, in the second phase of acute allergic asthma, infiltrating neutrophils (and eosinophils) probably contribute to the tissue damage.

Thus, although neutrophils form an indispensable element in our host-defense system, conditions exist in which the powerful mediators from these cells are harmful to the host. Therapeutic amelioration of these reactions is then necessary, but care must be taken to preserve the antimicrobial potential of the neutrophils.

NITRIC OXIDE

Stephen J McSorley, Institut de Pharmacologie Moléculaire et Cellulaire, Valbonne, France

Foo Y Liew, Department of Immunology, Western Infirmary, University of Glasgow, Glasgow, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Since the initial demonstration in 1987 that nitric oxide (NO) is produced by mammalian cells and regulates blood flow, several reports have described a number of diverse functions that can be traced to the production of this gaseous molecule. The production of NO is now known to play an integral part in the maintenance of several physiological functions, being involved in the control of cardiovascular and nervous systems as well as in the regulation of the immune system.

The induction of NO production is observed under conditions of immune activation where it can be both beneficial, in the eradication of microorganisms and tumor cells, and harmful, in the generation of a number of pathologic conditions. In both cases, upregulation of NO is implicated in the terminal stage of the inflammatory process: killing of the invading organism or sensitive host tissues. The induction of NO by the immune system during this process has been extensively studied and has allowed insight into the microbicidal mechanisms used by the host to expel invading pathogens and the factors contributing to the development of pathology.

Induction of nitric oxide production

Nitric oxide production has been demonstrated to occur in a number of cells of the immune system including neutrophils, and some transformed B cells, although most research has focused on the induction of NO in cells of the macrophage/monocyte lineage. The induction of macrophage NO production begins in response to an inflammatory stimulus such as that provided by the cytokines interferon γ (IFN γ), tumor necrosis factor α (TNF α), interleukin 1 β (IL-1 β) or bacterial lipopolysaccharide (LPS). IFN γ acts synergistically to upregulate NO production in the presence of the other mediators mentioned and is therefore particularly important in the generation of large amounts of NO. Two to four hours after receiving this stimulus, newly synthesized inducible nitric oxide synthase (iNOS; type II NOS) is produced in the macrophage cytoplasm. This enzyme is one isoform of at least three distinct NOS isoforms, all of which catalyze the production of NO and L-citrulline from L-arginine and molecular oxygen (Figure 1). The other two NOS isoforms are constitutive proteins, termed neuronal cNOS (type I NOS) and endothelial eNOS (type III NOS), both of which are

Figure 1 The generation of NO via nitric oxide synthase.

expressed in a number of tissues and catalyze the production of small quantities of NO. All three proteins contain four consensus sequences important for the binding of the cofactors NADPH, FAD, FMN and calmodulin. While all three proteins require calmodulin binding for enzymatic activity, the iNOS isoform is constitutively bound to calmodulin and therefore is not dependent on calcium flux for activity. The continuous production of large amounts of NO is catalyzed by iNOS while the other isoforms allow the production of small amounts of NO in response to calcium flux. It is this NO production by iNOS which is toxic to many microorganisms and certain host tissues, although under conditions of sustained calcium elevation within a cell the constitutive enzymes can produce appreciable quantities of NO.

Regulation of NO production

A number of immunosuppressive cytokines can inhibit macrophage expression of iNOS, including transforming growth factor β (TGF β), interleukin 4 (IL-4), and interleukin 10 (IL-10). Both IL-4 and IL-10 are produced by the T_H2 subset of CD4⁺ T cells, whereas T_H1 cells produce IFN γ and induce NO production. Thus the regulation of NO production by macrophages can be directly controlled by the activation of opposing T cell subsets (Figure 2). This functional polarization of T_H1 and T_H2 cells in the ability to induce NO reflects a greater requirement for host NO production in defense against intracellular pathogens. In addition to cytokines controlling NO production, the production of NO itself can also serve to inhibit further NO induction by inactivating NOS in a feedback manner. Thus, perhaps due to its toxic properties when in contact with self tissues, the

Figure 2 T cell subset regulation of NO production.

expression of iNOS and subsequent production of NO is under tight-regulation.

Microbicidal activity of nitric oxide

The production of NO, catalyzed by iNOS, is important in the destruction of a number of pathogenic organisms by the host. This role is most clearly observed in the control of infection with intracellular organisms such as *Leishmania* and *Listeria* which infect macrophages, but NO is also cytotoxic for tumor cells and extracellular pathogens and thus is not restricted to the effector mechanisms involved in destruction of intracellular pathogens. While the direct measurement of NO is difficult due to its short half-life, the dependence of the immune system on NO production in resolving infections can be clearly demonstrated.

The ability of activated macrophages to kill the protozoan parasite *Leishmania major* clearly correlates with the production of NO *in vitro* and the expression of iNOS *in vivo*. Furthermore, production of NO by macrophages can be inhibited using arginine analogs such as L-N^G-monomethylarginine (L-NMMA) which effectively blocks the ability of macrophages to kill *Leishmania* *in vitro* and *in vivo*. The use of gene-targeted disruption has also allowed the generation of mice which have no productive iNOS enzyme and while these mice are otherwise healthy, they succumb to infection with intracellular bacteria and parasites, demonstrating conclusively the importance of NO in the control of such pathogens.

In addition to the role that NO plays in curing an initial infection with these and other organisms, there is also evidence that the continual production of NO after an apparent disease cure is required to prevent

recurrence of infection in some chronic disease models. The treatment of mice which have 'cured' *L. major* infection with L-NMMA allows the resurgence of an otherwise unobserved infection. It is not clear whether this is true for other chronic diseases but it does underline the importance of NO in the maintenance of health as well as in the initial resolution of infection in conditions where the organism persists.

The actual mechanism by which NO mediates destruction of a microorganism is unclear but may involve a disruption of electron transport in the mitochondria by NO itself or alternatively may involve the interaction of NO with the oxygen radical $O_2^{\cdot-}$, a reaction which produces the peroxynitrite anion ($ONOO^-$).

Interference in the process of NO production by products of invading organisms may explain why some organisms can evade the efficient killing process outlined above. The microorganism may induce suppressive cytokines in the host to aid survival, or alternatively inhibit NO production via products of its own such as bacterial LPS or glycoinositol-phospholipids of the *Leishmania* parasite which can both mediate inhibition of iNOS induction.

Pathology caused by nitric oxide

The production of elevated levels of NO can have pathological consequences for the host as NO is toxic to host cells as well as microorganisms. Disregulated production of NO during an inflammatory response to infection or allergens may cause severe damage to host tissues. In addition, under conditions where there is an autoimmune recognition of host tissues NO may mediate the actual tissue damage observed.

The induction of toxic shock in mice after injection with LPS can be prevented by treatment with L-NMMA and, similarly, iNOS 'knockout' mice recover from LPS-induced shock while normal littermates do not, indicating that a pathogenic role can be attributed to NO production in response to bacterial products. In addition to toxic shock, the disregulated production of NO has been demonstrated to contribute to the pathology associated with neurodegenerative and inflammatory disorders.

Self-recognition and the induction of autoimmune aggression may cause the production of NO which causes damage to cells within the inflammatory focus. NO has been implicated in the tissue damage observed in several models of autoimmune disease, including autoimmune diabetes and rheumatoid arthritis. In addition, intestinal enteropathy associated with graft-versus-host disease, which involves

recognition of host tissues by grafted immune cells, also depends on the induction of NO, as L-NMMA treatment in a mouse model of this disease reduces gut damage.

Human NO production

There has been considerable uncertainty about the ability of human macrophages to produce NO. Human peripheral blood monocytes and some human macrophage cell lines failed to produce appreciable amounts of NO in response to immunological stimuli which readily induce NO synthesis in rodent macrophages. Evidence is accumulating that human macrophages, especially those derived from patients with chronic infection or inflammatory conditions such as rheumatoid arthritis, can express significant levels of iNOS and produce relatively large amounts of NO *in vitro*. However, the conditions for the induction of NO synthesis by human macrophages are likely to be different from those studied in murine models. The optimal stimulatory components required for NO synthesis by human macrophages remains to be determined.

NOCARDIA, INFECTION AND IMMUNITY

Blaine L Beaman, Department of Medical Microbiology and Immunology, University of California School of Medicine, Davis, California, USA

Characteristics of the organism and its antigens

Members of the genus *Nocardia* are aerobic, gram-positive, filamentous bacteria that belong to the Actinomycetes (Figure 1). They share several biological properties with the closely related mycolic acid-containing genera *Corynebacterium*, *Gordona*, *Mycobacterium*, *Rhodococcus* and *Tsukamurella*. Most species of *Nocardia* are environmental organisms that reside primarily in the soils of all regions of the world. Many of the nocardiae may cause disease in a variety of animals and some plants. The *N. asteroides* complex (composed of *N. asteroides* sensu stricto, *N. farcinica* and *N. nova*), as well as *N. brasiliensis*, *N. pseudobrasiliensis* and *N. otitidiscaviarum*, cause disease in humans.

The *N. asteroides* complex is recognized most frequently as the etiology of nocardiosis in both immunocompromised and 'normal' individuals.

Figure 1 Different colonial morphotypes of *Nocardia asteroides* grown for 14 days at 37°C on glucose yeast extract agar. The photograph was made on Ectachrome film using a laser scanning camera with a macro focusing 100 mm lens. These colonies are approximately 0.5 cm in diameter.

Nocardiosis usually begins as a pulmonary infection that may remain localized, or it may become disseminated via the bloodstream to any organ; however, the brain is the usual secondary target, followed by the skin, kidneys, adrenals, eyes, heart, etc. The disease may range from a self-limited, subclinical infection to a progressive, aggressive disseminated infection that fails to respond to therapy resulting in death. *N. brasiliensis* and *N. otitidiscavarium* (*N. caviae*) may also cause nocardiosis; however, these organisms usually cause skin infections following trauma. The skin lesions may range from a benign, self-limited condition to a chronic, progressive disease that extends from the skin into the deeper tissues including the bone. This latter process is referred to as an actinomycetoma. Deep-seated, systemic infections previously attributed to *N. brasiliensis* are usually caused by the closely related *N. pseudobrasiliensis*.

The antigenic structure of *Nocardia* is complex and numerous antigenic components have been recognized. Several of the antigens of *Mycobacterium*, *Rhodococcus* and *Corynebacterium* share epitopes with *Nocardia*. Thus, a major obstacle for developing specific antigens that have diagnostic value is cross-reactivity (nonspecificity). Because of the antigenic heterogeneity of *Nocardia*, it has been difficult to identify antigens that are broadly specific for *Nocardia*, yet not so selective as to exclude different strains of *Nocardia*. Currently, the 55 kDa antigen identified by Angeles and Sugar (probably the same as the diagnostic 54 kDa antigen described by Boiron and colleagues) appears to be most promising for recognition of patients infected with *Nocardia* spp. Unfortunately not all strains of *Nocardia* infecting humans express the 55/54 kDa antigen. Skin test antigens (purified protein derivatives, PPDs) have been prepared; however, both the sensitivity and specificity for using these antigens to identify individuals infected with *Nocardia* have not been determined adequately.

Serodiagnosis of disease caused by nocardiae is problematic. It was reported in the USA that 20% of a relatively young, healthy population of medical students in California (>100 individuals) had antibody titers of $\geq 1:100$ to all of the diagnostic antigens of nocardiae using western blot immunoanalysis. The same study reported that 50% of an elderly population (>160 people) in Kansas were seropositive for nocardiae using these same western blot assays, whereas only 85% of individuals with culturally proven nocardiosis were seropositive. These observations indicate that there is significant exposure to nocardiae with probable subclinical infection developing in the absence of overt disease,

the incidence of which appears to increase with age. Furthermore, a significant number of individuals do not express detectable antibody against nocardial antigens during progressive disease (even in 'normal', nonimmunocompromised patients).

Immune responses of the host

Naturally acquired, progressive nocardial infections (excluding mycetomas) are recognized more frequently in humans that are immunocompromised. In general, persons with a deficiency in cell-mediated immunity appear to be more susceptible to infection than those that are deficient in complement or immunoglobulin. Furthermore, defects in polymorphonuclear function (i.e. chronic granulomatous disease) or in macrophage function enhance host susceptibility.

In vitro studies have shown that virulent strains of *N. asteroides* are not killed by either human polymorphonuclear leukocytes (PMNs), monocytes or macrophages. Indeed, these organisms readily grow in monocytes and macrophages. The PMNs were demonstrated to inhibit the growth of *Nocardia in vitro*, but this inhibition is only temporary. Activated macrophages, but not monocytes, are also inhibitory to *Nocardia*, but the ability of these cells to kill *Nocardia* is minimal. Studies demonstrated that pre-activation of either murine macrophages or human monocytes with recombinant interferon γ (IFN γ) and tumor necrosis factor α (TNF α) enhanced nocardial growth. Furthermore, the addition of a secondary signal such as lipopolysaccharide (LPS) enhanced nocardial filamentation even more. In contrast, coincubation of *Nocardia* spp. with either recombinant IFN γ or TNF α and normal human monocytes resulted in inhibition of intracellular nocardial growth.

Host responses to *Nocardia* have been studied using a variety of experimental animals. There have been numerous reports on nocardial interactions with *in vitro* maintained rabbit and murine macrophages. Virulent strains of *Nocardia* are readily phagocytosed by macrophages in the absence of serum or complement. Once the nocardiae are intracellular, they readily initiate growth that leads to macrophage destruction. Methods to prevent nocardial growth of macrophage monolayers have been explored. Macrophages killed all of the cells of virulent *Nocardia* only when activated macrophages were combined with specific immune serum and T lymphocytes. Physical interaction between the T lymphocyte and the macrophage appears to be essential. Furthermore, it was discovered that mice immunized against whole cells of *N. asteroides* have T cells that

demonstrate immunologic specificity for binding directly to *Nocardia*. These T cells kill nocardiae directly.

In vivo studies in mice, rabbits and guinea pigs support the *in vitro* observations. Virulent cells of *Nocardia* are not killed by the 'normal' naive animal. At both 3 and 6 h following intravenous injection of virulent nocardiae, one can readily recover 100% of the inoculum dose. The lag phase for nocardiae is about 6–8 h, thus no increase in colony-forming units occurs during this time period. Furthermore, no bacteria are killed during this same period. After 6 h, the nocardial numbers increase, especially in the brain and kidneys. Only 48–72 h after i.v. injection, do the number of nocardiae within the host decrease.

The use of germ-free mice demonstrates that activation of the host by the presence of a normal microflora is important for innate resistance of the animal to nocardiae. *N. asteroides* grow unimpeded in germ-free mice, whereas the 'normal' control animals are able to delay *in vivo* growth. Athymic, nude mice, which are T cell deficient, are more susceptible to nocardiae than their littermate controls, while in contrast, B cell-deficient mice are not. In addition, adoptive transfer of purified T cells from immunized mice to nonimmunized athymic mice, confers resistance. Adoptive transfers of B cells do not have the same effect. These observations indicate that T cells, but not B cells, are essential for host immunity to nocardial infection.

Evasive strategies by *Nocardia*

The relative virulence of strains of *Nocardia* for mice can be determined, and the *Nocardia* can be grouped into three general categories: 1) high virulence, 2) moderate virulence, and 3) low virulence. A large variety of factors affect the relative virulence of *Nocardia* in these models. These include the following: stage of growth; growth temperature; composition of the growth media; conditions of inoculum preparation; strain differences; route of exposure to the host; method of exposure to the host; and the type, age, weight and condition of the host.

By comparing differences in properties between highly virulent isolates and those with low virulence, correlations emerge that relate certain capabilities to virulence. By selecting specific mutants of these strains, the precise role of each factor in pathogenesis can be measured.

Cells of virulent strains of *Nocardia* 1) inhibit phagosome-lysosome fusion in macrophages and monocytes, 2) block or neutralize phagosomal acidification, 3) reduce the lysosomal enzyme acid phosphatase, 4) resist oxidative microbicidal activities of

phagocytes, and 5) grow within monocytes, macrophages and PMNs. In contrast, low-virulence strains of *Nocardia* do not have any of these capabilities, whereas moderately virulent strains are intermediate. It was shown that the highly virulent organisms secrete a unique superoxide dismutase (SOD) into the environment and this SOD becomes cell surface associated. In addition, these cells have high levels of intracytoplasmic catalase. *In vitro*, these highly virulent strains are very resistant to superoxide, hydroxyl ion, hydrogen peroxide, and to halides combined with these metabolites. In contrast, low-virulence *Nocardia* do not secrete SOD, and they have low levels of catalase. These organisms are killed by the above-listed components of oxidative metabolism. In addition to SOD and catalase, other cell wall components such as glycolipids appear to be involved in nocardial pathogenesis. *Nocardia* that contain the glycolipid trehalose-dimycolate (cord factor) are more virulent for mice and affect phagocyte function more completely than low-virulence strains that lack cord factor. Furthermore, the size and degree of unsaturation of the mycolic acids in the cord factor appear to be critical in modulating host cell function.

Vaccines

There are currently no effective vaccines developed against *Nocardia*. However, studies have suggested that immunization with certain nocardial components enhances host resistance, one of the most promising of these utilizing nocardial SOD as the protective antigen. In addition, *Nocardia* have cell wall components that enhance or augment the immune response. These components (peptidoglycolipids) can completely replace mycobacterial products in Freund's adjuvant. Also, the nocardial cell wall contains a potent T-independent B cell mitogen. Therefore, nocardial components are being explored as powerful immunomodulators.

NORTHERN BLOTTING

Akihiko Muto and Ken-ichi Arai, Department of Molecular and Developmental Biology, Institute of Medical Science, University of Tokyo, Tokyo, Japan

Cells in different states express different sets of genes. Some of these genes are specifically expressed in particular types of cells, and the specific expression of such genes is apt to determine the phenotypes of the cells. Although the expression of genes may be regulated at multiple steps in the pathway leading from DNA to protein, it has been proven to be regulated mainly at the level of transcription. Various techniques in molecular biology have been developed to examine transcripts qualitatively and quantitatively. Among them, northern blotting is an important and commonly used technique to determine both the size and the relative amount of the transcript of the gene of interest. The procedure of this technique is similar to that of Southern blotting (DNA blotting), and was named by analogy. The northern blotting technique is composed of three experimental steps: 1) agarose gel electrophoresis under a denaturing condition to separate RNA; 2) transfer of the separated RNA to a membrane; and 3) hybridization with a radiolabeled probe to detect a specific sequence. There are several variations in each step, and a brief summary of each step in the protocol is described here.

1. Separation of RNA by denaturing gel electrophoresis

For northern blotting, either total or poly(A)⁺ RNA can be used. Most cellular RNAs are single-stranded polynucleotides and generally have secondary structures formed by intramolecular base-pairing. The secondary structures prevent RNA from being separated according to size by electrophoresis through an agarose gel. To disrupt the secondary structure of RNA, either formaldehyde or glyoxal/DMSO (dimethyl sulfoxide) is commonly used as a denaturing reagent. Formaldehyde is simply added to the samples and gels, so that the method using formaldehyde is easier to run the gels than that using glyoxal/DMSO. In the glyoxal/DMSO method, RNA is denatured by association with glyoxal, and the association is kept under a condition where the pH is neutral or acidic. Therefore, the gels must be run slowly and the buffer must be circulated to avoid the formation of an H⁺ gradient in the buffer during electrophoresis. Despite this inconvenience, the resolution of RNA is better in the glyoxal/DMSO system because a specific RNA is detected as a sharper band by hybridization. The size of the RNA fragment can be determined by comparing the migration distance

of the RNA with those of molecular weight markers, which should be run in parallel, or those of the 28S (4.7 kb) and 18S (1.9 kb) rRNAs contained in the samples of the total RNA. The molecular markers and rRNAs can be detected by staining gels with ethidium bromide after electrophoresis.

2. Transfer of RNA to a membrane

After electrophoresis is completed, the separated RNA is transferred from the gel to a membrane. Two types of membrane, nitrocellulose and nylon, are generally used. Nylon membranes have advantages in that they are more durable than nitrocellulose membranes, allowing repeated hybridization without significant loss of signal. However, a higher level of background hybridization tends to be detected when the nylon membranes are used. Using an increased amount of salmon sperm DNA as a blocking reagent contained in the hybridization solution may decrease the level of background. RNA is transferred to membranes by capillary transfer or vacuum transfer. RNA is carried from the gel in the flow of the transfer buffer in both methods. Vacuum transfer requires a special transfer apparatus and is more efficient than capillary transfer. In addition, the electrophoretic transfer method is available only for nylon membranes. This method cannot be recommended for use with nitrocellulose membranes because a high concentration of salts is required for the binding of RNA to nitrocellulose membranes but not to nylon membranes. The high ionic strengths of the transfer buffers permit efficient conduction of electric current, leading to depletion of the buffering power by electrolysis and causing overheating. The use of large volumes of buffers and continuous external cooling are therefore required to avoid these problems. The transferred RNA is fixed to either membrane by baking at 80°C for 2 hours in an oven. Alternatively, the RNA transferred to a nylon membrane can be immobilized by ultraviolet cross-linking or alkaline fixation.

3. Hybridization with a radiolabeled probe

To detect a specific RNA immobilized on the membrane, hybridization is performed using a radiolabeled probe prepared from the gene of interest. Several types of probe can be used, including double-stranded DNA, single-stranded DNA, RNA and end-labeled oligonucleotides. The double-stranded and single-stranded DNA probes are prepared by nick translation, random oligonucleotide priming method or polymerase chain reaction (PCR). A fragment purified from the vector by restriction digestion and a single-stranded plasmid containing the sense strand of cDNA are used as templates for the double-stranded and single-stranded (an antisense strand) DNA probes, respectively. On the other hand, the

RNA probe, which should also be antisense, is made by *in vitro* RNA synthesis using RNA polymerases from bacteriophages such as SP6, T3 and T7. In this case, the template is constructed by cloning the DNA fragments which will be transcribed to RNA into a double-stranded vector incorporating promoters for these RNA polymerases. The specific activity of these probes should be $>10^8$ c.p.m. μg^{-1} . The RNA-RNA hybrid is more stable than the RNA-DNA hybrid, so that RNA probes provide increased sensitivity but require more stringent hybridization and washing conditions. The hybridization solution should contain 50% formamide, permitting hybridization at a lower temperature and minimizing the degradation of RNA. After hybridization, the membrane is washed in the buffer containing a lower concentration of salts. The washing conditions become more stringent by decreasing the concentration of salts or by increasing the temperature of the buffer. The specific transcript is subsequently detected by autoradiography. The northern blotting is a sensitive technique by which at least 1 pg of a specific transcript can be detected.

Recently, various types of hybridization systems using DNA or RNA probes labeled with nonradioactive reagents including digoxigenin (DIG), biotin and fluorescein have been developed. In these systems, the probes are labeled by incorporating nonradioactive reagent-conjugated nucleotides. Although the standard methods described above can be applied for probe labeling, hybridization and washing, additional experimental procedures similar to those used in western blotting are necessary to detect the hybridized probes. After washing, the hybridized probe is bound with an enzyme-linked antibody for the nonradioactive reagent (DIG or fluorescein) or enzyme-linked streptavidin (biotin). Alkaline phosphatase or peroxidase is usually used as the enzymes of these conjugates. The membrane is subsequently exposed to the detection reagent containing a substrate for the enzyme, and a specific transcript is detected by chromogenic or chemiluminescent visualization. The sensitivities of these methods are comparable to those using a radioisotope.

NUDE (ATHYMIC) MICE

Yasunobu Yoshikai, Laboratory of Host Defense, Research Institute for Disease Mechanism and Control, Nagoya University School of Medicine, Nagoya, Japan

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The congenitally mutant mice characterized by hairlessness were discovered in 1963 and were subsequently demonstrated to carry the autosomal recessive mutant gene 'nu' located on chromosome 11. The 'nu' gene has recently been found to encode a new member of the winged helix domain family of transcription factors that is expressed specifically in skin and thymus. Since the finding, in 1968, that hairless nu/nu (nude) mice were congenitally athymic and had severely reduced numbers of T cells, nude mice have been extensively used as a T cell-deficient system for studies on the role of T cells in immunological responses and as an *in vivo* experimental tool for propagation and expansion of tumor cells in oncology research. Recent experimental advances reinforce the notion that nude mice do have some lymphocytes which are comparable to the T cells of normal mice. Therefore, nude mice also provide us with an interesting experimental system for the study of T cell differentiation along an extrathymic pathway. However, it is likely that such studies in the future will rely more heavily on the use of targeted gene knockout mice.

Breeding and maintenance of nude mice

Good animal husbandry and strict precautionary monitoring for microbiological control are mandatory if meaningful experimental results are to be obtained from nude mice. Housing systems for maintaining nude mice are as follows:

1. A system of plastic cages with sealed air filters is usually used for successfully housing and conducting experiments with nude mice.
2. The best system from the point of view of isolation from the environment for maintenance of pathogen-free nude mice is the use of isolator units.
3. Another secure but more expensive system is provided by laminar air flow cage units and laminar air flow rooms.

The development of congenic lines of nude mice with a definite genetic background is also essential for immunological research. Female nude mice lactate poorly and are often infertile. Thus, mating schemes generally involve mating heterozygous (nu/+) females with homozygous (nu/nu) males. Three breeding systems are used: outbreeding, inbreeding

and cross-breeding. Inbreeding (generally using brother × sister pairs set up at the time of weaning) is used to obtain mice of specific and uniform genetic background. The available strains of nude mice are as follows: B6CByF1/J-nu, CByB6F1/J-nu. NU/J nu, BALB/cByJ-nu, C57BL/6J-nu, AKR/J-nu^{str}+, C57BL/6-nu^{str}.

An additional mutation at the nu locus, called streaker (nu^{str}) was found to occur on the AKR/J strain backgrounds. Homozygotes (nu^{str}/nu^{str}) do not express leukemogenic retroviruses and fail to show leukemic changes in the lymphocytes. However, when grafted with thymic epithelial tissue nu^{str}/nu^{str} mice develop the high incidence of T cell lymphoma.

Immunological characteristics of nude mice

Phagocytes and natural killer (NK) cells

The activities of phagocytes including phagocytic uptake, FcR expression and killing of tumor cells and bacteria are greater in nude mice than in euthymic (nu/+) littermates. These alterations are considered as a result of stimulation with lipopolysaccharide (LPS) derived from gut microflora. However, the fact that increased activities of phagocytes are also detected in nude fetuses suggests that the athymic mutation influences the state of professional phagocytes. The NK activity is also higher than that in nu/+ mice even bred under specific pathogen-free conditions. The increased NK cell activity appears to be due to elevated levels of interferon in nude mice. High levels of NK activity may lead to increased immunosurveillance, and the occurrence of spontaneous tumors is not greater than in euthymic mice.

T lymphocytes

The presence of the thymus is essential for the full development of the immune system. The thymic primordium, which is derived from pharyngeal epithelium, is first colonized by bloodborne lymphoid stem cells at the 11th day of gestation in the mouse embryo. These stem cells proliferate and give rise to thymocytes, some of which become capable of immune responsiveness shortly before birth. Stem cells for the T cell lineage are clearly present in nude mice and T cell precursors have been demonstrated in bone marrow. However, they cannot differentiate

to a substantial number of immunocompetent T cells in the absence of thymic influence. Anatomically, all the T cell compartments of the lymphoid system in nude mice appear empty with very few, if any, functional T cells. A thymic rudiment exists at 12 days' gestation in nude mice. Major histocompatibility complex (MHC) molecules on thymic epithelial cells play an important role in T cell development in the thymus. Normal thymic epithelial cells express MHC class II by day 13 of gestation, whereas such expression is not detected in the 13-day thymic rudiment of nude mice. The thymic rudiment degenerates by birth. Electron microscopic surveys of the early embryonic thymus reveal no lymphoblasts within the thymic lobes.

There are, nevertheless, several lines of convincing evidence that some cells sharing phenotypic and functional properties of T cells do develop in nude mice. Limiting-dilution studies have shown that antigen-specific precursors of both cytolytic and helper T cells exist in such animals, albeit at a significantly (5- to 10-fold) lower frequency than in *nu/+* mice. Since the thymus rudiment is not settled by lymphocytes at any stage of development, the possibility that a few T cells do mature in the early thymus of nude mice can be excluded. An appreciable number of T cells are also detected in nude mice born to *nu/nu* homozygous mothers, suggesting that maternal T cells are not the origin of the T cells in such animals. Systemic study of the age-associated increase in lymphocytes expressing the T cell markers Thy-1, CD4 and CD8 in nude mice suggests that T cell precursors can differentiate along a thymus-independent pathway.

Although only a minor population of peripheral T cells express TCR $\gamma\delta$, this population is relatively abundant in intraepithelial lymphocytes in intestine, skin and uterus in euthymic mice. Nude mice contain intraepithelial lymphocytes expressing V γ 1 in intestine and epidermis, suggesting that this subset of $\gamma\delta$ T cells can develop extrathymically.

$\alpha\beta$ T cells also can develop outside the thymus in nude mice. The cell surface density of the TCR complex, however, is lower on the T cells in nude mice than on those in euthymic mice although it is higher than on the majority of immature thymocytes. The $\alpha\beta$ T cells with intermediate levels of TCR, which are preferentially found in the liver of euthymic mice, express NK1.1 (a member of NKR-P1 family) and interleukin 2 (IL-2) receptor β chain, both of which are NK markers. The T cells with NK markers consist of CD4⁻8⁻ double-negative T cells and CD4⁺ T cells and have a restricted TCR V α /V β repertoire such as V α 14 and V β 2,7,8. The development of these T cells is dependent on MHC class Ib or CD1 mol-

ecules which are abundantly expressed by epithelial cells in intestine and liver. During T cell differentiation in the thymus, T cells with intermediate affinity for self-MHC gene products are selected (positive selection) and T cells reactive to self antigen are eliminated (negative selection). T cells differentiating outside the thymus have not undergone negative selection and seem to be capable of generating the full range of TCRs randomly. However, functional, serological and molecular analyses of the TCR repertoire in nude mice have revealed that the nude T cell repertoire is more limited than the normal one. It can be speculated that nude T cell precursors can differentiate at epithelia in liver, intestine or skin, which express preferentially MHC class Ib including TL, Qa and CD1 molecules exhibiting only minimal polymorphism. Restricted antigen presentation by these molecules could be involved in positive and negative selection of the T cells outside thymus, resulting in the generation of a limited TCR repertoire in nude mice. It is also possible that environmental antigens are responsible for expansion of such T cell clones dominating the T cell repertoire.

It is not clear at present whether the reduced TCR density on nude T cells is just a curious abnormality or may be informative with regard to pathological T cell development. TCRs, either $\alpha\beta$ or $\gamma\delta$ chains, are associated with CD3 γ , δ , ϵ and $\zeta\zeta$ chains. Some subsets of T cells, especially epithelia-associated T cells use the common γ chain of FcR instead of ζ chain of TCR complex. In nude mice, the epithelia-associated T cells have CD3 γ , and ϵ chains but not δ or ζ chains. T cells in nude mice may therefore be activated via a different pathway from those in euthymic mice.

B lymphocytes

Although nude mice do have an appreciable level of T cells, most of the lymphocytes in the peripheral lymphoid tissues are B cells. The absolute number of B cells is much the same as that in *nu/+* littermates. B cells can be divided into three lineages: B1-a cells expressing CD5, B1-b cells expressing Mac-1 and conventional B cells. B1-a and B1-b cells, both of which express IL-5R, are present in the peritoneal cavity at an early stage of ontogeny and secrete natural antibodies including anti-phosphatidylcholine antibody. The nude mutation does not result in a lack of B1 cells but there are slightly reduced levels of such B cells, which might imply a relative independence from thymic influence in the generation of B1 cells but some T cell influence on the maintenance of such cells.

As compared with euthymic controls, nude B cell responses are considerably lower, very deficient in

IgG1, and somewhat limited in IgG2, indicating a significant part of these responses is induced and/or amplified by helper T cells. T cell-independent (TI) and T cell-dependent (TD) antigens were originally defined as ones that could, or could not, stimulate antibody production in nude mice, respectively. TI antigen induces essentially IgM and IgG3, whereas TD antigen induces mainly IgG2a and IgG2b. The amount of IgM in the serum of nude mice is much the same as that in nu/+ mice, while the level of IgA, IgG1 and IgG2 are reduced. The antigen-specificity repertoire of immunoglobulins in nude mice is much less well-defined. This is in part due to the fact that age, strain and environmental stimulation affect the repertoire of immunoglobulins in the blood of the nude mice.

Use of nude mice in immunology and oncology

Studies of T cell differentiation and host defense mechanisms

The lack of a thymus has rendered the nude mouse a good model for the study of T cell differentiation. Analysis of T cells present in nude mice reveals the characteristics of T cells differentiating along extrathymic pathways. Thymus-grafted nude mice are useful for studying the roles of thymic components in T cell differentiation. The nude mouse also provides a model for studying host defense mechanisms against microbial infection and tumors. Inoculation of *Mycobacterium leprae* into the paws of nude mice has produced a disease very similar to human leprosy in many of its symptoms. Treatment with chemotherapeutic agents of nude mice affected by leprosy has given essentially the same results obtained with such agents in humans. Accordingly, the nude mouse has proved to be a valuable model for the study of experimental chemotherapy of leprosy in humans.

Growth of transplants of normal and neoplastic tissues

Although an appreciable level of functional T cells

and an increased level of NK activity are detected in nude mice, these mice show an inability to reject allo- and xenografts. Therefore, nude mice have been used as recipients of normal tissues and for the expansion of various tumor cell lines, as well as for the maintenance of hybridomas for monoclonal antibody production. Skin from other species has been grafted successfully and remained viable indefinitely. All skin grafts survived and continued to perform their normal functions such as hair and feather growth, production of sebum, and renewal of epithelium. Tumors developing in other species, especially humans, have been inoculated into nude mice. Anatomical structure at both the macro- and microscopic levels is well preserved and the grafted tumor is generally indistinguishable from the structure of the tumor in the patients. Secretion of hormones in secretory tumors and production of other biological substances is maintained. Human tumors growing in nude mice produce metastases, albeit not frequently. Therefore, nude mice have been an invaluable tool for characterizing tumors and establishing the effectiveness or lack of effectiveness of a drug on a specific tumor.

NUTRITION AND THE IMMUNE SYSTEM

Malnutrition is the most common cause of immunodeficiency worldwide. The frequent presence of nutritional deficiencies in developing countries is well known. It has now been revealed that mild to moderate undernutrition is not uncommon even in industrialized countries. For example, iron deficiency is seen in at least 9% of the North American population. In hospitalized patients, obvious malnutrition is frequent. The combination of malnutrition and infection is responsible for much of the morbidity and mortality in all age groups. In patients with a variety of primary diseases, such as cancer and Crohn's inflammatory bowel disease, nutritional deficiencies further complicate the picture and increase the risk of infectious complications. Although much of the initial work on nutrition and immunity was done on young children in developing countries, the general principle that nutrition is a critical determinant of immunocompetence is applicable universally.

Protein-energy malnutrition

Epidemiological studies have documented the adverse effect of protein-energy malnutrition (PEM) on morbidity and mortality. Pathological examination of tissues from children dying of PEM showed the frequent presence of several opportunistic microorganisms including *Pneumocystis carinii*. Morbidity due to diarrheal disease, respiratory infection, measles, tuberculosis, and perhaps even to human immunodeficiency virus is increased.

Lymphoid tissues show a significant atrophy. For instance, the size of the thymus is small. Histologically, there is a loss of corticomedullary differentiation, there are fewer lymphoid cells, and the Hassall's corpuscles are enlarged, degenerated and, occasionally, calcified. In the spleen, there is a loss of lymphoid cells around small blood vessels. In the lymph node, the thymus-dependent areas show depletion of lymphoid cells.

Delayed cutaneous hypersensitivity responses both to recall and new antigens are markedly depressed. There is a significant positive correlation between the size of skin response and visceral protein synthesis as judged by serum albumin concentration. It is not uncommon to have complete anergy to a battery of different antigens. These changes are observed in moderate deficiencies as well. Findings in patients with kwashiorkor were more striking compared with

those in patients with marasmus. One plausible reason for reduced cell-mediated immunity in PEM is the reduction in the number and function of mature T lymphocytes particularly CD4⁺ helper T cells. The reduction in serum thymic factor activity observed in PEM may underlie the impaired maturation of T lymphocytes. There is an increase in the amount of deoxynucleotidyl transferase activity in leukocytes, a feature of immaturity. The number of CD4⁺ cells is decreased markedly, often to values less than 50% of controls. The change in number of CD8⁺ T cells is less marked. Thus the 'helper/suppressor' ratio is significantly decreased. Lymphocyte proliferation and synthesis of DNA are reduced, especially when autologous patient plasma is used in cell cultures. This may be the result of inhibitory factors as well as a deficiency of essential nutrients lacking in patients' plasma.

Serum antibody responses are generally intact in PEM, particularly when antigens in adjuvant are administered or in the case of T cell-independent antigens. Rarely, the antibody response to organisms such as *Salmonella typhi* may be decreased. Before impaired antibody response can be attributed to nutritional deficiency, one must carefully rule out infection as a confounding factor. Antibody affinity is decreased in patients who are malnourished. This may provide an explanation for a higher frequency of antigen-antibody complexes found in such patients. As opposed to serum antibody responses, secretory immunoglobulin A (IgA) antibody levels after immunization with viral vaccines are decreased; there is a selective reduction in secretory IgA levels. This may have several clinical implications, including an increased frequency of septicemia in undernourished children.

The process of phagocytosis is also affected in PEM. Complement is an essential opsonin and the levels and activity of most complement components are decreased. The best documented is a reduction in complement C3, factor B, and total hemolytic activity. Although the ingestion of particles by phagocytes is intact, subsequent metabolic activation and destruction of bacteria and fungi is reduced. Finally, recent work in humans and animals has demonstrated that the production of several cytokines, e.g. interleukin 2 and interferon γ , is decreased in PEM.

Selected nutrient deficiencies

Clinical malnutrition is usually a complex syndrome of multiple nutrient deficiencies. However, observations in laboratory animals deprived of one dietary element and findings in rare patients with a single nutrient deficiency have confirmed the crucial role of several vitamins and trace elements in immunocompetence. Deficiencies of pyridoxin, folic acid, vitamin A, vitamin C and vitamin E result in impaired cell-mediated immunity and reduced antibody responses. Vitamin B₆ deficiency results in a decreased lymphocyte stimulation response to mitogens such as phytohemagglutinin. A moderate increase in vitamin A intake enhances immune response and affords partial protection against the development of certain tumors in animals. Zinc deficiency, both acquired and inherited, is associated with lymphoid atrophy, decreased cutaneous delayed hypersensitivity responses and homograft rejection, and lower thymic hormone activity. In laboratory animal models, these findings can be confirmed and in addition one can demonstrate a reduced number of antibody-forming cells in the spleen and impaired T killer cell activity. Wound healing is impaired. Excess zinc also depresses neutrophil function and lymphocyte responses and is associated with increased morbidity in the elderly.

A deficiency of iron is the most common nutritional problem worldwide, even in industrialized countries. On the one hand, free iron is necessary for bacterial growth (removal of iron with the help of lactoferrin or other chelating agents reduces bacterial multiplication, particularly in the presence of specific antibody) and, on the other, iron is needed by neutrophils and lymphocytes for optimal function. The lymphocyte proliferation response to mitogens and antigens is impaired: response to tetanus toxoid and herpes simplex antigens is low in iron-deficient subjects and iron therapy results in a significant improvement in their response. There are many molecular explanations for impaired lymphocyte and neutrophil function in iron deficiency, including the deficiency of myeloperoxidase and ribonucleotidyl reductase.

Copper-deficient animals show a reduction in the number of antibody-producing cells compared to healthy and pair-fed controls. Dietary deficiencies of selected amino acids decrease antibody responses; in other states of amino acid imbalance, the overall response may be enhanced, indicating that changes in suppressor cells may occur. The phagocytic clearance of macromolecules from the blood is reduced, as is antibody affinity in inbred animals. A modest increase in the intake of arginine and glutamine,

especially orally, improves immune responses and enhances resistance to infection.

Nutritional regulation of immune function in low birth weight infants and in the elderly

There are many striking similarities between the two ends of the age spectrum. Both neonates and the elderly have suboptimal immune responses and are susceptible to infection. When nutritional deficiency complicates the picture, impairment of immunocompetence is more marked and longer-lasting.

The immune system develops during fetal life and the first few months after birth. If an infant is born preterm or if he or she exhibits growth retardation as a result of a number of environmental factors, including maternal malnutrition or infection, immunocompetence is reduced. The impact on T lymphocyte numbers and cell-mediated immunity is most discernible. The preterm infant of low birth weight generally recovers its ability to mount immune responses by the age of 3 months. However, the small-for-gestational-age (SGA) infant may continue to show reduced cell-mediated immunity for several months and years. There is a significant difference in the immunocompetence of SGA infants who exhibit a higher level of morbidity and that of infants with lower morbidity. In laboratory animal models of intrauterine malnutrition, immune responses are impaired both in first- and second-generation offspring.

At the other extreme of life, many but not all elderly individuals show a progressive loss of immune function. Cell-mediated immunity is impaired. This may be due in part to a marked reduction in the putative thymic hormone(s). It is interesting that about 35% of subjects above 65 years retain immunocompetence at levels seen in young adult life. Other studies have documented alterations in nutritional status and body composition, including decreased lean body mass, loss of visceral protein, and increase in the relative proportion of body fat. These changes in body constituents may result from a variety of pathogenic factors, such as altered taste acuity, reduced food intake, malabsorption, and the metabolic consequences of concurrent disease. Deficiencies of vitamins and trace elements are observed in almost one-third of all elderly. To date, there are only a few studies that have looked concurrently at both nutrition and immunity in the elderly.

The age-related decline in immunity is similar to that seen in protein-calorie malnutrition. Since the elderly are known to be among the most poorly nourished in industrialized countries and since

changes in food intake, body composition and protein metabolism are known to occur with advancing age, the possibility arises that altered immune status in the elderly could be ascribed in part to nutritional deficiency. A number of recent studies have shown the frequent occurrence of nutritional deficiencies in the elderly. When these are corrected even partially, there is a significant improvement in a variety of cell-mediated immune responses and in natural killer (NK) cell activity and cytokine production. Even morbidity may be reduced when such nutritional support is provided. The causal contribution of altered nutritional status in the elderly to deficits in their immune responses needs further study. Recent data indicate that a causal relationship does exist between undernutrition and impaired immunity in many elderly individuals and that this is a correctable abnormality in the majority of them. It is not clear whether maintenance of good nutrition and improved immunocompetence will alter morbidity and longevity. Obviously, long-term prospective studies are required to answer these questions.

Practical applications

The many observations on the interactions between nutrition and immunity have led to several practical applications:

1. The outcome of surgery can be predicted on the basis of preoperative assessment of nutritional status and of immunocompetence.
2. Tests of immunocompetence can be used as sensitive functional indices of nutritional status and for determination of the upper and lower safe limits of nutrient intake.
3. Response to prophylactic immunization can be improved if nutritional support is provided before, and even after, the administration of the vaccine.
4. The incidence of opportunistic infections can be reduced when nutritional care is provided at the same time as medical treatment in many chronic diseases, such as inflammatory bowel disease, HIV infection, cancer, etc.
5. Feeding formulas have been developed that selectively enhance immune responses and resistance to infection.
6. Megadoses of certain nutrients can impair immune responses.

ONCHOCERCIASIS

Bulbul Chakravarti, Clinical Immunology, Allergy and Rheumatology Unit, Department of Medicine, University of Rochester School of Medicine, Rochester, New York, USA

Onchocerciasis or river blindness, a filarial parasitic disease caused by infection of humans with *Onchocerca volvulus*, is a severe public health problem in different parts of Africa, Central and South America and Yemen. The major pathology of the disease is debilitating dermal and ocular complications; in fact onchocerciasis is the second leading cause of infective blindness. An estimated 120 million people live in endemic areas, of whom 18 million are infected. Approximately 2% of the infected individuals eventually become blind, although this may be 30% or higher in hyperendemic areas. The life cycle and antigens of the parasite, the complex immune responses of the host and its evasion by the parasite, and different means of controlling onchocerciasis will be discussed with particular reference to the human disease, although many other species of *Onchocerca* can infect cattle (*O. gibsoni*, *O. gutturosa*, *O. lienalis*, *O. ochengi*), horses (*O. cervicalis*, *O. reticulata*) and a variety of wildlife, particularly ungulate hosts.

Characteristics of the organism and its antigens

O. volvulus is a parasitic filarial nematode worm which undergoes a complex set of developmental stages involving two different hosts. Infection is transmitted when the insect vector, female black flies of the genus *Simulium*, bites the human host and introduces infective larvae which subsequently molt twice and mature to male and female adult worms over a period of 3–18 months. The adult worms are encapsulated in subcutaneous nodules of host collagenous tissue called onchocercomata. The adult worms are unable to replicate within the human host, where they can survive up to 10–15 years. Following reproduction within the onchocercomata, the females release microfilariae which migrate out of the nodules to invade the host tissue and concentrate in

the dermis. Approximately 7–34 months (prepatent period) pass before microfilariae are detected in the skin (patent infection). Completion of the life cycle is initiated when infected individuals are bitten by a female black fly which ingests microfilariae along with host tissues from the skin. A small portion of the ingested microfilariae migrate from the gut to the thoracic muscles of the fly, develop into infective larvae over a period of 6–8 days and then migrate to the head of the fly. When this fly bites another individual the infection is transmitted. **Figure 1** illustrates the life cycle of *O. volvulus*.

Major impediments for characterization of *O. volvulus* antigens have been its complex life cycle and limited availability in the absence of a suitable *in vitro* culture system. Since only adult worms

Figure 1 Life cycle of *Onchocerca volvulus*. The sizes of different forms of the parasite are: infective larvae 440–700 μm long, 19–28 μm wide; male adult worms 3–6 cm long, 130–150 μm wide; female adult worms 23–70 cm long, 275–325 μm wide; microfilariae 300–320 μm long, 6–9 μm wide.

obtained by nodulectomy of infected individuals offer reasonable amounts of material, initial studies on the characterization of onchocercal antigens focused mainly on adult worms. However, advances in recombinant DNA technology have led to characterization of a number of antigens of microfilariae, adult worms and infective larvae at the molecular level. The antigens of *O. volvulus* have a wide range of biochemical and physical properties and specificity with respect to their surface-bound, secretory or intracellular nature as well as their characteristic occurrence in particular stages of the life cycle. Antigenic differences have also been observed between different geographical isolates of *O. volvulus*, e.g. savannah and rain forest areas of West Africa. Cross-reactivities between onchocercal antigens with other filarial as well as host antigens have been documented, suggesting structural similarities. Many of the parasite antigens are potent immunogens, as they stimulate production of antibodies in infected individuals.

Immune responses of the host

O. volvulus infection leads to the development of parasite antigen-specific immunoglobulin G (IgG), IgM, IgE and IgA antibodies as well as polyclonal B cell activation. Although the exact time of onset of immune reactions in humans is not known, experimental onchocerciasis in chimpanzees (permissive host for *O. volvulus*) indicates the onset of humoral and cell-mediated immune responses as early as 1 month following infection. The precise role of antibodies in protection or pathogenesis is not well defined; however, antibodies directed against microfilariae can mediate *in vitro* adherence of granulocytes, and eosinophils and neutrophils can mediate antibody-dependent killing. In fact eosinophils may be the major effector cells in antibody-dependent killing of microfilariae, as evidenced by degranulation of eosinophils *in vivo* in areas of the skin surrounding microfilariae, suggesting local and even distant tissue damage from repeated and massive eosinophil degranulation.

Many *O. volvulus*-infected individuals have elevated IgE levels which possibly contribute to acute inflammatory complications, including some ocular lesions. Interestingly, compared with IgG, a higher proportion of IgE antibody is *O. volvulus* antigen specific. Antigen-antibody complexes are also present in the sera of infected persons. Immune complex deposition may cause acute inflammation, tissue damage and downregulation of the host immune response.

Both *in vivo* (skin testing) and *in vitro* (lymphocyte

proliferation) evidence suggests that cell-mediated immune responses are downregulated to *O. volvulus*-specific as well as non-specific antigens in infected individuals. Diminished reactivity is more prominent in those with microfilariae distributed throughout the skin but with little cutaneous reaction compared with those with highly active skin disease and few demonstrable microfilariae. The lymphocyte reactivity of infected young persons (12–16 years) is greater than that in older infected individuals, indicating acquired downregulation of their cellular immune response. Studies on immunoregulation in onchocerciasis show a predominant T_H2-type cytokine response to *O. volvulus* antigens in individuals with demonstrable ocular pathology (both in human and murine models), whereas a T_H1-type response is observed in exposed but infection-free 'putatively immune' persons. The roles of interleukin 4 (IL-4) and IL-5 in killing of infective larvae and clearance of microfilariae have been demonstrated in murine models. While for experimental onchocercal keratitis induced in mice there is predominant infiltration of CD4⁺ T cells, both CD4⁺ and CD8⁺ T cells have been demonstrated to have roles in protective immunity against microfilariae in murine models. The widely used microfilaricidal drug ivermectin (a semisynthetic macrocyclic lactone) improves delayed-type hypersensitivity responses and cellular proliferation and modifies antibody levels as well as the cytokine pattern in onchocerciasis patients, at least temporarily.

The host immune response appears to play a role in both pathology and protection in onchocerciasis, onchocercal pathology being associated with the host immune response to dying or degenerating (but not intact) microfilariae. Based on clinical evaluation of dermal pathology, endemic populations can be broadly divided into three categories: 1) generalized onchocerciasis – common among infected individuals with microfilariae but few clinical symptoms and hyporesponsiveness to parasite antigens; 2) localized onchocerciasis (sowda) – infected individuals with few microfilariae but intense dermal pathology and hyperresponsiveness to parasite antigens; and 3) putatively immune individuals – without any detectable microfilariae or clinical symptoms. The course of *O. volvulus* infection has been shown to be influenced by HLA-D alleles. Ocular pathology is the most deleterious effect of onchocerciasis and can affect both anterior (punctate keratitis, sclerosing keratitis and iridocyclitis) or posterior (optic neuritis, optic atrophy and chorioretinitis) segments of the eye. Host inflammatory responses against dead microfilariae possibly lead to pathological changes in the anterior segment, while migrating microfilariae,

circulating immune complexes, direct interaction of immune cells with microfilariae as well as auto-immune mechanisms may be involved with the posterior segment pathology.

Evasive strategies by the organism

How the parasites survive within the human host is not clear; however, it is obvious that they have evolved ways to avoid or downregulate the host inflammatory response which is detrimental not only to the parasite but also to the host, as onchocercal pathology is associated with dying or degenerating and not intact microfilariae. Immunological hyporeactivity is more prominent in patients with skin microfilariae showing mild clinical symptoms, in contrast to those with few skin microfilariae who manifest severe clinical symptoms and relatively strong cellular and humoral immune responses. Successful transmission of the parasite is thus facilitated. Although the exact mechanism of the observed immunological hyporeactivity is not clear, it may exist at different stages of T cell activation and possibly involves immune tolerance, parasite-derived immunosuppressive antigens, etc. In addition, the onchocercomata may be an effective means by which the adult worms can shield themselves from host defense mechanisms.

Vaccines

Prevention of onchocerciasis based on vector control by spraying larvicides has achieved partial success in some areas. The drug ivermectin, widely used to control onchocerciasis, is effective only against microfilariae and needs repeated dosage, thus requiring a sophisticated primary health care infrastructure, which is lacking in most endemic areas. Development of a vaccine that confers immunity to infection over a prolonged period is considered a more realistic solution.

Epidemiological, clinical and animal model data suggest the existence of protective immunity to onchocercal infection. For example, the level of skin microfilariae in infected individuals attains a plateau level after the fourth decade of their lives; in hyperendemic areas, in spite of repeated infection, a percentage of the exposed population remains infection free throughout their lives, even in the absence of a chemotherapeutic agent; residents in many areas are exposed to thousands of infective larvae per year but only a small percentage of these develop into adult worms; and it has been possible to induce protective immunity in mice immunized with radiation-attenuated infective larvae. Larval antigens seem to be the

best targets for developing a prophylactic vaccine. Heterologous protection by antigens conserved among different filarial parasites remains a possibility. Availability of suitable animal models (*O. volvulus*/*O. lienalis* – mouse, *Acanthocheilonema vitae* – jird, *O. ochengi*/*O. lienalis*/*O. gibsoni* – cattle) and sufficient quantities of recombinant parasite antigens have made it possible to study the efficacy of vaccine candidates. Although no vaccine is yet available to control onchocerciasis, the recent demonstration of the ability of some onchocercal antigens, e.g. OvB20 and tropomyosin, to induce partial protection in a rodent model of onchocerciasis is encouraging.

ONTOGENY OF THE IMMUNE RESPONSE

Constantin A Bona, Department of Microbiology, Mount Sinai Medical School, New York, USA

The acquisition by lymphocytes of the ability to mount immune responses is related to a series of complex cellular and molecular processes which take place during ontogeny. Lymphocytes are divided into two major functionally distinct but morphologically indistinguishable subsets: B and T cells. These are distinguished by different functions, but in the course of ontogeny their precursors can be distinguished by other phenotypic traits and molecular features.

Lymphocytes are derived from multipotent stem cells harbored in the fetal hematopoietic organs such as the fetal liver. During the differentiation process, multipotent progenitors give rise to the progenitors of B and T lymphocytes (Figure 1). In adult life, B cells differentiate in the bursa of Fabricius in birds and in the bone marrow in mammals, whereas T cells differentiate within the thymus.

Phenotypic changes during ontogeny

Various receptors specific for biologically active ligands together with cell differentiation antigens are associated with the membrane of all cell types, including the lymphocytes. Immunoglobulins are the specific receptors of B cells, whereas T cell receptors (TCR) are the specific antigen receptors of T cells.

A number of cell differentiation antigens are associated with mature B and T cells, and others are expressed at certain stages of ontogeny of the immune system. Thus, multipotent progenitors express a low density of Thy-1 antigen present on mature T cells, Gr-1 (an antigen characteristic of granulocytic lineage), Mac-1 of monocytic lineage, B220 of B cell lineage, and Sca-1 antigen. During the differentiation of multipotent progenitors into B cell progenitors, they lose the Gr-1, Mac-1 and Sca-1

Figure 1 Different pathways of T and B lymphocyte.

antigens, and their phenotype can be defined as Thy-1⁺, Ig⁻, B220⁺. There are no good markers to distinguish the progenitors of B cells from pro-B cells, which are the most primitive B cells giving rise to the B lineage.

Stroma cells in fetal liver and bone marrow constitute the microenvironment in which lymphocytes of the B lineage differentiate. Stroma cells are considered to be nonhematopoietic and are a very heterogeneous population, but it is not clear whether or not stroma cell subsets have different effects on the differentiation process of various lineages. Stroma cells produce biologically active substances which can play an important role in the differentiation and proliferation processes. For example, there is good evidence that interleukin 7 (IL-7), which promotes the proliferation of pro-B cells as well as of the double negative (CD4⁻ CD8⁻) T cells, is a product of stromal cells.

The pro-B cell (pre-B I cell) is the most primitive cell of the B lineage. It expresses leukosialin (CD43), CD19, *c-kit* and surrogate receptor λ encoded by *VpreB* and $\lambda 5$ genes associated with a glycoprotein complex gp35–gp130. Pro-B cells differentiate into pre-B cells (pre-B II cells). The hallmark feature of this heterogeneous set of cells is the absence of surface immunoglobulin (Ig) and the presence of cytoplasmic μ chain. They also express major histocompatibility complex (MHC) class II antigens. Two discrete stages of differentiation have been distinguished in pre-B II cells: 1) cycling large pre-B cells which have lost *c-kit* expression and partially lost expression of CD43, express $V\lambda 5$ associated with μH and express CD25; 2) resting small pre-B cells in which V_L (κ and λ) genes are rearranged and in which CD40 is expressed.

Pre-B cells differentiate into immature B cells expressing surface IgM, CD19, CD25, CD40 and Fc and complement receptors. These cells differentiate into mature virgin B cells which lose CD25 but co-express IgM and IgD.

T cell lineage development is divided into three stages: the prethymic phase, the thymic phase, and the mature phase. The prethymic phase, during which multipotent stem cells develop into prethymic cells, begins with hematopoiesis in the fetal liver and then in bone marrow. These cells lack TCR as well as the CD4 and CD8 antigens, and are called double negative. Prethymic cells reach the thymus via the bloodstream, and enter by passing between endothelial cells in venules and then lodge in the medulla and at the corticomedullary junction. At the beginning of the thymic phase, cells divide rapidly and have the appearance of lymphoblasts and express a pre-T α receptor. Initially, these cells differentiate

into lymphocytes which acquire both the CD4 and CD8 antigens ('double-positive' cells) and then TCR and CD3. These cells give rise to CD4⁻ CD8⁻ and CD4⁺ CD8⁺ mature lymphocytes.

Molecular changes associated with ontogeny

There are complex molecular events associated with the development of the B cell lineage consisting of activation or repression of genes encoding cytodifferentiation antigens, or activation of genes encoding various receptors associated with the lymphocytic membrane. However, the most important molecular events are related to the expression of immune receptor; namely, the Ig of B cells and the TCR of T cells. The surface Ig of B cells is the product of rearranged V, D, J and C gene segments of heavy chain and V, J, C segments of κ and λ light chains.

The earliest B cell-specific rearrangement of Ig genes occurs in pro-B cells and consists of $D \rightarrow J_H$ rearrangement. This process is associated with the activation of recombination activating genes RAG-1 and RAG-2 as well as of terminal deoxynucleotidyl transferase (TdT) which plays a role in augmentation of diversity by addition of nucleotides during the gene rearrangement process. The activation of these genes leads to the rearrangement of the heavy chain locus and expression of μ chain. At this stage, the pro-B cells begin to multiply and differentiate into large pre-B II cells. At this point the RAG genes are downregulated, perhaps in order to achieve allelic exclusion. They are reactivated at the small pre-B II stage to permit the rearrangement of the Ig light chain loci and are then irreversibly shut down when pre-B cells differentiate into immature small lymphocytes.

Following the successful assembly of a complete Ig light chain and its combination with the heavy chain, a complete IgM antibody molecule appears on the surface of mature B lymphocytes. κ light chain loci rearrange before λ loci. Successful κ gene rearrangement seems to prevent further V gene rearrangement. If κ rearrangement is unsuccessful in both alleles, λ genes will then recombine.

Mature B cells are characterized by coexpression of surface IgM and IgD. This phenomenon is possible since a single VDJ, associated with two different isotypes, is enabled by differential splicing of mRNA.

In contrast to B cells which have a single type of immune receptor – namely, immunoglobulin molecules – T cells can express one of two types of receptor: α/β or γ/δ . Both of these receptors are associated with the CD3 molecules, a cytodifferentiation antigen present only on the T cell lineage and which

plays a role in the activation of T cells. The α , β , γ , and δ chains of heterodimeric TCR molecules are encoded by V, J, and C segments similar to Ig molecules, with the β and δ chains additionally containing D segments as found in Ig heavy chains.

The $\gamma\delta$ bearing T cells are the first to appear in murine fetal thymus, before day 14 of gestation. At this early stage, T cells are Thy-1⁺, CD4⁻ and CD8⁻, and about 5–10% express $\gamma\delta$ TCR. The proportion of these cells decreases dramatically after day 16 of gestation to 0.2% in adult thymus. The appearance of $\gamma\delta$ cells in thymus is followed by their migration to spleen, epidermis, and intestinal epithelium. There is strong evidence that $\gamma\delta$ T cells do not differentiate from $\alpha\beta$ T cells. This is supported in particular by data that show that δ genes are deleted in $\alpha\beta$ T cells; the location of δ genes in the α locus results in the deletion of δ genes during V α -J α rearrangement.

In ontogeny, the rearrangement of V β , DJ β genes is delayed by 1–2 days and rearrangement of the α locus occurs at a later date. The expression of $\gamma\delta$ or $\alpha\beta$ receptor is associated with the synthesis of CD3 antigen; the CD3 gene is probably expressed in prothymocytes before the rearrangement of the $\gamma\delta$ or $\alpha\beta$ genes and before the appearance of the CD4 or CD8 cytodifferentiation antigens.

At the double-negative stage, the cells express RAG genes which generate a functional β chain. This event promotes the differentiation of the double negative to the double positive stage, which express low levels of CD3. At the double-positive stage β chain is expressed on the surface with pre- α chain. The expression of this pre-TCR signals the progression to the rearrangement of the TCR α locus.

Targeted gene deletion technology allowed the determination of the precise role of several genes in the development of B and T cells. One transcription factor that governs the early commitment of stem cell precursors to the lymphoid lineage is Ikaros. Knock-out of the Ikaros gene prevents the appearance of pro-B cells, double-negative T cells as well as natural killer (NK) cells, indicating that the Ikaros gene controls the differentiation of lymphoid lineage precursors from stem cells. The deletion of RAG genes arrests the differentiation of B cells at the pre-B I stage, since no pre-B cells containing μ chain are detected in RAG knockout mice. Three other targeted mutations arrest the development of B cells at the same stage. They are inactivation of transcription factors such as Pax-5/BsAP, of $\lambda 5$ and of the Ig β signal molecules associated with cell surface Ig.

Collectively, these observations show that, in particular, molecular events that concern the genes which encode the immune receptor are associated

with various stages of the differentiation of T and B lineages.

Ordered expression of various V gene families and acquisition of antigen specificities during ontogeny

In pioneer studies, Silverstein demonstrated that responses of lambs to certain antigens, such as viruses, ferritin, azoproteins, ovalbumin and hemocyanin, could be obtained during fetal life, whereas responses to diphtheria toxoid, O antigen, and BCG occurred only after 40 days of postnatal life. Studies on antibody responses and of idiotype expression in young mice have also helped to show that there is a sequential or ordered activation of clones during postnatal life. There are some polysaccharides such as $\beta 2$ –6 fructosan, *S. tranaroe* lipopolysaccharide (LPS) bearing the α -methyl-D-galactoside immunodominant sugar, or $\beta 1$ –6 galactan, which can elicit an immune response in 1-day-old mice. Immunization with $\beta 2$ –6 fructosan is not paralleled by an increased expression of A48 and UPC10 cross-reactive idiotype (IdX). In contrast, about 25% of LPS-specific antibodies express MOPC387 IdX of a myeloma protein specific for *Salmonella tranaroe* LPS. Similarly, 1-day-old mice immunized with gum ghatti develop a significant antigalactan plaque-forming cell (PFC) response, of which 30% expressed the X24 idiotype. Studies on the ontogeny of antiphosphocholine (PC), phenylarsonate (Ars), and trinitrophenyl (TNP) antibody responses have shown that the production of antibodies against these antigens, which share the IdX of myeloma proteins with the same specificity, can be induced in 1-week-old mice. Thus the majority of the PC specific precursors bearing T15 IdX can be detected 4–5 days after birth, while cells able to produce IdX⁺ Ars-specific antibodies are present before day 7 in neonatal mice. Immunization of 1-day-old mice with TNP-LPS and of 1-week-old mice with TNP-Ficoll elicited a significant anti-TNP response. However, the 460Id expressed on the DNP-binding myeloma protein MOPC460 was detected only in 1-week-old mice immunized with TNP-LPS and in 3-week-old mice immunized with TNP-Ficoll. The activation of 460Id⁺ anti-TNP clones in 7-day-old mice coincided with the age when diversification of the anti-TNP response occurs. In the case of $\alpha 1$ –3 dextran, although the precursors expressing MOPC104Id can be detected during the first week of life, J558IdX precursors appear only 15–22 days after birth and then rapidly become dominant. We have further observed a substantial ontogenic delay in the case of anti- $\beta 2$ –1 fructosan (inulin) responses. A substantial increase

in the anti-inulin response bearing IdX has been observed only in 28-day-old mice. This delayed response is associated with a lack of precursors in young animals. A delayed ontogenic response was also observed in the case of α 1-6 dextran and is also related to the absence of precursors. Fernandez and Moller actually showed that the precursors of anti- α 1-6 dextran can only be detected in 1-month-old mice.

The majority of the data discussed above concern T independent antigens and, therefore, the delayed ontogenic responses are not due to the immaturity of T cells. The sequential activation of some antibody responses cannot be ascribed to a lack of V gene rearrangements in young mice. It seems unlikely that the late maturation of some responses can be explained by the tolerance of the precursors in young animals. In the case of late anti- β 2-1 fructosan responses, the tolerogen would have to be inulin rather than levan. The lack of responsiveness is limited to β 2-1 fructosan and not to β 2-1 fructosan linkage, and both epitopes are carried by bacterial levan which is an environmental antigen. A more plausible explanation is that the sequential activation is acquired by antigen-independent generative mechanisms or T cell influences. Certain unknown mechanisms may determine the time of particular $V_H:V_K$ pairing that might be critical for the specificity of the combining sites recognizing particular epitopes.

Finally, the sequential activation of clones expressing a particular set of V genes can be driven by internal forces such as anti-idiotypic antibodies. This idea is strongly supported by the data of Vakil and Kearney who, while analyzing the binding specificity for some major IdX of antibodies produced by hybridomas originating from fetal liver or neonates, observed that a high number (7%) of them exhibited anti-Id activity.

There are numerous V_H and V_K germ-line genes both in mice and humans. Based on protein sequence homology, the V_H and V_K germ-line genes were classified into several subgroups and now, based on DNA homology, they have been classified into various families. The germ-line genes belonging to a family are grouped in clusters, rarely interspersed, and provide an order on chromosome 12 for heavy chain or on chromosome 6 for V_K light chain.

Analysis of V gene family expression in Abelson-transformed pre-B cell lines has shown a preferential usage of 3' families. In fact, V_H 81X, the most D-proximal member of this family of genes, has been observed in hybridomas of pre-B cell type as well as those prepared from fetal liver. In contrast, different results have been obtained in studies in which the usage of gene family was investigated in nontransfor-

med pre-B cell lines prepared from 6- to 8-week-old nude BALB/c mice. In this study, it was shown that all probes hybridized with detectable intensity to RNA from resting pre-B cells. These data indicate that all V_H gene families were transcriptionally active in resting pre-B cells from adult mice. Incubation for 7 days with dendritic cells and mitogen-stimulated T lymphocytes caused a higher expression of the V_H 7183 family suggesting that the expression of this family is regulated by factors other than ontogeny and, perhaps, is related to specific stages of the differentiation of the B cell lineage. The functional significance of the nonrandom rearrangement of V_H genes is of considerable importance in terms of the emerging functional B cell repertoire of the fetus.

Yancopoulos and Alt have hypothesized that the position-dependent preference of V_H family utilization in pre-B cells and neonatal liver is most likely related to a one-dimensional tracking mechanism, mediated by recombinases, during VDJ joining rather than to a dissociative joining related to collisions during three-dimensional diffusion. There are data which indicate that V_H genes from one family can be replaced by V_H genes from another family in young lymphocytes. It appears that V gene replacement is a rather rare event; however, it may contribute to the establishment of the pre-B cell repertoire. A highly restricted set of V_H gene segment usage has also been observed in human fetal B cells. Analysis of human V_H repertoire at 130 days of gestation has shown a biased usage of certain J_H genes (J_H 3, J_H 4 and J_H 5) and, also a V_H gene designated 56P1 which shows a high homology with murine V_H 81X, a member of the V_H 7183 family preferentially rearranged in murine pre-B cells.

Similarly, certain V_K families are preferentially expressed during ontogeny. Kaushik and colleagues analyzed the usage of V_K families by neonatal murine B cells using an LPS-induced B cell colony assay. The results show that a group of V_K families such as V_K 1, V_K 9 and V_K 8, located in the middle of the V_K locus, are highly used by neonatal C57BL/6 mice. Interestingly, the expression of V_K 21, the most J_K proximal family, was not observed among neonatal B cell colonies. These data suggest that V_K usage in neonatal mice does not reflect positional bias for the expression of 3' families, rather a preferential usage of V_K 1 and V_K 9 family, located in the center of the V_K locus. The differences imply that the mechanisms for V_K gene rearrangement and expression differ from those controlling the V_H locus.

OPISTHORCHIASIS-CLONORCHIASIS

Stitaya Sirisinha, Department of Microbiology, Mahidol University, Bangkok, Thailand

Opisthorchiasis, caused by *Opisthorchis viverrini* and *O. felineus*, and clonorchiasis, caused by *Clonorchis sinensis*, are the two most important liver fluke infections in humans. Juvenile flukes, excysted from infective metacercariae present in poorly cooked fishmeal, migrate from the duodenum into the bile duct where they develop into mature worms and survive for several years. The most obvious pathological change is the proliferation of the biliary epithelium thought to be the result of worm movement, toxic metabolites or the immunological response of the host. The most serious complications are biliary obstruction with or without cholangiocarcinoma. Diagnosis is currently based on the demonstration of eggs in stool, duodenal fluid or bile. However, serodiagnosis for antibody detection in the patient's serum has been reported to give satisfactory results. A monoclonal antibody-based ELISA has been recently reported for the detection of soluble antigen secreted in the feces of infected individuals. Specific DNA probes are also useful for the demonstration of parasite egg DNA. Praziquantel is highly effective and is currently the drug of choice for treatment. Vaccination is neither available nor practical.

Characteristics of the liver fluke antigens

Both somatic extract and metabolic or excretory-secretory products (ES antigens) of *Opisthorchis* and *Clonorchis* are highly immunogenic in humans and

the antibodies produced cross-react extensively. Polyacrylamide gel electrophoretic analysis of the somatic extracts from both parasites shows similar protein patterns.

Detailed analysis of adult *Opisthorchis* somatic extract shows the presence of a large number of antigens ranging from 16 to >116 kDa. The predominant components of 16–17 kDa are associated with the parasite tegument and the 16 kDa protein reacts strongly with opisthorchiasis serum. The ES antigens obtained by *in vitro* maintenance of the parasites contain predominantly an 89 kDa glycoprotein that reacts strongly with sera from patients with opisthorchiasis. A number of sera from patients with clonorchiasis also react. Monoclonal antibodies (mAb) to the secreted 89 kDa and the somatic 16 kDa proteins give intense immunofluorescent staining of the gut secretion and surface tegument, respectively. In addition, mAb against another somatic component of around 90 kDa reacts most strongly with muscle fibers underneath the surface tegument as well as those lining both oral and ventral suckers, pharynx and cecum.

Immune response of the host

Patients infected with *Opisthorchis* or *Clonorchis* have antibody responses that can be detected by a number of immunological techniques including ELISA, immunoelectrophoresis, passive agglutination and immunofluorescence. Although a high

degree of sensitivity and specificity has been achieved using crude somatic antigen, the availability of a more refined antigen should enhance the potential of these techniques for the diagnosis of the infection.

Antibodies in the serum of patients and of experimentally infected animals react with all developmental stages of the parasites. Both stage-specific and cross-reactive common antigens have been detected and identified. Although the predominating classes of antibodies in the serum are immunoglobulin G (IgG) and, to a lesser extent, IgE, on rare occasions small amounts of IgA and IgM have also been detected. On the other hand, a predominant class of antibodies in the bile is secretory IgA. However, IgG, IgE and rarely IgM antibodies have also been detected. It should be mentioned that parasite antigens also have IgE-potentiating activity, as is evident from elevated total IgE levels in the serum.

Although high antibody titers have been reported in the serum of patients and experimental animals, the protective capacity of these antibodies is still questionable. It was previously reported that these liver flukes were killed in the presence of fresh serum from infected humans or experimentally infected animals, thus suggesting the protective role of complement-fixing antibody. However, there was also a report that *Opisthorchis* could activate complement via the alternative pathway, resulting in tegumental damage and parasite killing. Cell-mediated immune responses also develop following natural infection or in animals immunized with the parasite antigen. The role of such T cell responses have yet to be established. However, different lines of evidence suggest that following a primary infection there is little, if any, protection against reinfection by the same parasite. Passive transfer of either serum or lymphoid cells or both from infected donor animals fails to confer protection in recipients against a subsequent challenge. Epidemiological data and clinical observations of patients residing in endemic areas are consistent with a lack of protective acquired immunity.

Evasion of the host defenses

Several parasite and host factors may contribute to the longevity and survival of these flukes within the biliary system, which may be considered to be an immunologically privileged site. Both IgG antibody and complement previously reported to kill these parasites are present in low quantities in bile. However, overwhelming evidence points to the conclusion that the antibody produced, regardless of its isotype, seems to have very little protective power. Moreover, a suppressive serum factor that interferes with macrophage function has been reported in patients

with opisthorchiasis. One other liver fluke (*Fasciola hepatica*) is also known to secrete lymphotoxic substance(s). It is possible, therefore, that these factors may be responsible, at least in part, for the immunosuppression noted during *O. viverrini* infection in experimentally infected animals, since following praziquantel treatment immune responses return to normal. Lastly, these parasites can readily shed their surface tegument following damage by immune mechanisms, thus providing them with another strategy to evade the host's defenses.

Vaccines

Although vaccines may be neither essential nor practical for the control of liver fluke infection, for academic reasons several attempts have been made to induce immunity in experimental animals using a number of parasite preparations. However, the results have been largely unsatisfactory. This is not unexpected in view of the fact that natural infection itself is known to confer little, if any, immunity to reinfection. For instance, a large proportion of individuals in an endemic area of infection can be readily reinfected following praziquantel treatment. Moreover, even if an effective vaccine becomes available, it would have to be given during the first few years of life, as young children in endemic areas are known to acquire infection very early. Furthermore, if the infection induces immunosuppression in humans, as it does in experimental animals, the vaccine will need to overcome such effects.

OPPORTUNISTIC INFECTIONS

Christopher Bunch and **Derrick WM Crook**, Nuffield Department of Medicine, John Radcliffe Hospital, Oxford, UK

Opportunistic infections occur when host defenses are compromised by disease or its treatment. The pattern of infection that may occur in a compromised host can be predicted to some extent from an understanding of the nature of the underlying defect and the normal mechanisms that protect against infection with particular microorganisms. Table 1 illustrates the effect of various disease states on host defenses, and the kinds of infection typically encountered. By far the commonest conditions associated with opportunistic infection are malignant disease,

organ transplantation, and human immunodeficiency virus (HIV) infection. Immune defects in these patients may be selective, but frequently affect more than one aspect of the immune response. In general, the risk of infection is influenced more by the duration of immune suppression than its degree.

Infections occur readily with organisms that are recognized pathogens, but are typically caused by commensal or other normally nonpathogenic agents. Thus community-acquired infections may be caused by ubiquitous saprophytic microorganisms such as

Table 1 Pattern of infection in disease states associated with impaired host defenses

Disease state	Main host immune defects	Typical pattern of infection
Hospitalization, various conditions	Damage to mechanical barriers from i.v. cannulation, malignancy or cytotoxic therapy, obstruction or perforation	Bacteremias, phlebitis, pneumonias, empyemas, peritonitis, etc.
Acute leukemias, aplastic anemia	Neutropenia, phagocytic deficiency	Bacterial infections (bacteremias, pneumonias, soft-tissue infections); invasive candidal and fungal infections
Primary hypogammaglobulinemia, common variable immunodeficiency	Impaired antibody production	Bacterial infections, esp. pneumonias with <i>H. influenzae</i> , <i>S. pneumoniae</i> , <i>S. aureus</i>
B cell lymphomas, chronic lymphocytic leukemia, myeloma	Secondary hypogammaglobulinemia	As primary hypogammaglobulinemia
Transplantation, immunosuppressive and cytotoxic therapy	Impaired T cell responses; neutropenia and phagocytic impairment	Bacteremias; pneumonitis; herpesvirus and mycotic infections; EBV-induced lymphoma
HIV infection (AIDS)	CD4 and monocyte/macrophage impairment	Pneumocystis, toxoplasma, cryptosporidium, atypical mycobacteria, CMV, HSV, candidiasis; Kaposi's sarcoma, EBV-induced lymphoma

Aspergillus spp., *Nocardia* and *Cryptococcus*, or by exposure to geographically localized mycoses such as histoplasmosis, as well as by more common pathogens such as the pneumococcus, respiratory viruses and – in some communities – tuberculosis and common parasitic infections such as strongyloidiasis. Immunosuppressed patients are also prone to more general public health hazards such as the presence of cryptosporidium in water supplies, *Listeria monocytogenes* in unpasteurized milk products, and salmonella food-poisoning.

Hospital-acquired (nosocomial) infections are particularly significant, as hospitals may harbor organisms that are resistant to standard antimicrobial therapy, as well as more serious pathogens such as *Pseudomonas* spp. Hospitalized patients are more likely to undergo invasive procedures, and may acquire infection from blood transfusion. Furthermore, some hospital buildings are potential sources of *Aspergillus* and *Legionella* spp.

The successful management of infection in the compromised host requires a high degree of suspicion, a knowledge of the underlying disorder, and a willingness to investigate rapidly and aggressively. The usual signs of infection may be absent: for example, fever may be reduced or suppressed in patients taking corticosteroids, and local inflammation and abscess formation may be impaired in patients with neutropenia. Diagnostic tests may also require different interpretation: antibody responses may be impaired in patients with humoral immunodeficiency, and skin tests may be similarly unreliable in those with cellular immunodeficiency. Standard microbiological culture techniques may require modification to detect opportunistic invaders, and tissue biopsy may be required to characterize some invasive infections.

The pattern of infection in the compromised host has been altered somewhat by the availability of effective prophylaxis for some of the commoner opportunistic infections. Cotrimoxazole effectively prevents pneumocystis pneumonia in patients with hematologic malignancy and in transplant patients. It is less useful in HIV infection as hypersensitivity reactions to the sulfonamide component are common. Inhaled pentamidine is a useful alternative. Herpes simplex virus (HSV) reactivation can be prevented by acyclovir; some protection may also extend to other herpesviruses including cytomegalovirus (CMV). Some of the newer quinolone antibiotics such as ciprofloxacin and norfloxacin can reduce the incidence of bacteremia in neutropenic patients.

Infections in patients with malignant disease

Epithelial malignancy

Patients with epithelial malignancy do not typically have any intrinsic immune defect, although impaired responses to infection may result from treatment with radiation or cytotoxic chemotherapy. On the other hand, the tumor itself may promote local infection through obstruction (for example of the bronchus leading to pneumonia), ulceration or perforation of a viscus. Hospitalization, with its attendant risk of instrumentation may predispose to infection through damage to mechanical barriers (e.g. skin or mucous membranes).

Hematologic malignancy

Hematologic malignancies are typically associated with profound defects in one or more aspects of host defense, with the result that infection is a major cause of morbidity and mortality in this group of patients.

Neutropenia and impaired phagocytic capacity due to bone marrow failure is an intrinsic feature of the acute leukemias but can occur from marrow infiltration in the later stages of other malignancies, and is an almost inevitable if temporary side-effect of curative cytotoxic chemotherapy for these and other conditions. Neutropenic patients are particularly susceptible to bacteremia from Gram-negative bowel commensals, although the increasing use of long-term central venous catheters for vascular access has been associated with a rise in the incidence of staphylococcal and other Gram-positive bacteremias and local tissue infections.

Focal sepsis in neutropenic patients commonly affects the lungs, oropharyngeal mucosa, perineum and skin. Invasive mycotic infections with *Candida* spp. or *Aspergillus* spp. commonly occur in patients with prolonged neutropenia. These are usually associated with intensive cytotoxic therapy – which also impairs cell-mediated immunity, and prolonged antibiotic therapy – which reduces the so-called ‘colonization resistance’ afforded by normal commensals.

Fever in severely neutropenic patients must be treated promptly. Blood and other appropriate cultures must be taken and the patient given intravenous antibiotics without waiting for the results. The choice of suitable antibiotics is normally determined by local policy in the light of knowledge of typical pathogens and patterns of antibiotic resistance. A typical approach is to use ceftazidime or a combination of an aminoglycoside with a semisynthetic

penicillin such as piperacillin. If cultures are negative and the fever persists for more than 48 h, empiric antimycotic therapy with amphotericin should be considered.

Impaired humoral immunity with hypogammaglobulinemia is a feature of low-grade B cell malignancies including some types of non-Hodgkin lymphoma, chronic lymphocytic leukemia, and myeloma. The pattern of infection closely resembles that seen in primary humoral immunodeficiency – predominantly respiratory tract infections with *Streptococcus pneumoniae* or *Haemophilus influenzae*. The incidence of such infections can be reduced by regular infusions of normal immunoglobulin.

Cellular immunodeficiency is common in patients with Hodgkin's disease, but is also an undesirable effect of cytotoxic and corticosteroid therapy and thus affects a much wider range of patients. The commonest associated infections are due to reactivation of latent herpesviruses, described below. *Pneumocystis carinii* infection may occur in patients who have received particularly prolonged or aggressive chemotherapy, but can now be largely prevented in this population by co-trimoxazole. Meningitis and other infections with listeria or cryptococci are seen occasionally. Tuberculosis is classically associated with Hodgkin's disease but is now uncommon, although previously infected patients undergoing cytotoxic therapy are at high risk of reactivation and should receive prophylactic medication such as isoniazid.

Corticosteroid therapy

Corticosteroids are commonly used in the treatment of lymphoid malignancies, but are also used as an anti-inflammatory agent in nonmalignant conditions such as autoimmune diseases. They act in these conditions in part by suppressing cell-mediated immunity (T cell responses), but their beneficial effects are at the expense of a risk of infection, particularly reactivation of latent herpes virus. Particular care must be taken in patients who have not previously had varicella (chickenpox). Primary chickenpox infection in patients with impaired cell-mediated immunity – including those on steroids – is frequently severe and potentially fatal. Early visceral dissemination is common and may be the presenting feature. Special care should therefore be taken in children, who may not previously have been exposed to chickenpox.

Infection in transplant recipients

Successful organ transplantation requires a profound modification of the recipient's immune system to prevent graft rejection. Not surprisingly, graft recipients

are susceptible to infection. As graft rejection is predominantly a cell-mediated process, immunosuppression is directed primarily at T cell responses, and the pattern of infection is again predictable. Agents commonly used are prednisolone, cyclosporine and azathioprine; antilymphocyte globulin is used occasionally. The duration of immunosuppression required is variable: marrow graft recipients typically require only a few months' immunosuppression to prevent graft-versus-host disease (GVHD), whilst renal graft recipients generally require life-long immunosuppression.

Bone marrow transplantation (BMT)

Although allogeneic BMT is occasionally performed for primary marrow failure (aplastic anemia), it is most widely used to allow very high doses of cytotoxic chemotherapy or radiation to be administered to patients with hematologic malignancy without fear of fatal marrow toxicity. Following such therapy, rejection of histocompatible grafts is rare, but immune competent cells derived from the graft may react against the host, producing damage to skin, gastrointestinal tract and liver. This GVHD can be prevented by selectively eliminating the cytotoxic T cell population from the donor marrow prior to transplantation, or modified by short-term immunosuppression with cyclosporine and/or other agents such as methotrexate, cyclophosphamide or prednisolone.

Following successful BMT, the recipient's immune system is replaced by cells of donor origin. Immune reconstitution takes about a year, but is delayed or prevented in patients with GVHD. Responses to infection are impaired until this process is complete, and may be severely compromised by GVHD.

The pattern of infection in BMT recipients changes with time after transplant. In the first 3–4 weeks patients experience severe mucosal ulceration, are profoundly neutropenic, and are prone to bacteremia and reactivation of herpes simplex infections. During the second and third months a major and often fatal problem is interstitial pneumonitis. Total body irradiation is an important factor in the development of pneumonitis, but about one-half are associated with CMV infection or reactivation. Pneumocystis pneumonia is uncommon. Primary CMV infection can be avoided in CMV-negative patients provided their donor is also CMV-negative and only CMV-negative blood products are used. Prevention of reactivation in CMV-positive recipients is difficult, but early detection and therapy with ganciclovir may be effective. Fatal CMV infections are less common following recovery of endogenous antibody production about 2 months after transplantation.

Life-threatening infections are uncommon after the first 3 months unless GVHD persists. Zoster reactivation occurs in about one-half of BMT recipients, but later than HSV and CMV infection. It may be typically segmented or more disseminated. Primary chickenpox is uncommon in adults, but less so in children. Presentation may be atypical with symptoms or signs of visceral rather than skin involvement.

Infections in other transplant recipients

Although long-term immunosuppression is usual in recipients of kidney, liver and heart transplants, the major risk of infection occurs in the first few months after transplantation. Immunosuppressive therapy is at its most intense as rejection is most likely to occur during this period. Patients are hospitalized for much of this time and therefore nosocomial infections are common. In addition, patients may develop bacterial infections associated with surgery or other invasive interventions, may experience exacerbations of pre-existing infections, or may even acquire infection transmitted via the grafted organ itself.

In the first month after transplantation bacterial infections and HSV reactivation are common. CMV and pneumocystis pneumonia are a hazard especially in the second and third months, though routine co-trimoxazole prophylaxis has reduced the latter. Herpes zoster occurs in around 25% but generally at a later time. Other opportunistic infections are seen occasionally.

Epstein-Barr virus (EBV) primary infection or reactivation is not uncommon following transplantation. It generally produces little or no distinctive clinical illness and may only be recognized retrospectively by serology. Its major importance is the increased incidence of EBV-associated B cell malignant lymphoma in transplant recipients.

Acquired immune deficiency syndrome (AIDS)

Human immunodeficiency virus (HIV) infects helper (CD4⁺) lymphocytes and cells of the monocyte/macrophage series. This produces a slowly progressive, profound immune defect which may be further exacerbated by opportunistic infection with, for example, CMV, EBV and other viruses. Several months or years may intervene between initial HIV infection and the development of opportunistic infection. A febrile prodrome associated with general malaise, intermittent diarrhea, and severe weight loss may precede the first identifiable opportunistic infection.

The pattern and timing of opportunistic infections seen in HIV patients depends upon their geographical location and the local prevalence of infectious dis-

eases. In Africa, for example, where the general prevalence of infection is high, opportunistic infections tend to occur early in the course of HIV illness and with similar organisms to those encountered commonly in the general population such as tuberculosis, pyogenic infections and salmonellosis. In contrast, in Western countries infections occur later, with pneumocystis pneumonia, toxoplasma encephalitis, cryptococcal meningitis, cryptosporidial diarrhea and local candidal infections, being the most commonly encountered. As the disease progresses, multiple simultaneous infections may occur with any of the above and in addition atypical mycobacterial infections and CMV infections of the retina and gastrointestinal tract.

Two patterns of malignant disease occur in HIV-infected patients. Kaposi's sarcoma (KS) has been particularly associated with the homosexual population and is seen rarely in infected hemophiliacs. Recent evidence has linked Kaposi's sarcoma in HIV-infected individuals to concurrent infection with human herpesvirus 8 (HHV8). EBV-associated non-Hodgkin lymphoma and also Hodgkin's disease have an increased incidence in all HIV-infected groups.

OPSONIZATION

Pieter S Hiemstra and Mohamed R Daha, Department of Pulmonology, Leiden University Hospital, Leiden, The Netherlands

Phagocytes (granulocytes, monocytes and macrophages) can kill a wide variety of prokaryotic and eukaryotic cells, including microorganisms and tumor cells. Killing can occur intracellularly after endocytosis (e.g. after phagocytosis of bacteria) or extracellularly by secretion of factors from the phagocytes that are harmful to the foreign cell. In both cases, recognition of the particle by the phagocyte is essential. It has been known for more than 90 years that recognition and ingestion of microorganisms by phagocytes is facilitated by the binding of serum factors (opsonins) to these microorganisms.

In 1903, Wright and Douglas discovered that the uptake of staphylococci by human granulocytes is enhanced by serum. They concluded that 'the body fluids modify the bacteria in a manner which renders them a ready prey to the phagocytes'. This opsonic effect of serum (*L. opsono*, 'I cater for'; 'I prepare victuals for') was reduced, but not completely lost, when the serum was heated. Nowadays it is known that the major heat-stable opsonin is immunoglobulin G (IgG), whereas the major heat-labile component in the opsonization process is composed of components of the complement system.

Receptors for IgG and complement are the best characterized receptors involved in recognition and phagocytosis, but receptors for IgE and IgA may also serve as opsonin receptors. Antibodies and complement components usually act synergistically in the opsonization of particles (Figure 1). In addition to these opsonins, other factors may stimulate the ingestion of particles, including acute phase proteins, collectins, defensins, extracellular matrix components and tuftsin. Microorganisms that are not opsonized can also be recognized by phagocytes because of, for example, the presence of carbohydrate residues

(mannose, L-fucose, galactose, glucose and *N*-acetylneuraminic acid) on the microorganisms that bind to sugar-specific receptors on macrophages. Also, receptors belonging to the CD11/CD18 integrin family may mediate the binding of unopsonized microorganisms to phagocytes, indicating that these receptors are involved in the phagocytosis of both opsonized and nonopsonized microorganisms.

Immunoglobulins

Immunoglobulin G

The capacity of antibodies of the IgG class to promote phagocytosis is well established. IgG increases the uptake of particles by an interaction with receptors for IgG (Fcγ receptors) that are present on phagocytes. In humans, immunoglobulins of the IgG1 and IgG3 subclasses are the most effective heat-stable opsonins, and are the subclasses that are bound with the highest affinity to Fcγ receptors. Binding to antigenic determinants on the particles is mediated by the Fab fragment of the IgG molecule, whereas the Fc part of IgG interacts with Fcγ receptors on the phagocyte cell membrane. Human phagocytes can express three classes of Fcγ receptors (FcγRI, FcγRII and FcγRIII) that have different and partly overlapping functions. The low-affinity FcγRII is probably the receptor that is most important in mediating phagocytosis of IgG-coated particles. For the interaction between IgG and its receptor, it is essential that IgG is located on the outer surface of the particle (e.g. the bacterial capsule), where its Fc part is accessible to the Fcγ receptor.

In addition to forming a bridge between the particle and the phagocyte, IgG enhances the uptake of bacteria by increasing their hydrophobicity. This mechanism is probably less important than the aforementioned specific interaction between the IgG-coated particle and the phagocytic Fcγ receptor.

Immunoglobulin M

Human phagocytes do not bear a receptor for IgM on their surface. Therefore IgM itself cannot act as an opsonin. However, since IgM is a very effective activator of the classical pathway of the complement system, IgM-coated particles can be opsonized with complement components, and thus be recognized by phagocytes.

Figure 1 Opsonization by IgG alone, IgG and complement, and complement alone, and interaction of these opsonins with specific membrane receptors present on phagocytes.

Immunoglobulin A

Two types of receptors that may mediate binding and ingestion of IgA-coated particles are present on the cell surface of phagocytes: receptors for the constant part of IgA (FcR α) and the asialoglycoprotein receptor (ASR). IgA was originally thought to lack opsonic activity, or even to act as a dysopsonin (a molecule that inhibits phagocytosis). Recent reports demonstrate the capacity of IgA to promote phagocytosis of microorganisms and erythrocytes. Since IgA activates the alternative pathway of complement, opsonization of particles by IgA may be enhanced by the binding of complement components to the particle.

Immunoglobulin D

No opsonic activity for IgD has been reported.

Immunoglobulin E

High-affinity receptors for IgE (Fc ϵ RI) are present on mast cells and basophils, and low-affinity receptors (Fc ϵ RII) on macrophages, eosinophils and platelets. The expression of Fc ϵ RII on monocytes can be induced by interleukin 4 (IL-4). The main function of the phagocytic Fc ϵ RII receptor resides in the defense against parasites. Since most parasites are too large to be ingested, IgE usually does not act as an opsonin.

Complement components

Optimal phagocytosis requires the presence of both antibodies and complement components on the particle. Particles opsonized with IgG or IgM antibodies can activate complement through the classical pathway, resulting in binding of fragments of complement components to the particle. These particles will be ingested to a higher extent than particles opsonized with antibodies alone because of the presence of receptors for complement components on the surface of the phagocytes. Fc γ receptors and complement receptors have been shown to act synergistically in mediating the phagocytosis of particles opsonized with IgG and complement components. Many microorganisms do not require the presence of specific antibodies for activation of the complement system. Gram-negative bacteria can activate the alternative pathway of complement due to the presence of lipopolysaccharide in their outer membrane. Other microorganisms bear surface structures that activate complement in the absence of antibodies. These microorganisms can be opsonized with complement components in nonimmune serum or serum deficient in immunoglobulins.

The complement components known to be involved in opsonization are C1q, C4b, C3b, iC3b, C3dg and C3d. Bound C3-derived fragments are the most important opsonins generated upon complement activation by either the classical or the alternative pathway. Activation of either pathway results in the formation of a C3 convertase that cleaves C3. The major cleavage product of C3, C3b, binds covalently to the particle surface. Subsequently C3b can be degraded by a number of inactivators of complement to iC3b, C3dg and C3d. Because C3b is rapidly degraded to iC3b (especially on particles that activate the classical pathway of complement), and C3dg and C3d are poor opsonins, iC3b is probably the most important opsonin generated upon cleavage of C3.

Phagocytes bear three types of receptors that may mediate the binding and uptake of C3-coated particles: CR1, CR3 and CR4 (p150/95). The role of CR1 and CR3 in enhancing phagocytosis of IgG-coated particles by neutrophils, monocytes and macrophages is well established. However stimulation of either CR1 or CR3 alone by, respectively, C3b- or iC3b-coated particles does not result in their ingestion, although the particles are bound to the receptors. Ingestion requires the presence of very small amounts of IgG on the particle or an additional stimulus that activates CR1 or CR3. Stimuli that can induce phagocytosis *in vitro* through CR1 or CR3 alone are extracellular matrix proteins (fibronectin, serum amyloid P and laminin) or soluble components such as C5a and the tumor-promoting phorbol ester phorbol myristate acetate (PMA).

The site of binding of the C3 fragments to the activator is essential for its capacity to function as an opsonin. Studies with encapsulated pneumococci have demonstrated that the capsule forms a physical barrier between the C3b bound to the cell wall of the bacteria and C3 receptors on the phagocyte.

Other opsonins or phagocytosis-stimulating factors

Acute phase proteins

The serum concentration of C reactive protein (CRP) increases many fold during inflammation, tissue injury and bacterial infection. CRP binds to *Streptococcus pneumoniae* and mediates the phagocytosis of these bacteria. Its opsonic activity is dependent on its ability to activate the classical pathway of complement. Since it binds to *S. pneumoniae* and possibly to a few other bacteria, its importance as an opsonin in the defense against bacterial infections is limited. It has been suggested that CRP may be more important in the clearance of damaged or dead cells

from sites of tissue injury. The opsonic activity of another acute phase protein, α 2-HS glycoprotein, is a result of its ability to increase the hydrophobicity of the bacterial surface, thereby promoting ingestion of these bacteria. Since during inflammatory reactions the serum concentration of α 2-HS in contrast to that of CRP decreases, its opsonic role *in vivo* is not clear.

Collectins

Recently the collectin family of humoral lectins has been described. It includes pulmonary surfactant proteins SP-A and SP-D, and mannose-binding protein (MBP). Collectins contribute to host defense against infection through their opsonic activity and their ability to activate the complement system. Their lectin domain mediates the binding to carbohydrate structures on microorganisms, whereas collagenous regions are involved in binding to the collectin receptor on, for example, phagocytes. The collectin receptor also functions as a receptor for the complement component C1q.

Fibronectin and vitronectin

Fibronectin is a multifunctional molecule that is found in extracellular matrix and plasma. Although it primarily plays a role in cell adhesion, it is involved in many parts of the inflammatory reaction. It binds to a variety of structures, including some bacteria and immune complexes. Two mechanisms are involved in the enhancement of phagocytosis by fibronectin. Fibronectin-coated particles are recognized by fibronectin receptors on the phagocyte and thereby fibronectin promotes the attachment of these particles. However, binding of fibronectin-coated particles does not result in their ingestion and therefore fibronectin is not regarded as an opsonin. In addition to promoting attachment, binding of fibronectin to its receptor on monocytes and macrophages results in the enhanced ingestion of IgG- and iC3b-coated particles. Furthermore, fibronectin activates CR1 and CR3 receptors, resulting in phagocytosis of particles opsonized with C3b or iC3b without IgG.

Receptors for IgG and iC3b can also be activated by vitronectin (also named S protein), a glycoprotein that shares many functional properties with fibronectin. An arginine-glycine-aspartic acid sequence (RGD) present in both fibronectin and vitronectin is recognized by the receptors for these molecules. These receptors belong to the same integrin family. Since vitronectin binds to some bacteria, it may also promote attachment of these bacteria to phagocytes. Its role as an opsonin is however not yet established.

Defensins

Defensins are small cationic proteins with microbicidal activity against a wide variety of microorganisms. They are present in the granules of phagocytes and are involved in nonoxidative killing of microorganisms by these phagocytes. Certain defensins, macrophage cationic peptide-1 (MCP-1) and MCP-2 (present in neutrophils and alveolar macrophages of rabbits), can enhance the ingestion of certain bacteria and fungi by rabbit alveolar macrophages. These defensins bind to both the microorganisms and to the alveolar macrophages.

Tuftsins

The tetrapeptide tuftsins (Thr-Lys-Pro-Arg), which is derived from the CH₂ domain of IgG, has been reported to affect a wide variety of biological responses in neutrophils and mononuclear phagocytes, including phagocytosis. The stimulation of phagocytosis by tuftsins appears to be mediated by binding of the peptide to phagocytes. Therefore tuftsins can not be regarded as an opsonin itself.

Influence of antimicrobial drugs on opsonization of microorganisms

Antimicrobial drugs can change the opsonic requirements of bacteria by inducing changes on the surface of the bacteria. Drugs that inhibit protein synthesis are especially effective in this respect. For example, treatment of *Streptococcus pyogenes* with clindamycin or lincomycin decreases the expression of M protein on the bacteria. Since M protein inhibits complement activation, decreased expression of M protein results in an increased deposition of C3 molecules on the surface of the bacteria. This explains the enhanced phagocytosis of clindamycin- or lincomycin-treated *S. pyogenes* by granulocytes and monocytes. Clindamycin has also been shown to increase the phagocytosis of *Staphylococcus aureus* by granulocytes and macrophages. This has been attributed to a decreased protein A synthesis by clindamycin-treated *S. aureus*. This may result in more effective opsonization since protein A binds to the Fc part of IgG.

ORAL IMMUNOLOGY

WP McArthur, College of Dentistry, Periodontal Disease Research Center, University of Florida, Gainesville, Florida, USA

The oral cavity is a unique anatomical environment consisting of specialized tissues and fluids required for the initial food intake and processing, speech, taste and other sensory perceptions. The uniqueness of the oral cavity lies in the complex association of the hardest tissue in the body, enamel on teeth, with epithelium. The teeth and oral epithelium as well as the junction between them are continuously under considerable physical, chemical and microbial pressures. Soon after birth the human oral cavity becomes colonized with a unique microbial flora which undergoes compositional alterations and additions as the oral cavity undergoes developmental changes associated with the maturation of the child. The eruption of teeth provides a unique surface for the colonization of specifically adapted microorganisms. Bacteria attached to teeth are a unique problem for the body's protective immune system since they are both difficult to reach by conventional antimicrobial cells or agents (e.g. leukocytes, antibodies and complement) and they can remain colonized for an indeterminate period of time. The shallow crevice between the tooth and gum contains the second unique problem for the host's defenses within the oral cavity. Bacterial plaques accumulate on the surface of the teeth down to the point of attachment to the tooth surface by a specialized epithelium, called the junctional epithelium. The immediate proximity of the plaque to the gum tissue in the crevicular area results in the bacterial stimulation of the host's inflammatory and immune systems. Some of these responses are seemingly protective but are not able to effectively remove the total plaque and a chronic inflammatory response to the resident bacterial plaque results. This chronic inflammatory response causes tissue destruction, resulting in loss of the epithelial attachment to the tooth and a deepening of the crevice between the tooth and gum, which then is able to harbor more and different plaque bacteria (i.e. subgingival plaque) some of which are considered pathogens.

Dental caries and saliva

Teeth are constantly exposed to saliva and bacteria in the oral cavity. Through a complex series of events the teeth are coated with salivary proteins, resulting in an acquired pellicle, which both protects the surface of the tooth and facilitates the binding of specific oral bacteria to the tooth. Attachment of free bacteria to adherent bacteria and their proliferation result in the growth and maturation of deposits of bacterial plaques on the exposed surfaces of teeth. The development of bacterial plaque deposits on teeth is a dynamic event with net results being a continuous increase in size and complexity of the plaques. Unlike the epithelium, which sloughs off the outer cell layer or the mucus-bacterial aggregates, mechanical removal is required to clean teeth of plaque deposits and within hours after cleaning the colonization process repeats itself. Consequently, there is a chronic source of microbial challenges to the teeth and to the connective tissues abutting the teeth, resulting in oral diseases.

To protect teeth, the body uses a combination of immune mechanisms contained in saliva. Caries, a major oral infectious disease, is due to the accumulation of acid-producing bacteria, *Streptococcus mutans*, in plaque and a high sucrose diet, which result in acid demineralization of localized areas of the enamel tooth surface (i.e. dental caries) under the plaque deposit. Saliva originates from the submandibular, sublingual, parotid and other minor salivary glands. It contains components common to other mucosal secretions, which vary as to the specific functions of the epithelium to be serviced. Saliva in the oral cavity is referred to as whole saliva since it contains the glandular secreted materials plus serum proteins from the gingival crevicular fluid. In addition to the rinsing effect of saliva, salivary mucins (MG1 and MG2), parotid agglutinin, lysozyme, and β_2 -microglobulin agglutinate bacteria into large aggregates which are easily cleared. Secretory

immunoglobulin A (sIgA), the adaptive immune component, is generally derived from sIgA-secreting plasma cells in the salivary glands which were stimulated through the common mucosal immune response system, although local stimulation and synthesis in the salivary gland can occur. sIgA is antigen-specific and can prevent the initial binding of bacteria, virus or fungi to epithelial cells or the acquired pellicle on teeth. sIgA can also specifically agglutinate bacteria and neutralize viruses. IgA consists of two isotypic forms, IgA1 and IgA2. IgA1 is predominant in serum as a monomer and IgA2 in saliva and other secretions in a dimeric form held together by a J chain and also having an attached secretory peptide. IgA1 is susceptible to degradation to Fab and Fc fragments by an IgA protease produced by a number of microbial pathogens. The role of sIgA specific for *Strept. mutans* in the control of dental caries remains controversial. Serum-derived IgG is also found in whole saliva, but its role in host defense in the oral environment is not defined. Other salivary proteins with antimicrobial activities are lysozyme, histatins, lactoferrin and proline-rich proteins. Histatins and acidic proline-rich proteins are only found in saliva. Interestingly, histatins appear to be tailor-made for the protection of the oral cavity, as they are potent candidacidal agents and neutralize lipopolysaccharides, as well as having antimicrobial activities against strains of *Strept. mutans* and *Porphyromonas gingivalis*, two oral pathogens. Acidic proline-rich proteins are antimicrobial as well as being active in mineral homeostasis and toxin neutralization. Lactoferrin binds iron, which is required for microbial proliferation, and lysozyme either lyses the bacterial wall or induces autolysis by the bacterium. In parallel to the antigen-specific and antigen-nonspecific antimicrobial activities, salivary proteins also help maintain the integrity of the fragile oral epithelium, buffer pH fluctuations in plaque thereby slowing acid induced tooth demineralization, and help maintain a calcium balance to counteract demineralization of the teeth.

Gingivitis/periodontitis

Gingivitis and periodontitis (G/P) make up the second major oral infectious disease. They are inflammatory conditions of the connective tissues that support the teeth. Gingivitis differs from periodontitis in that no permanent damage has occurred to the connective tissues. Loss of both normal gingival structures and alveolar bone are characteristic of periodontitis. G/P illustrate both the protective and destructive natures of the immune response in the oral cavity and closely resemble immune responses to chronic antigen deposition in the lungs,

kidneys and liver. The accumulation of bacterial plaques on teeth at the interface of the tooth and gum initiates an inflammatory response to bacterial and immune products generated from the plaque. Classical acute inflammation is the initial host response to plaque accumulation in the gingival tissues. Clinical indicators are redness and swelling of the local gingival tissue, an increase in gingival crevicular fluid (GCF) flow rate, and an increase in the concentration of polymorphonuclear leukocytes (PMNs) in the GCF. Mechanical removal of the plaque usually results in the arrest of the inflammatory disease and, in the case of gingivitis, a return of the gingival tissue to normal, with no tissue destruction and loss of attachment of the junctional epithelium to the tooth.

Polymorphonuclear leukocytes

The initial acute inflammatory response to plaque accumulation near the gum line provides the first evidence for the importance of the PMN in the protection of the gingival tissues and ultimately the periodontium. In healthy gums PMNs constantly migrate from the vascular system, through the gingival tissue, and into the gingival crevice (GC) in response to chemoattractants released from the bacteria or to immune factors (e.g. C5a, interleukin 8 (IL-8)) triggered by bacterial products. The bacterial accumulation on the teeth and in the GC directly affects the numbers of PMNs migrating into the GC and the extent to which those cells are activated. In the GC the PMNs interact with plaque bacteria or aggregates of bacteria usually coated with complement and Igs. PMNs phagocytose the bacteria or bacterial components, degranulate and synthesize and secrete cytokines. A margin of PMNs is often observed between the plaque deposits and the junctional epithelium. PMNs from healthy individuals have been shown to be bactericidal for suspected periodontal pathogenic bacteria only if the bacteria is phagocytosed after being opsonized by IgG antibodies and complement.

Strong evidence for the protective role of PMNs in the dentogingival area comes from the increased severity of disease in the periodontium of patients with neutropenia, genetically determined deficiencies in leukocyte functions (e.g. leukocyte adhesion deficiency, chronic granulomatous disease), chronic disease with an associated leukocyte functional suppression (e.g. diabetes), or drug-induced suppression of PMN activities. In contrast, immunodeficiencies of either T cell or B cell origin, including human immunodeficiency virus 1 (HIV-1) infection, are usually not associated with an accelerated loss of

tooth support tissues. The dentogingival margin may be the area in the body most sensitive to the loss of PMN function. Localized juvenile (LJP) and prepubertal periodontitis are two specific forms of periodontal disease found in young adults and children, respectively – populations not commonly afflicted by periodontal diseases. The majority of patients with these conditions have PMN functional deficiencies. In most of the LJP patients there are no other symptoms of a leukocyte functional problem. Identified defects in PMNs from these patients include genetic defects in the maximum expression of chemoattractant receptors on the cell membrane, an intracellular signal transduction defect, or an inability to kill *Actinobacillus actinomycetemcomitans*, a plaque bacterium thought to be the etiological agent in LJP. Clinical and *in vitro* experimental data strongly indicate that the PMN is the protective immune cell for the dentogingival area.

Humoral immunity

In addition to sIgA the adaptive systemic vascular humoral immune response is involved in oral immunity; however, its exact role is not clearly defined. Elevated levels of IgG and often IgA antibodies specific for subgingival plaque bacteria are usually detected in serum of patients with periodontal diseases compared with normal age-matched controls. In the majority of cases the bacterium to which the elevated serum antibodies specifically bind are the putative etiological bacteria for the type of periodontal disease identified clinically in the patient. For example, LJP patients almost always have elevated levels of polyclonal IgG antibodies specific for *A. actinomycetemcomitans* antigens and adults with chronic adult periodontitis have elevated levels of serum polyclonal IgG antibodies specific for antigens of *P. gingivalis*, a putative etiologic bacteria for that form of periodontal disease. Moderately elevated levels of antibodies to other plaque bacteria are sometimes found, but they are not definitive. The route of immunization is thought to be through the adjacent gingival tissues utilizing the tissue macrophages or Langerhans cells to process and carry the antigens to the regional lymph nodes. Tonsils and adenoids have recently become possible candidates for oral induction of immune responses. In general, plaque bacteria do not invade. *A. actinomycetemcomitans* and *P. gingivalis* are the only plaque bacteria shown to invade gingival tissues. Bacterial products such as endotoxins can be found in gingival tissues and a bacteremia is often produced during teeth cleaning, but elevated antibody responses to multiple plaque bacteria are not normally found in patients.

Local synthesis of Igs by resident plasma cells is a major feature of advanced periodontitis lesions. IgM, IgG and IgA synthesis has been identified in the inflamed gingival tissues and locally produced antibodies specific for plaque bacterial antigens have been identified. Antibodies specific for certain plaque bacteria have also been identified in GCF. Whether or not they were synthesized locally or derived from the vasculature is difficult to determine. In GCF from periodontitis sites the levels of IgG4 are found to be significantly greater than in serum, suggesting local synthesis of this IgG subclass. Further support for a role of local Ig synthesis contributing to the Ig in the GCF is indicated by the predominance of plasma cells producing IgG3 and IgG4 subclasses.

The significance of antibodies in serum or GCF specific for certain plaque microorganisms is thought to be generally protective, especially early in the disease process when colonization can be affected by a combination of PMNs, opsonic antibodies, protective antibodies such as antileukotoxin, and complement. A protective role for anti-*A. actinomycetemcomitans* antibodies is suggested by the observation that LJP patients have significantly higher levels of anti-*A. actinomycetemcomitans* than do patients with the generalized version of the disease. High levels of specific serum antibodies in immunized monkeys are associated with a decrease in oral colonization by potential periodontal pathogenic bacteria and a decrease in alveolar bone loss in infected animals compared to unimmunized controls. Immunization of gnotobiotic rats with fimbriae from *P. gingivalis* prevented periodontal disease, as indicated by alveolar bone loss in *P. gingivalis*-infected animals. However, high levels of specific antibodies in serum are more accurately indicative of disease and the presence of alveolar bone loss than identification of the suspected etiologic bacterium in the subgingival plaque, suggesting that the antibody response may be a consequence of infection rather than a controlling factor.

T cells

The relative contribution of T_H1 cells and T_H2 cells in the immune response to plaque bacterial pathogens has not been defined. Clearly the immune response to the periodontal pathogens mentioned above involves T_H2 cells, as significant polyclonal IgG antibodies are generated against specific immunogens from those microorganisms. Interestingly, in a significant percentage of HIV-1-infected individuals with very low $CD4^+$ T cell counts, rampant periodontal disease is not apparent, even in the presence of high plaque loads. In addition SCID mice are more

resistant to the invasion and distant abscess formation by the periodontal pathogen, *P. gingivalis* than normal immune competent mice, suggesting that active T cell-dependent immunity may not be important in the prevention of adult periodontitis. However, T cells and macrophages are a major feature of the histology of periodontitis lesions, especially relatively early in the progression of the disease. Early reports identified both CD4⁺ and CD8⁺ T cells in periodontitis lesions with the ratio of CD4/CD8 being less than in the peripheral blood. As would be expected, a majority of both subsets of T cells were CD45RO⁺, activated T cells. The antigen specificities of the T cells in the diseased gingival tissues have not been identified, but plaque bacterial-specific T cell clones have been generated from mononuclear cells isolated from diseased gingival tissue. mRNAs for interferon γ (IFN γ), IL-6 and IL-13 but not IL-2, IL-4 and IL-5 were identified in CD4⁺ T cells isolated from periodontal lesions. However, the significance of these findings is dependent on a precise status of the disease progression at the time of sampling. The general progression of the disease lesions to ones with significant numbers of plasma cells might suggest that the effective TH cell response is of the T_H2 type. The relatively high proportion of B cells synthesizing IgG3 and IgG4 in the lesions would also indicate that the B cell response is being locally driven by type 2 cytokines. Levels of prostaglandin E₂ (PGE₂) and the cytokines, IL-1 and IL-6, have been reported to be increased in periodontal disease lesions, with IL-2 levels decreased. IL-1 and PGE₂ are both potent stimulators of bone resorption and have been proposed as a potential cause of the alveolar bone loss in advanced disease lesions.

Immunodeficiencies and oral health

The oral cavity can be considered a window to the health and immune status of an individual. Although the oral cavity is anatomically unique, it enjoys both the benefits and liabilities of systemic immunity. Perturbations of the T cell compartment of the immune system are often indicated by oral mucosal infections by opportunistic microorganisms, resulting in oral ulcerations. Children with severe combined immune deficiency (SCID) have rampant growth of *Candida albicans* on their oral mucosal surfaces. Most individuals with T cell deficiencies, as in major histocompatibility complex (MHC) class II deficiency, DiGeorge anomaly, ataxia telangiectasia, Wiskott-Aldrich syndrome and HIV-1 infections, develop oral opportunistic infections most often candidiasis. Infants before the complete development of the T cell

response are prone to develop oral thrush, *C. albicans* infection of the oral mucosa. Boys with a deficiency of the CD40 ligand are unable to develop leukocytosis in response to a bacterial infection, and many develop neutropenia, resulting in severe local gingival infections by oral bacteria. Passive administration of granulocyte-macrophage cell-stimulating factor reverses the neutropenia and alleviates the dentogingival infections. Hereditary angioneurotic edema due to a lack of the complement component, C1 inhibitor, manifest oral symptoms characterized by the swelling of oral tissues, especially the lips. As described above, deficiencies in the number or function of PMNs are associated with oral bacterial infection of the gingival crevicular area and rapid loss of tooth supporting tissues. The loss or significant decrease in saliva flow in Sjögren's syndrome or after glandular damage from radiotherapy results in rampant dental caries, increased severity of periodontal disease, recurrent bacterial and fungal infections of the oral epithelium, difficulties in chewing and swallowing food as well as in speech, and loss of the taste sensation. Regardless of the cause, a deficiency in one or more of the innate or adaptive immune mechanisms can seriously jeopardize oral health.

Immune-mediated oral disease

Although PMNs are essential for oral health, periodontitis does occur in individuals with normal PMN function, indicating that there are numerous immune mechanisms involved in the protection or destruction of the oral tissues. A significant number of middle-aged adults develop adult chronic periodontitis, a chronic inflammation of the gingival tissues that varies from site to site in its progression and can eventually cause extensive loss of tooth-support tissues. All the components required to initiate and maintain the immunopathologic processes involved in hypersensitivities types II, III and IV are present at some time during the progression of this disease. During the entire inflammatory response, PMNs are migrating from the vascular system into the gingival fluid and eventually into the oral cavity. Consequently, both PMNs and mononuclear immune cells have the opportunity to contribute biologically active agents which promote inflammation or tissue destruction at the disease sites. The loss of collagen fibers, junctional epithelium, periodontal ligament and alveolar bone adjacent to the tooth are the hallmark signs of progressing disease resulting in the loss of the teeth. Current dogma suggests that products from both the acute and chronic inflammatory cells in the lesions contribute to the observed tissue destruction. Metalloproteinases, elastase and

other proteolytic enzymes, prostaglandins and cytokines are examples of the host-derived tissue modulating agents possibly responsible for the loss of bone and other connective tissue. In the majority of cases removal of plaque deposits and/or antibiotic therapy will arrest the disease. A very low percentage of periodontitis patients do not respond to conventional therapies and continue to lose tooth-supporting bone in spite of having subclinical levels of plaque. The reason for the continued loss of tissue is not understood but a hypersensitive immune mechanism is one possibility. A significant problem in the treatment of periodontitis is predicting which patients will develop progressive disease. Recently a variation in the IL-1 β gene has been identified, resulting in an identifiable genotype for the proinflammatory cytokine IL-1 which regulates extracellular matrix metabolism and bone resorption. This genotype is associated with increased levels of IL-1 synthesis which promotes bone resorption and it is a strong statistical indicator for susceptibility to advanced periodontitis.

Vaccines

Actively enlisting the immune response to prevent oral infectious diseases is under investigation. Work with experimental animals suggests that immunization may be useful in the prevention or control of dental caries and periodontal diseases. Oral (gut-induced) and/or intranasal routes of vaccine administration may potentially be very useful in regard to oral infections because both mucosal and systemic humoral responses are stimulated by those routes. Induction of protective immunity to oral viral and fungal infections may profit from the recent finding in mice that the oral administration of recombinant IL-12, a type 1 cytokine, in liposomes along with the vaccine antigen result in stimulation of type 1 responses as well as sIgA. Other approaches to immunologically modulate oral infections by *Strept. mutans* and *P. gingivalis* have generated provocative results. In both experimental animals and humans, exposure of freshly cleaned teeth to a solution of a murine monoclonal IgG antibody specific for an epitope on *Strept. mutans* several times during the first week after cleaning is associated with the absence of recolonization of the supragingival plaque with *Strept. mutans* for many months longer than in controls. In a similar experimental design, passive transfer orally of murine monoclonal antibody to an epitope specific for *P. gingivalis* also was associated with a major delay in recolonization of the subgingival plaque by *P. gingivalis*. The mechanism by which short-term passive immunization results in relatively

long-term prevention of colonization by oral pathogenic microorganisms is not currently understood. However, if the initial findings hold up after further independent experimentation, the two most prevalent oral infectious diseases could be prevented by self-administration of passive antibodies in a mouth rinse or toothpaste or by annual or semiannual treatments during routine dentist visits.

As the understanding of the immune response and how to use it to promote health rapidly moves forward, that knowledge as well as the delineation of the subtleties of oral immunology will ultimately result in the improvement of the overall health of individuals.

ORAL TOLERANCE

Howard L Weiner, Center for Neurologic Diseases, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA

Oral tolerance refers to the observation that if one administers a protein orally and then immunizes with the same protein, a state of systemic hyporesponsiveness to that protein exists. It was first described in 1911 when Wells fed hen's egg proteins to guinea pigs and found them resistant to anaphylaxis when challenged. In 1946, Chase fed guinea pigs the contact sensitizing agent, dinitrochlorobenzene (DCNB), and observed that animals had decreased skin reactivity to DCNB. Subsequently, numerous investigators have found that animals fed proteins such as ovalbumin or sheep red blood cells do not respond as well to these antigens when subsequently immunized, but do respond normally to other antigens. The phenomenon of oral tolerance has also been observed in humans fed and immunized with keyhole limpet hemocyanin (KLH).

Immunologic tolerance is a basic property of the immune system that provides for self/nonself discrimination so that the immune system can protect the host from external pathogens without reacting against self. When the immune system reacts against itself, autoimmune disease may result. For a time it was thought that self/nonself discrimination was a simple matter of deleting autoreactive cells in the thymus, but it is now clear that the maintenance of immunologic tolerance is a much more complicated process. Autoreactive cells, such as those reacting with brain, are not deleted and can be found in normal individuals. Why these cells become activated and cause disease in some individuals whereas in others they remain harmless is a major question in basic immunology. How to control the autoimmune process once it has been initiated is a major problem in clinical medicine.

These two areas have come together in recent years as oral tolerance has been successfully used to treat autoimmune diseases in animal models and is now being applied to the treatment of human disease states. Furthermore, an understanding of the basic mechanisms by which orally administered antigens induce immune tolerance is beginning to emerge. As

with immunologic tolerance in general, oral tolerance involves multiple mechanisms. Thus the term 'oral tolerance' is misleading as it implies that there is one unique mechanism of tolerance induction when antigens are administered orally. This is not the case. Although the gut has unique properties that favor tolerance induction, oral tolerance is not a single immunologic event.

Gut-associated lymphoid tissue

Orally administered antigen encounters the gut-associated lymphoid tissue or GALT (**Figure 1**), a well-developed immune network that evolved not only to protect the host from ingested pathogens, but also developed the inherent property of preventing the host from reacting to ingested proteins. The GALT consists of villi which contain epithelial cells capable of antigen presentation, intraepithelial lymphocytes, and lamina propria lymphocytes. In addition, there are Peyer's patches, lymphoid nodules interspersed among the villi, which are one of the primary areas in the GALT where specific immune responses are generated. Investigators have attempted to use the GALT as a route for vaccination but have been hampered by the systemic hyporesponsiveness or oral tolerance that is naturally generated. Nonetheless, as described below, active induction of selected immune responses in the GALT is one of the primary mechanisms by which oral antigen suppresses systemic immunity.

In addition to inducing immune responses in the GALT, some oral antigen is absorbed. Although most dietary antigens are partially degraded by the time they reach the small intestine, studies in humans and rodents demonstrate that some undegraded or incompletely degraded antigen is absorbed into the systemic circulation. Absorbed or processed antigen may also be involved in inducing tolerance although the mechanism associated with this pathway has not yet been defined.

Figure 1 Histological structure of gut-associated lymphoid tissue (GALT). Cross-section of murine small intestine illustrates the main areas of gut lymphoid tissue: lamina propria, intraepithelial lymphocytes (IEL), and lymphoid nodules (Peyer's patches).

Mechanisms of oral tolerance

The primary mechanisms by which oral tolerance is mediated include deletion, anergy and active cellular suppression with the determining factor being the dose of antigen fed (Figure 2). Low doses favor active suppression mediated by the induction of regulatory T cells in the gut-associated lymphoid tissue, such as Peyer's patches, which then migrate to the systemic immune system. When higher doses of antigen are fed, clonal anergy or deletion results.

Active cellular suppression of immune responses has been studied extensively over the years and has remained ill-defined due to difficulties in cloning sup-

pressor cells and defining their mechanism of action. More recently, it appears that one of the primary mechanisms of active cellular suppression is via the secretion of suppressive cytokines such as tumor growth factor β (TGF β), interleukin 4 (IL-4) and IL-10 after antigen-specific triggering. In this sense the GALT is unique as it favors the induction of cells which secrete these cytokines, T_H2 as opposed to T_H1 cells and T cells which secrete TGF β , a potent immunosuppressive and antiinflammatory cytokine. T Cells in lymphoid organs drained by mucosal sites secrete IL-4 as a primary T cell growth factor, whereas those drained by nonmucosal sites secrete IL-2. Oral tolerance has often been demonstrated by a decreased delayed-type hypersensitivity (DTH) response to the fed antigen and it is known that DTH is a T_H1 response inhibited by IL-4-producing T_H2 cells. TGF β plays an important role in local function of the gut as it serves as a switch factor for IgA production in the mucosa and may also be involved in the homing mechanism of the cells to high endothelial venules. TGF β is produced by both CD4 $^{+}$ and CD8 $^{+}$ GALT-derived T cells and is an important mediator of the active component of oral tolerance. Mice that are TGF β -deficient have inflammation that affects multiple organ systems, demonstrating the importance of this cytokine in maintaining immune homeostasis. TGF β is also associated with natural recovery from experimental autoimmune encephalomyelitis (EAE), and regulatory cells which suppress certain forms of inflammatory colitis act via secretion of TGF β .

We cloned TGF β -secreting myelin basic protein (MBP)-specific CD4 $^{+}$ cells from the mesenteric lymph nodes of SJL mice. These clones were structurally identical to T_H1 disease-inducing clones in T cell receptor (TCR) usage, major histocompatibility com-

Suppression	T_H2	T_H1	T_H1/T_H2

plex (MHC) restriction and epitope recognition but suppressed rather than induced disease. We have also recently cloned TGF β -secreting CD4⁺ cells from orally tolerized (low dose fed) MBP TCR transgenic mice. These latter clones do not secrete IL-2, interferon γ (IFN γ), IL-4 or IL-10 and their primary growth factor is IL-4. Thus, CD4⁺ cells which primarily produce TGF β appear to be a unique T cell subset with both mucosal T helper function and downregulatory properties for T_H1 and other immune cells. In contrast to T_H1 and T_H2 cells, these cells provide help for immunoglobulin A (IgA) production. These TGF β -secreting T cells have been termed T_H3 cells (Table 1) and have also been observed in multiple sclerosis (MS) patients orally dosed with myelin. TGF β -secreting T_H3 clones grow poorly, which has thus far hampered rapid characterization of these cells. The fact that T_H3 cells do not proliferate well may also account for their relative resistance to deletion as compared to T_H1 and T_H2 cells following oral administration of high-dose antigen to ovalbumin (OVA) TCR receptor transgenic mice.

Bystander suppression

Bystander suppression was described during the investigation of regulatory cells induced by oral administration of low doses of MBP. It solves a major conceptual problem in designing antigen- or T cell-specific therapy for inflammatory autoimmune diseases such as multiple sclerosis, type 1 diabetes and rheumatoid arthritis, in which the autoantigen is unknown or where there are reactivities to multiple

autoantigens in the target tissue. During the course of chronic inflammatory autoimmune process in animals there is intra- and interantigenic spread of auto-reactivity at the target organ. Similarly, in human autoimmune diseases there are reactivities to multiple autoantigens in the target tissue. For example, in multiple sclerosis there is immune reactivity to at least three myelin antigens, myelin basic protein (MBP), proteolipid protein (PLP) and myelin oligodendrocyte glycoprotein (MOG). In type 1 diabetes, there are multiple islet cell antigens that could be the target of autoreactivity, including glutamate decarboxylase (GAD), insulin and heat shock proteins. Because regulatory cells induced by oral antigen secrete antigen-nonspecific cytokines after being triggered by the fed antigen, they suppress inflammation in the microenvironment where the orally administered antigen is localized. Thus, for a human organ-specific inflammatory disease, one need not know the specific antigen that is the target of an autoimmune response but only orally administer an antigen capable of producing regulatory cells which then migrate to the target tissue and suppress inflammation.

Bystander suppression was demonstrated *in vitro* when it was shown that cells from MBP-fed animals suppressed proliferation of an ovalbumin line across a transwell, but only when triggered by the fed antigen. The soluble factor was identified as TGF β . Bystander suppression has been demonstrated in a number of autoimmune disease models (Table 2). PLP peptide-induced EAE can be suppressed by oral administration of MBP, and MBP-specific T cell clones from orally tolerized animals which secrete TGF β also suppress PLP-induced disease. In the Lewis rat EAE model, MBP peptide 71–90-induced disease can be suppressed by oral administration of peptide 21–40. In arthritis models, adjuvant- and antigen-induced arthritis can be suppressed with oral type II collagen. A viral-induced model of diabetes was developed by expressing a lymphocytic choriomeningitis virus (LCMV) protein on the insulin promoter and then infecting animals with the LCMV virus. In this model, the viral-triggered diabetes can be suppressed by oral administration of insulin. Bystander suppression *in vitro* has recently been shown in humans using common dietary proteins

Table 2 Bystander suppression

Immunizing antigen	Oral antigen	Target organ
Proteolipid protein	Myelin basic protein	Brain
BSA, mycobacteria	Collagen type II	Joint
Lymphocytic choriomeningitis virus	Insulin	Pancreatic islets
MBP peptide 71–90	MBP peptide 21–40	Brain

(OVA, bovine gammaglobulin) to stimulate cells *in vitro* which then suppressed *in vitro* tetanus toxoid responses. Bystander suppression may be more difficult to induce in uveitis models and feeding OVA has been reported to induce bystander suppression in adult animals but anergy in young animals.

Bystander suppression theoretically could be applied for the treatment of organ-specific inflammatory conditions which are not classic autoimmune diseases, such as psoriasis, or to target anti-inflammatory cytokines to an organ where inflammation may play a role in disease pathogenesis even if the disease is not primarily inflammatory in nature. Although initially described in association with regulatory cells induced by oral antigen, bystander suppression could in principle be induced by any immune manipulation that induces T_H2- or T_H3-type regulatory cells.

Modulation of oral tolerance

If oral tolerance is broadly defined as the inhibition of T_H1 responses in the periphery either by large doses of antigen that induce anergy or deletion or by gut-induced T_H2- or T_H3-type regulatory cells, anything that favors T_H1 versus T_H2 responses would abrogate oral tolerance and the converse (Table 3). Thus, large doses of IFN γ abrogate oral tolerance and similar results would be expected with IL-12. Indeed investigators have found that anti-IL-12 enhances oral tolerance in OVA TCR transgenic animals and is associated with increased TGF β secretion. In the uveitis model, IL-2 potentiates oral tolerance and is associated with increased production of TGF β , IL-4 and IL-10 in Peyer's patches. We have recently found that IL-4 administration enhances low-dose oral tolerance to MBP in the EAE model. Lipopolysaccharide (LPS) enhances oral tolerance to MBP and is associated with increased expression of IL-4 in the brain, and IFN β synergizes with the induction of oral tolerance in SJL/J mice fed low doses of MBP.

Cholera toxin (CT) is one of the most potent

mucosal adjuvants and feeding CT abrogates oral tolerance when fed with an unrelated protein antigen. However, when a protein is coupled to recombinant cholera toxin B subunit (CTB) and given orally, there is enhancement of peripheral immune tolerance. It is not known how CTB enhances oral tolerance, though it may do so by the more efficient induction of regulatory cells due to the special binding properties of the CTB subunit. The abrogation of oral tolerance by CT may also be the result of an active immune process in the gut, as it has been shown that CT given orally with KLH primes both T_H1 and T_H2 responses, even though T_H2 responses may be preferentially generated. The priming of T_H1 responses via the gut may make it impossible to suppress systemic T_H1 responses following peripheral immunization. It has also been reported that antibodies to the chemokine MCP-1 abrogate oral tolerance, perhaps by interfering with chemotaxis of the T_H2- or T_H3-type regulatory cells generated in the gut or by acting as a factor required for the generation of such cells. Oral antigen delivery using a multiple emulsion system also enhances oral tolerance.

Nasal and aerosol mucosal tolerance

Investigators have also begun to investigate other forms of mucosal tolerance, especially the administration of antigen via the nasal route using aerosols. This route appears equally, and in some instances may be more, effective in suppressing autoimmune diseases in animal models. Smaller doses of antigen are administered, perhaps because there is less degradation of the proteins before they reach the mucosal surface. The degree to which the mechanisms of oral versus nasal tolerance are the same remains to be elucidated.

Treatment of autoimmune diseases in animals (Table 4)

Experimental autoimmune encephalomyelitis (EAE)

Several studies have demonstrated the effectiveness of orally administered myelin antigens (MBP, PLP) in both the rat and mouse models of EAE. In the Lewis rat high doses of MBP result in clonal anergy whereas lower doses induce transferable cellular suppression. In the nervous system of animals orally administered low doses of MBP there is the down regulation of inflammatory cytokines such as TNF and IFN γ and the upregulation of TGF β . Administration of myelin to sensitized animals does not exacerbate disease. EAE can also be suppressed in MBP TCR transgenic animals fed MBP. Nasal MBP peptides have also been reported to suppress EAE.

Table 3 Modulation of oral tolerance

Table 4 Suppression of autoimmunity by oral tolerance

	<i>Oral antigen</i>
<i>Animal models</i>	
EAE	MBP, PLP
Arthritis	Type II collagen
Uveitis	S-Antigen, inter-photoreceptor retinoid binding protein (IRBP)
Diabetes (NOD mouse)	Insulin, glutamate decarboxylase
Myasthenia gravis	Acetylcholine receptor
Thyroiditis	Thyroglobulin
Transplantation	Alloantigen, MHC peptide
Colitis	Haptenized colonic proteins
<i>Human disease trials</i>	
Multiple sclerosis	Bovine myelin
Rheumatoid arthritis	Chicken type II collagen
Uveoretinitis	Bovine S-antigen
Type 1 diabetes	Human insulin

Arthritis

Oral administration of type II collagen (CII) suppresses several models of arthritis including collagen-induced arthritis (CIA), adjuvant arthritis and pristane-induced arthritis. One of the first studies to demonstrate that an orally administered autoantigen can suppress an autoimmune disease was the use of oral CII in CIA. Of note is that oral type I collagen has also been shown to suppress adjuvant arthritis. Oral administration of an immunodominant human collagen peptide modulates CIA in mice and CII peptides given nasally also suppress CIA in mice.

Uveitis

Oral administration of S-antigen (S-Ag), a retinal autoantigen that induces experimental autoimmune uveitis (EAU), or of S-Ag peptides prevents or markedly diminishes the clinical appearance of S-Ag-induced disease as measured by ocular inflammation. Oral administration of interphotoreceptor-binding protein (IRBP) suppresses IRBP-induced disease and is potentiated by IL-2.

Myasthenia gravis

Although myasthenia gravis is an antibody-mediated disease, either oral or nasal administration of the Torpedo acetylcholine receptor to Lewis rats prevented or delayed the onset of myasthenia gravis. Large doses of antigen were required.

Diabetes

Oral insulin has been shown to delay and in some instances prevent diabetes in the NOD (nonobese diabetic) mouse model. Such suppression is transferable and it has been transferred primarily with CD4⁺ cells. Immunohistochemistry of pancreatic islets of

insulin-fed animals demonstrates decreased insulinitis associated with decreased IFN γ and tumor necrosis factor α (TNF α) together with increased expression of IL-4, IL-10, TGF β , and prostaglandin E₂ (PGE₂). It has also been recently reported that nasal administration of the insulin B chain or GAD suppresses diabetes in the NOD mouse.

Transplantation and other models

Oral allogeneic cells prevents sensitization by skin grafts, and transforms accelerated rejection of vascularized cardiac allografts in primed animals to a time course typical of unsensitized recipients. Orally administered allopeptides in the Lewis rat reduces delayed-type hypersensitivity (DTH) responses to the peptide. Oral but not intravenous alloantigen was accompanied by elevation of intragraft IL-4. Oral thyroglobulin has been shown to suppress autoimmune thyroiditis and oral administration of peptides from the Der p I allergen suppressed responses to the whole allergen. Recently it has been shown that experimental granulomatous colitis in mice is abrogated by TGF β -mediated oral tolerance after administration of haptenized colonic proteins.

Treatment of autoimmune diseases in humans

Investigators have shown that exposure of a contact sensitizing agent via the mucosa prior to subsequent skin challenge led to unresponsiveness in a portion of patients studied. Orally administered KLH, 50 mg, given daily for 2 weeks over a 3-week period to human subjects has been reported to decrease subsequent cell-mediated immune responses although antibody responses were not affected. Nasal KLH has also been reported to induce tolerance in humans.

Based on the success of oral tolerance in animals models of diseases and the safety of the approach, human trials have been initiated in multiple sclerosis, rheumatoid arthritis, uveitis, and type I diabetes. Although these phase I/II trials have shown positive results, the final demonstration of clinical efficacy of oral antigen in these diseases must await the results of large-scale phase III trials that are in progress, or planned (Table 4). What can be concluded from the initial trials is that there has been no toxicity or exacerbation of disease and results in humans have paralleled in many respects what has been observed in animals. Specifically, in MS patients, MBP- and PLP-specific TGF β -secreting T_H3-type cells have been observed in the peripheral blood of oral myelin-treated but not control patients. These results demonstrate that it is possible to orally immunize via the

gut for autoantigen-specific TGF β -secreting cells in a human autoimmune disease simply by oral administration of the autoantigen. Furthermore, it also appears that continuous oral administration of oral antigen is required as MS patients had worsening of disability over a 3-year observation when they were not taking oral myelin.

In rheumatoid arthritis, a 280 patient double-blind phase II dosing trial of CII in doses ranging from 20 μ g to 2500 μ g demonstrated statistically significant positive effects in the group fed the lowest dose (20 μ g). Feeding larger doses of bovine CII (1–10 mg) did not show a significant difference between tested and placebo groups though a higher prevalence of responders was reported for the CII-treated groups. These results are consistent with animal studies of orally administered CII in which protection against adjuvant and antigen-induced arthritis, and the generation of bystander suppression, was observed only at the lower fed doses. An open label pilot study of oral collagen in juvenile rheumatoid arthritis found positive results with no toxicity. This lack of toxicity is an important feature for the clinical use of oral tolerance, especially in children, for whom the long-term effects of immunosuppressive drugs is unknown.

In multiple sclerosis, a recently completed 515 patient double-blind phase III trial of single-dose bovine myelin in relapsing-remitting MS did not show differences between placebo and treated groups in the number of relapses. Preliminary analysis of magnetic resonance imaging data showed significant changes favoring oral myelin in certain patient subgroups.

In uveitis, a pilot trial of S-antigen and an S-antigen mixture has also recently been completed and showed positive trends with oral bovine S-antigen. Finally, trials have been initiated in new-onset diabetes in which recombinant human insulin is administered orally and trials are planned in subjects at risk for diabetes or part of the diabetes prevention trial (DPT-1).

Future directions

Although it is clear that oral antigen can suppress autoimmunity in animals and results to date suggest that this approach may have utility in humans and is safe, much remains to be learned about the immunologic mechanisms associated with antigen-specific mucosally driven tolerance. Important areas of investigation include cytokine milieu, antigen presentation, costimulation requirements, routes of antigen processing, form of the antigen, role of the liver, the effect of oral antigens on antibody and CTL

responses and the role of $\gamma\delta$ T cells. As the mechanisms of oral tolerance are better understood, the ability to successfully apply mucosal tolerance for the treatment of human autoimmune and other diseases will be further enhanced.

ORGAN CULTURE OF LYMPHOID CELLS

David A Crouse, Department of Cell Biology and Anatomy, University of Nebraska Medical Center, Omaha, Nebraska, USA

Techniques for culturing organs or tissues were developed in the beginning of the twentieth century. The classic studies of Harrison as well as Carrel first employed fetal tissues (e.g. neural tube or heart) explanted into a drop of 'homologous' lymph or plasma for subsequent study over a period of days or even months. The technique was used widely in the study of embryogenesis, especially in light of the landmark studies of Strangeways and Fell in the study of the developing fetal limb bud. Such experiments with organ culture systems provided an early demonstration of the utility of this approach and encouraged many investigators to employ similar protocols which are used today.

In the early 1960s, Auerbach was successful in using and popularizing techniques of organ culture for the study of lymphoid tissues. Organ cultures were initially used to define morphologically the ontogeny of the tissues but, in more recent studies, many investigators have begun to use such techniques in combination with sensitive cell selection and/or detection techniques (e.g. molecular biology, flow cytometry or immunohistochemistry) in an attempt to understand more detailed interactions of early lymphoid progenitor cells and their micro-environments.

Methods of organ culture

Several general methods exist for the organ culture of lymphoid tissue. The first of these is termed the 'plasma clot' method, and is very similar to the method described in the early 1900s. In the plasma clot method, crude embryo extract is added to a small amount of plasma and allowed to clot. The tissue or organ to be cultured, usually derived from fetal donors, is placed on top of the clot (**Figure 1A**) and cultured for various time periods to observe temporal changes in morphology and/or cell populations. Plasma clot techniques, like other organ culture methods to be described, allow the sequential analysis of development without the complexities of cell traffic (immigration and emigration), found *in vivo*. In addition, it frequently allows the maintenance of an organotypic three-dimensional structure with a complex cellular heterogeneity similar to the *in situ* organ. However, its utility in the study of the interactions between selected lymphoid populations or their precursors and their cellular micro-environment, and how that interaction may change with time, is limited by the heterogeneity of the initial population.

A similar technique for conducting these cultures without the plasma clot by using a supporting mem-

Figure 1 Approaches to the organ culture of lymphoid tissues. Fetal or adult tissues can be organ cultured in systems that employ: (A) plasma clot cultures; (B) raft cultures; (C) transmembrane cultures; or (D) hanging drop cultures. Raft cultures of fetal materials may be treated with deoxyguanosine or low temperature to first deplete the lymphoid populations, prior to being used as a 'target' tissue for a source of donor cells in the transmembrane system

brane raft in liquid culture (Figure 1B) is now employed by most investigators. Like the plasma clot technique, the raft systems allow the target tissue to be maintained at a gas:media interface in a relatively well-controlled *in vitro* environment. In addition, raft techniques provide for better control of soluble factors through the use of defined media and growth factors, if necessary. Clearly, one of the major drawbacks of the plasma clot method is its required use of an undefined embryo extract as a source of growth

promotion in the culture medium. Thus raft techniques allow controlled studies on the role of soluble factors on lymphocyte differentiation and function.

In many studies it would be useful to be able to separate the developing and/or functional lymphopoietic cells from their native stromal cell microenvironment and then selectively recombine them to better understand the nature of their interactions. Further modifications of raft organ culture techniques which employ temperature change or media supplements allow for the preferential depletion and/or enrichment of cell populations, with the potential for a purification of specific cell populations. Using these organ culture purification techniques, elements of the microenvironment have been isolated from the progenitor cell population and the two purified populations recombined under controlled conditions for the study of the influence of the microenvironment on differentiation of the progenitors. Such techniques have been utilized extensively in the study of lymphocyte differentiation in the thymus or B lymphocyte development in a marrow environment, as well as the ability of various tissues to serve as a potential source of lymphopoietic progenitor cells.

Application of organ culture techniques to the culture of lymphoid tissues

Organ culture techniques have been widely applied to examine normal development and the role of microenvironmental elements on hematopoietic differentiation in several different species. Many of these studies have also employed a transmembrane system (Figure 1C) that allows the initial separation and subsequent controlled recombination of purified progenitor and stromal cell populations. For example, since chick and quail cells can be distinguished on the basis of nuclear morphology, Le Douarin and colleagues employed the primitive thymic rudiment of the chick and the yolk sac, spleen or bone marrow cells of the quail in a transmembrane organ culture system to demonstrate that the thymic anlagen taken prior to colonization can become lymphoid if given a source of lymphopoietic progenitors at an appropriate time. In related studies, several waves of receptivity of the thymus anlagen could be demonstrated. The same group has used similar organ culture systems to investigate the relative lymphopoietic potential of the embryonic bursa.

In the murine system, the use of organ cultures to define the role of the thymic microenvironment has been widespread. Early studies of thymic epithelium and the thymic microenvironment utilized monolayer cultures derived from thymocyte cell suspen-

sions. Although many investigators reported the isolation of 'epithelial' cells, the techniques were generally unsatisfactory. A major problem in these systems was the presence of excessive numbers of macrophages and fibroblasts within the cultures, often overshadowing the role of the epithelium. In addition, since several epithelial cell populations found within the thymus *in vivo* may be required for normal lymphocyte development, one runs the risk of deleting an important cell population by preferential growth conditions or subcloning, both of which are common in monolayer systems.

Techniques which use treatment of thymic rudiment organ cultures with deoxyguanosine, low temperature or even a change in oxygen tension have all been shown to selectively enrich for the epithelial cell populations and thus facilitate the study of T cell differentiation, both *in vitro* and *in vivo*. Like the uncolonized thymic anlagen, purified thymic epithelium may become lymphoid when the appropriate progenitor cells are provided in transmembrane organ cultures where donor tissue explants are placed below a cell permeable filter upon which the lymphoid-free thymic explants are placed. These experiments have generally used bone marrow, fetal liver, or fetal thymus as a stem cell source. In situations where cell suspensions are used for the donor cells, often first highly purified by positive and/or negative selection techniques, the lymphoid-free thymic anlagen can be directly injected with a single putative stem cell or another appropriate source of progenitors. Alternatively, a hanging drop modification of the organ culture system (Figure 1D) may be used to facilitate cell interaction. Hanging drop systems also allow the selective continued separation of donor and target cell populations. In an elegant set of experiments utilizing deoxyguanosine-treated thymic rudiment organ cultures, combined with transmembrane cultures, hanging drop cultures or direct injections, Owen's group and others have demonstrated that single lymphopoietic progenitor cells were capable of giving rise to all of the subpopulations of thymocytes found within the developing thymus.

Organ culture-purified murine thymic epithelium of both fetal and young adult origin has been used in *in vivo* transplantation experiments to examine the ability of the grafts to recapitulate ontogeny and provide functional reconstitution. These studies have shown that although the grafts are colonized, they give rise to a variable number of peripheral T cells of possibly different subpopulation composition. Also *in vivo*, grafts of organ-cultured thymic epithelium have been used to investigate the role of epithelium on immune recognition and regulation. After grafting deoxyguanosine-treated thymic lobes into

allogeneic recipients, Jenkinson and colleagues were able to demonstrate that maturing host lymphoid progenitors were not rendered tolerant to the major histocompatibility complex (MHC) antigens expressed by the grafted thymic epithelial organ culture.

More recently, similar organ culture systems have been applied effectively to the study of human materials. Many of these procedures utilize 'tissue slices' and their utility in evaluating three-dimensional interactions of cell populations in assays with functional end-points is just emerging. Furthermore, the additional potential to use human fetal thymic fragment organ culture models to assess human immunodeficiency virus (HIV) pathogenesis may serve as an important functional model for that critical area of research.

Finally, in addition to the more traditional organ culture techniques already described, another system has been used which is often considered to be a method of organ culture. Utilizing a system similar to that described by Dexter and coworkers, Whitlock and Witte developed a monolayer culture system which supported the long-term production of B cells from an initial inoculum of mouse bone marrow cells. Once established, the cultures consist of a dense stromal cell adherent layer associated with a number of loosely adherent developing B cells. These cultures are capable of maintaining a population of early B cell progenitors in the presence of heterogeneous and poorly defined stromal cell population. Many stromal cell lines have been isolated from these cultures, a number of which are capable of inducing early events of B cell differentiation in B cell progenitors. Thus, like more classical organ culture techniques, the Whitlock-Witte culture system may allow for the purification and recombination of the stromal components of lymphoid microenvironments with early lymphoid progenitor cells.

OVINE IMMUNE SYSTEM

Ian McConnell and John Hopkins, Department of Clinical and Veterinary Medicine, University of Cambridge, Cambridge, UK

The ovine immune system occupies a special place in immunology because the sheep is the best species for investigating the physiology of the immune system. The trend to reductionism in modern immunology, which is facilitated by the ease with which the cells of the immune system can be disaggregated from lymphoid tissue and studied *in vitro*, has meant that much of our knowledge of the immune system is based on the analysis of the cellular functions of *in vitro* immune systems divorced from any physiological limits. Although the *in vitro* analysis of the complex cell interactions of the immune system has considerably advanced knowledge, this needs to be integrated within the context of lymphoid tissue physiology at a whole-animal level.

The physiology of the immune system, especially in the context of the immunological compartments associated with different organ systems (e.g. lymph nodes, thymus, gut, mammary gland, respiratory system, urogenital system, central nervous system), can be studied separately in the sheep. These studies have gained much from the technique, first developed by Morris, Hall and Lascelles, of lymphatic cannulation of single lymph nodes in sheep, which provides a powerful system for analyzing immune cell popu-

lations within different immunological microenvironments. The lymph node is the heart of the immune system and cannulation of nodal afferent and efferent lymphatics provides a unique approach to the *in vivo* analysis of the immune system not possible in other species. The cannulated lymph node retains all its vascular and neurological connections. All the cells which enter the node, either from the blood or from the afferent lymphatics to the node leave the node in the efferent lymph. Cannulation of the efferent lymphatic therefore allows the monitoring of immunological events in a single lymph node. The system is currently being used to study the pathophysiology of the immune response to lymphotropic viruses such as the ruminant lentivirus, maedi-visna, the prototype lentivirus, which infects the accessory cells of organized lymphoid tissue. Intestinal immunity, especially to nematode parasites, can also be studied uniquely by cannulation of the lymphatic vessels draining the gut and mesenteric nodes.

In recent years, cellular and molecular markers for the ovine immune system have been produced by several laboratories. This has permitted the identification of lymphocyte populations, their subsets and receptors, major histocompatibility complex (MHC)

class I and class II genes and proteins, immunoglobulins and cytokines. Two international workshops have defined a large number of ovine CD molecules, T cell subset markers, MHC class I and II polymorphisms and cytokines including most of the cytokines associated with macrophages and lymphocyte subsets (e.g. IFNs, IL-1, IL-2, IL-4, IL-6, IL-7, IL-10 and IL-12, GM-CSF, TNF). These cytokine genes are cloned, sequenced and exist as recombinant proteins and several cytokine receptors are now defined (IL-2R etc). By using combinations of monoclonal antibodies and cytokine probes T_H1 and T_H2 subsets have been identified. Ovine equivalents of the integrins (CD11/CD18), L-selectins and lymphocyte homing receptors are also well characterised.

In terms of its overall organization, the ovine immune system is similar to that of humans but with some notable differences.

B cells

The ileal Peyer's patch in the gut functions as a primary lymphoid organ necessary for B cell lymphopoiesis. Judged by its cell content, architecture and surface phenotype of its constituent cells (98% sIgM⁺ B cells), this organ is analogous to the bursa of Fabricius in chickens. The entire B cell repertoire in the sheep is derived by hypermutation from a very limited set of V region germ-line sequences. Development of the B cell repertoire occurs in the ileal Peyer's patch. The immunoglobulin levels of IgG in serum are higher than in man (IgM, 2 mg ml⁻¹; IgG1, 17–20 mg ml⁻¹; IgG2, 8 mg ml⁻¹; IgA, 0.2 mg ml⁻¹) and no IgD has yet been described. IgG1, in addition to IgA, is a major immunoglobulin at mucosal surfaces necessary for antimicrobial immunity in the gut and mammary gland. High levels of IgG1 are present in the colostrum (IgG, 60 mg ml⁻¹; IgA, 2 mg ml⁻¹; IgM, 4 mg ml⁻¹) and all transfer of passive antibody to the fetus occurs via the colostrum and milk.

T cells

There are three major T cell subsets in sheep. The majority of cells are either CD4⁺ or CD8⁺ and express the $\alpha\beta$ T cell receptor structure along with the T3 molecule and other adhesion molecules. The third T cell subset is CD4⁻CD8⁻ (double negative), which predominantly contains the $\gamma\delta$ T cell subset. The $\gamma\delta$ T cell subset is a major subset in ruminants with very high levels (25–50% of PBMCs) being present in the blood and lymphoid tissues of young sheep (<6 months old). *In vivo* the $\gamma\delta$ subset is characteristically closely associated with epithelial surfaces and are migratory and recirculating cells.

Most of this subset expresses a marker unique to ruminants which is a 210–215 kDa molecule known as T19. The function of this molecule is unknown but serves as a useful marker for sheep $\gamma\delta$ T cells.

MHC

Sheep tissues express the classical class I and class II molecules. The ovine class II is at least as complex as the human, and sheep genes related to all the expressed human class II genes, with the exception of the DP α gene, have been found. The protein products of these genes have been characterized by immunoprecipitation, monoclonals and protein microsequencing, to reveal that the sheep α and β chains of the class II genes are similar to the DR and DQ- α and DQ- β chains in man. Sheep T cells, both resting and activated, constitutively express both DR and DQ, although the expression of the latter is less per cell than DQ, the more common isotype.

The non-classical class I molecules (CD1 family) are expressed both within the thymus and in the peripheral tissues of sheep. Five CD1 genes have been identified in the sheep and afferent lymph dendritic cells in peripheral lymph of sheep express high levels of cell surface CD1.

The core cells of the immune system involved in antigen processing and recognition are accessory cells (e.g. dendritic cells) and lymphocyte subsets. Their distribution and kinetics of flow through the tissues has been established through the analysis of these cells in afferent lymph, lymph node and efferent lymph.

Afferent lymph

The considerable phenotypic and functional differences between the cells in blood and afferent lymph suggests that there is selectivity in the extravasation of cells from the blood across the endothelium into the peripheral tissues (Table 1). Although the blood contains naive and memory T cells, afferent lymph T cells are mainly of memory cell phenotype. This implies that the endothelial cells in the periphery (e.g. skin) express adhesion molecules which only engage the receptors restricted to memory T cells. Although not blast cells, lymphocytes have an activated phenotype as judged by IL-2 responsiveness, class II expression, and mitotic activity. B cells are much reduced in afferent lymph (4–10%).

Sheep afferent lymph is a physiological source of antigen-presenting dendritic cells. In terms of their expression of CD1 and Fc receptor, there are at least four distinct phenotypic profiles for dendritic cells in afferent lymph, ranging from cells which either coexpress CD1 and FcR, or express neither of these two

Table 1 Ovine leukocyte markers: general characteristics and distribution in different lymphoid compartments^a

Marker ^b	Mol. wt (kDa)	Percentage of marker positive cells in:				Distribution on other cells
		Blood	Lymph node	Afferent lymph	Efferent lymph	
CD1b	44:12	<2	<2	6	<1	Also on cortical thymocytes and dendritic cells (DC)
CD1c	44:12	30	30	16	22	B cells and DC are CD1c ⁺
CD2 (T11)	55	50–60	50–60	70–75	50–60	Only expressed on $\alpha\beta$ TCR ⁺ cells; absent from $\gamma\delta$ T cells; low expression on naive T cells; adhesion and activation molecule; increased expression on memory T cells
CD3	19–25	NA ^c	NA ^c	NA ^c	NA ^c	Not yet defined by mAb; complex molecule involved in T cell activation
CD4	56	25–40	33	49–57	30–40	CD4:CD8 ratios in sheep can range from 2:1 to 5:1
CD5	67	55–60	55–60	84	60–75	On all T cells; low expression on B cells
CD8	36:32	12–16	13–16	13–16	14–18	CD8 appears to be expressed on $\alpha\beta$ and $\gamma\delta$ TCR ⁺ cells
CD11a (LFA-1)	180:95	100	100	100	100	All leukocytes; low expression on naive T cells; increased expression on memory T cells
CD44	95	100	100	100	100	Many tissues; low expression on naive T cells; homing receptor
CD45	220:200:190	100	100	100	100	Leukocyte common antigen; wide distribution
CD45R	220	35–50	35–50	8–15	15–30	B cells, NK cells and naive T cells; absent from memory T cells
CD58 (LFA-3)	42	100	100	100	100	All leukocytes; is ligand for CD2; low expression on naive T cells; increased expression on memory T cells
$\gamma\delta$ TCR	44:36	10–20	10	10–15	5	High numbers in blood of young sheep (30–60%); also identified by T19 mAb
sIgM	70:25	35–50	30–45	4–10	15–25	Expressed on B cells
MHC I	44:12	100	100	100	100	Widespread
MHC II	34:28	60	50–60	90–94	55	Also expressed on activated T cells and dendritic cells; T cell class II mainly DR

^aDrawn from authors' own data plus published data from other groups. In published data, there is considerable variation due to age, breed differences and exposure to pathogens. ^bParentheses refer to previous designation. NA^c, data not available.

molecules, or express only one. These phenotypic differences either identify functionally distinct dendritic cell subsets or represent different stages of differentiation of the one dendritic cell lineage. Dendritic cells in afferent lymph are functionally significant antigen-presenting cells involved in carriage of antigen in an immunogenic form from the skin to the draining node. Dendritic cells have a high level of IgM and IgG1 'cytophilic' immunoglobulin. This passively acquired immunoglobulin may be physiologically important in antigen processing, as it allows dendritic cells to specifically concentrate foreign antigen and localize it in the form of immunogenic complexes for internalization and presentation to T cells. Despite a high afferent input of dendritic cells into the node few, if any, appear in the efferent lymph, suggesting that in sheep there is a high turnover of dendritic cells within the node. This is consistent

with studies in other species that show that dendritic cells in afferent lymph are the precursors of the T antigen-presenting cells of the paracortical region of the lymph node which have a rapid turnover.

Emigration of T cells from the skin to afferent lymph across the peripheral vascular endothelium is profoundly influenced by the cytokines IFN- γ and TNF. Intradermal injection of each cytokine can induce significant lymphocyte migration across the vascular endothelium into afferent lymph. It is likely that these cytokines play an important role in the emigration of recirculating lymphocytes at the site of immune or inflammatory responses in the skin. The evaluation of the *in vivo* activities of cytokines is another good example of how the lymphatic cannulation model can be used to investigate cytokine physiology.

Lymph node

A total of 90% of lymphocytes within a lymph node are derived from the blood; the remainder come from lymphoproliferation within the node and afferent lymph. The route of entry is across a specialized part of the vascular endothelium known in other species as the high endothelial venule (HEV). There is no morphological equivalent structure in sheep, but functionally the postcapillary venules are the same as in rodents and humans. Lymphocyte-HEV interaction is now known to involve a complex family of adhesion molecules including homing receptors (or selectins) on lymphocytes and complementary ligands on endothelial (addressins) and cell matrix proteins. The nonrandom patterns of lymphocyte recirculation through different immunological compartments have been well defined in the sheep. Blast cells from intestinal lymph home to the lamina propria of gut, whereas blast cells from peripheral nodes home to spleen and lymph nodes. Within the small lymphocyte recirculating pool, there are subsets of lymphocytes that preferentially recirculate through the skin, peripheral nodes, or mucosal-associated lymphoid tissue such as the Peyer's patch and mesenteric node. These studies give physiological credence to more recent *in vitro* studies on lymphocyte-HEV which have clearly established the differential selectivity for lymphocyte subset adhesion to specialized vascular endothelial cells in peripheral or mucosal-associated tissues. CD4⁺ T cells are selectively enriched over CD8⁺ T cells in lymph nodes and B cells show a preferential traffic through gut-associated lymphoid tissue. Vascular endothelial cells in antigen-stimulated nodes in the sheep express MHC class II and can act as antigen-presenting cells to recruit selectively antigen-specific T cells into the node. In antigen-stimulated nodes, the rate of entry of lymphocytes is $2-4 \times 10^4$ cells s⁻¹. The immediate response to antigen challenge is a phenomenon known as cell shutdown, wherein the output during the first 24 h in response to secondary challenge with antigen is reduced by 90%. During this time, there is an increased input of cells into the node. This is followed 24-28 h later by a 5- to 6-fold increase in lymphocyte output in efferent lymph. These changes in cell kinetics reflect vascular changes within the node and inhibition of intranodal traffic by prostaglandins.

Efferent lymph

Immunological memory is disseminated from the node via the efferent lymph. Studies by Hall and Morris established that if all the cells leaving an antigen-stimulated lymph node were removed from the

sheep via the cannulated lymphatic, then no priming for a secondary response occurred. If the efferent lymph cells were returned intravenously, then immunological memory was established. Exit of T cell subsets from the node following antigen stimulation is nonrandom. Studies of secondary challenge with antigens show that there is a biphasic exit of CD4⁺ T cells followed by CD8⁺ T cells, presumably reflecting the sequential activation of CD4 and CD8 within the node. Efferent T cells contain a higher proportion of $\alpha\beta$ TCR⁺ T cells than $\gamma\delta$ and contain cells of both memory and naive phenotype. Efferent lymph T cells draining viral infected lymph nodes contain precursor cytotoxic T lymphocytes (CTLs) and the time course and kinetics of the CTL response to viral infection has shown that pCTLs can be detected as early as 5-7 days after infection.

This brief review of the ovine systems has outlined some of the more intriguing aspects of lymphocyte biology. The availability of cellular and molecular markers for the ovine immune system has confirmed the immense value of the sheep to fundamental immunology and provides for the future a central focus for the essential integration of the *in vitro* immune system(s) into a physiological framework.

P

PAPILLOMAVIRUS, INFECTION AND IMMUNITY

Karen J Auburn, Department of Otolaryngology and Communications Disorders,
Section of Otolaryngologic Research, New York, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Papillomaviruses induce tumors of the skin and mucosa. In the 1920s, Shope purified and characterized a rabbit papillomavirus from warts. These extracts could generate new warts, confirming their infectious nature. Moreover, Rous observed that warts induced by the rabbit papillomavirus could progress to carcinomas. Since then many animal and human papillomaviruses (HPVs) have been isolated. Typically, papillomaviruses cause tumors that are benign. However, infection with certain HPV types, particularly HPV type 16 and HPV type 18, are associated with cancer, usually cervical cancer.

The papillomavirus particles are small (55 nm diameter), icosahedral in structure and are composed of capsomers assembled from the major (L1) and minor (L2) surface proteins. The double-stranded

circular DNA genome is about 8 kb. This DNA codes for a small number of proteins necessary for its maintenance and replication in addition to the capsid proteins. The genome organization of all the papillomaviruses is similar, as is the function of the viral proteins (**Figure 1** and **Table 1**). Papillomaviruses share a genus-specific antigen (capsid antigen) that can be detected by antibodies made to detergent-disrupted particles. However, classification of types is based on host range and relatedness of the viral genomes. A papillomavirus must have greater than 50% DNA homology to be considered the same type.

The typical lifecycle of the papillomaviruses involves infection of the keratinizing epithelium. The viral genome replicates as an episome. In the replicating basal cells of epithelium, a maintenance replication of the viral DNA occurs with very little viral transcription. Differentiation of epithelial cells is required for increased replication and transcription and virion production. In HPV-induced precancerous and cancerous lesions, only viral proteins E6 and E7 (**Table 1**) are expressed, and no virus is made. Therefore, an interest in immunotherapy has centered on the E6 and E7 proteins, oncoproteins or transforming proteins of the virus. Other vaccines based on the viral capsids could possibly prevent infection.

Figure 1 The papillomavirus circular DNA genome. The open reading frames are E1–E7, L1 and L2. The noncoding upstream regulatory region (URR) contains promoter/enhancer elements and origin of replication.

Table 1 Papillomavirus proteins

Viral protein	Function
E1	DNA replication
E2	Transcription regulation, DNA replication
E4	Alteration of cell skeleton
E5	Transformation
E6	Binding to p53, transformation
E7	Binding to pRb, transformation

Immune response of the host

Humoral response

Sera from animals or humans with a history of infection generally react with papillomavirus capsid proteins. Antibodies to the E7 protein of HPV16 and HPV18 are frequently found in sera of patients with cervical cancer. Similarly, antibody titers against the E2, E6 and E7 proteins have been detected in patients' sera.

Cellular immune response

Infection with the common papillomaviruses of the skin and mucosa often results in a chronic infection. This chronic infection occurs in the immunocompetent host, suggesting that viral antigens are not recognized by the immune system. However, an increased incidence of clinically apparent HPV disease occurs in the immunosuppressed transplant recipient and also in patients with the acquired immune deficiency syndrome (AIDS). These observations indicate that cell-mediated immunity is important in controlling HPV infection. A decrease in the ratio of CD4⁺ (helper) to CD8⁺ (suppressor) T cells has been reported in patients with HPV infection or precancerous cervical intraepithelial neoplasia, which is usually a manifestation of HPV disease.

Other host responses

Natural killer (NK) cells may have a role in the cellular response to HPV infections. Patients with HPV-induced cancerous and precancerous lesions are reported to display decreased NK cell activity, and these NK cells have a restricted responsiveness to immunostimulatory cytokines.

Langerhans cells are specialized cells in epithelial tissues that are potent antigen-presenting cells. In most warts, there is a reduction of Langerhans cells resulting in a local immunodeficiency state in these lesions. Decreased numbers of Langerhans cells have been observed in the HPV precancerous lesions.

Class I MHC molecules present viral antigens to T cells. Downregulation of class I MHC and the TAP-1 transporter protein has been reported in HPV-induced cervical lesions and laryngeal lesions. Additionally, an association between certain class II MHC alleles (e.g. DQw3) and susceptibility to cervical cancer and laryngeal papillomatosis has been observed.

Evasive strategies by the organism

Examination of tissues reveals that papillomaviruses are ubiquitous, and much more epithelium contains

viral DNA than is manifested by lesions. The viral genome persists in apparently normal tissue with very little expression. Pathology of a papillomavirus infection is exacerbated by abrasion of infected epithelium, hormones and conditions of immunosuppression of the host. Moreover, differentiation of infected epithelium is required for increased expression and replication of the virus. It is clear that the virus has developed strategies to evade the immune system, as suggested by downregulation of MHC class I molecules and Langerhans cells and decreased susceptibility to NK cells.

Vaccines

Prophylactic vaccines appear to be possible with the structural virions and successful papillomavirus vaccines have been developed in animal models, most work involving cattle. Calves vaccinated with wart extract were protected when challenged with bovine papillomaviruses (BPVs). Protection is type specific. Animals inoculated with BPV4 are protected against infection with BPV4, but not BPV2, and vice versa. Subunit vaccines have been developed based on L1, L2 or E7 recombinant proteins and synthetic peptides. L1 vaccines conferred protection when animals were challenged with virus. L2 vaccines for BPV1 resulted in the production of neutralizing antibodies but not in the case of BPV4. However, the subunit vaccines of L2 for BPV2 or E7 of BPV4 did induce early regression of papillomas, even though these vaccines did not elicit neutralizing antibodies. Such lesions were characterized by infiltrating lymphocytes and macrophages, indicating a cell-mediated response.

Production of large quantities of virus has been problematic because of the difficulty of producing virus in tissue culture. However, production of recombinant structural proteins L1 and L2 and assembly into virus-like structures has led to promising early vaccine studies with a variety of papillomavirus types.

Therapeutic vaccines for persons already infected with papillomaviruses may be possible. The goal is to cause regression of tumors, particularly malignant tumors that have papillomaviruses as part of their etiology, using epitopes of viral oncoproteins. Regression of tumors should be possible if an immune response occurs. Trials in patients with advanced cervical cancer are in progress using E7 (Australia), E6-E7 (UK) and E7 peptides (The Netherlands).

PARAMYXOVIRUSES, INFECTION AND IMMUNITY

Trudy G Morrison, Department of Molecular Genetics and Microbiology, University of Massachusetts Medical School, Worcester, Massachusetts, USA

The family Paramyxoviridae is one of several families of viruses in the order Mononegavirales, a grouping which denotes enveloped, negative-stranded, nonsegmented RNA viruses. The Paramyxoviridae includes a variety of pathogens which infect many different hosts causing a diversity of diseases, ranging from more localized respiratory infections to systemic infections. Human paramyxoviruses are responsible for some common childhood diseases such as measles, mumps and respiratory tract infections. Members of this family are also responsible for distemper found in several animal species.

Paramyxoviruses encode six to ten proteins and initiate infection by attachment to and fusion with host cell plasma membranes. Viral transcription and replication occurs exclusively in the cell cytoplasm and virus assembly, budding and release takes place at the host cell membrane, thereby modifying the antigenicity of infected cells. A characteristic marker of these infections is the formation of syncytia or giant multinucleated cells. While infection with many of these viruses is lytic, some can result in persistent infections. Infections usually stimulate both soluble and cell-mediated immune responses.

Characteristics of the organisms and their antigens

Classification

Based on properties of the proteins, sequence analysis of individual genes, order and number of genes encoded by the genome, and sequences of intergenic regions and the 3' and 5' noncoding regions, this family of viruses is divided into two subfamilies encompassing four genera. One subfamily, Paramyxovirinae, includes the paramyxoviruses, rubulaviruses and morbilliviruses, while the other, Pneumovirinae, includes the single genus Pneumovirus. Individual members of each genus are listed in Table 1 as well as the proteins encoded by the viruses in each genus.

Virions

Paramyxoviridae virions are polymorphic structures composed of a helical nucleocapsid core surrounded by a lipid envelope with associated viral membrane proteins. Although filamentous forms can be seen, virions are usually roughly spherical (see Figure 1) with a diameter usually between 100 and 400 nm. Protruding 8–20 nm from the membrane are two spikes, one of which is a tetramer of the cell-attachment protein and the other a trimer or tetramer of the fusion protein. The lipid bilayer is derived from the host cell plasma membrane and,

therefore, its composition usually approximates the lipid content of the host cell plasma membrane. Lining the inner surface of the lipid are multiple copies of a single protein, the M or matrix protein, a nonglycosylated peripheral membrane protein, although pneumoviruses have an additional matrix-

like protein (M2) of unknown function. The helical core of these viruses contains negative-stranded RNA ranging in size from 15.2 to 15.9 kb and approximately 2200–2600 copies of a tightly bound nucleocapsid protein (NP). Also associated with this ribonucleoprotein complex (RNP) are smaller amounts

Figure 1 A paramyxovirus virion, showing the minimal structural components. The lipid bilayer is represented by a thick gray line surrounding the core of the virus. Spikes or peplomers, extending from the external surface of the lipid, are represented by two different shapes representing the oligomeric structure composed of the attachment proteins and the structure composed of the F proteins. The actual conformation of these structures is unknown. Some paramyxovirus virion membranes also contain SH proteins. Lining the inner surface of this lipid are matrix or membrane proteins. Precise details of M protein interactions with both the transmembrane proteins and the core are unknown. The virion core is composed of helical, negative-stranded, nonsegmented RNA with nucleocapsid protein bound along its entire length. Also shown are associated proteins, P and L, which form the virion-associated polymerase. C proteins are found in the interior of some viruses.

of two proteins, the L (large) and P (phosphoprotein), both of which form the virion-associated polymerase.

Paramyxovirus genomes contain minimally six genes, commonly in the order (from the 3' end): NP, P (V/C), M, F, attachment protein, and L. The P gene encodes several proteins in addition to P protein by novel use of open reading frames and insertion of nontemplated residues during transcription. Some rubulaviruses and the pneumoviruses contain extra genes, and the gene order of the pneumovirus attachment and F protein genes is reversed (Figure 2). In addition, all virus genomes contain extragenic 3' leader and 5' trailer sequences and intragenic sequences of various lengths.

Virus-encoded proteins

Attachment proteins

Attachment proteins initiate infection by binding to cell surface receptors and are a primary target for neutralizing antibody. All attachment proteins are type 2 glycoproteins with an uncleaved signal/anchor sequence near the N-terminus (Figure 3) and are modified with N-linked oligosaccharides, although the position and numbers of oligosaccharide chains in different proteins are variable. The pneumovirus-attachment proteins are also modified by O-linked carbohydrate. The attachment proteins of the paramyxoviruses and rubulaviruses, the HN (hemagglutinin-neuraminidase) glycoproteins, agglutinate red blood cells, an activity that may reflect cell binding activity. HN proteins also have a neuraminidase activity which may function in virus release from cell surfaces. The attachment proteins of morbilliviruses, H (hemagglutinin), have only red blood cell-binding activity. The pneumovirus-attachment protein, G (glycoprotein), has neither demonstrable hemagglutinating activity nor neuraminidase activity. Many of these proteins have an additional activity involved in

Figure 3 Paramyxovirus-attachment proteins: the linear sequence from the N-terminus to the C-terminus. Paramyxoviruses are represented by Sendai virus (SV), rubulaviruses by Newcastle disease virus (NDV), morbilliviruses by measles virus (MV), and pneumoviruses by human respiratory syncytial virus (RSV). While the positions of cysteine residues are relatively well-conserved within each genus, the positions and numbers (ranging from 3 to 10) of glycosylation addition sites (not shown) are not. Furthermore, studies of the simian virus 5, Newcastle disease virus, and measles virus attachment proteins have shown that not all addition sites are used. Thick lines correspond to the transmembrane domains (TM), which are approximately 20–25 amino acids. The cytoplasmic domains range in length from approximately 20 to 40 amino acids and the ectodomains range in size from 298 amino acids (RSV) to 617 amino acids. The structure of these proteins is unknown although it has been proposed that the HN proteins are folded like the influenza neuraminidase protein.

virus penetration termed fusion promotion. While the mechanism for fusion promotion is unclear, current data suggest that the attachment protein plays a role in activating the fusion protein activity.

Figure 2 Gene order of paramyxoviruses. The order of genes (not drawn to scale) in each genus is shown from the 3' end of the genome. Leader sequences of 44–70 nucleotides form the 3' end of the genome followed by the first gene (nucleocapsid or NS1). After the L gene are trailer sequences of 44–155 nucleotides. Intergenic regions range from a single nucleotide to 52 nucleotides and, in one case, respiratory syncytial virus, the start of the L gene overlaps the end of the M2 gene. All genes within each genome begin with the same 10–15 nucleotides and end with the same sequence.

Fusion proteins

These glycoproteins, the most conserved in the family, are the other major target for neutralizing antiserum. They are responsible for the fusion of viral membranes and cell plasma membranes, an event required for virus penetration. The proteins are synthesized as a precursor, F_0 , which must be cleaved at a site 100–130 amino acids from the N-terminus, by host cell enzymes, into disulfide-linked F_2 and F_1 for fusion activity (see Figure 4). Some fusion proteins (exemplified by set 1, Figure 4B) have an amino acid sequence at the cleavage site which is a substrate for the furin family of proteases and are thus cleaved intracellularly in the trans-Golgi membranes. Other fusion proteins (Figure 4B, set 2) do not have this sequence motif and are cleaved by extracellular enzymes such as a protease released by Clara cells in the respiratory tract or a factor X-like activity in the allantoic fluid of embryonated eggs. As well-illustrated by different strains of Newcastle disease virus (NDV), the sequence at the cleavage site is a major determinant of the pathogenesis of a virus. NDV strains possessing a furin-recognition site result in systemic infections and are virulent viruses while those without this motif are avirulent and have a more restricted replication within the infected animal.

Fusion proteins have several domains which have

been shown by mutation to be important to their activity. The N-terminal 15–20 amino acids of F_1 , exposed after cleavage and termed the fusion peptide, is thought to directly insert into the target membrane. This sequence is conserved across the family and is composed of hydrophobic and short-chain amino acids. Also present in the F protein sequence are two heptad repeats, one just C-terminal to the fusion peptide and the other, a leucine zipper, just N-terminal to the transmembrane domain.

M proteins

Typical of most enveloped RNA viruses, the inner surface of the envelope is lined with an abundant, nonglycosylated membrane or matrix protein. These proteins, which vary from 256 to 375 amino acids in length, are basic with hydrophobic regions. Phosphorylated forms of some M proteins are also observed. Because of an affinity for lipid, for the nucleocapsid protein, and for itself as well as the cytoplasmic domains of either or both glycoproteins, these proteins serve as a link between the lipid bilayer of the virion and the inner core and may play a central role in virus assembly and budding. The protein also has a role in the regulation of RNA synthesis likely important during the budding of the virus.

Figure 4 Paramyxovirus fusion proteins. (A) A diagram representing the linear sequence of fusion proteins (ranging in size from 529 to 564 amino acids) from the N-terminus to the C-terminus. Structural determinants, with the exception of glycosylation addition sites (not shown), are well conserved across all genera. The number and position of glycosylation addition sites varies within each genus and the actual usage of these sites has been defined for a very limited number of these viruses. The regions of the sequence corresponding to F_2 and F_1 are shown by arrows above the line. Also shown on these arrows are the positions of cysteine residues responsible for the disulfide linkage of F_1 and F_2 . Important structural domains within the sequences are shown by thick lines. The fusion peptide is approximately 15–20 amino acids; the heptad repeat one, 30–40 amino acids; heptad repeat 2, approximately 30 amino acids; transmembrane domain (TM), 20–30 amino acids; and the cytoplasmic domain ranges from approximately 20 to 30 amino acids. (B) Sequences at the cleavage site are shown for some representative viruses. Set 1 sequences have a furin recognition sequence (R, X, K/R, R) while set 2 do not and must be cleaved by extracellular proteases. TM, transmembrane domain; NDV, Newcastle disease virus; RSV, respiratory syncytial virus; SV5, simian virus 5; PIV, parainfluenza virus; SV, Sendai virus.

SH (small hydrophobic) proteins

Pneumoviruses and the rubulaviruses, SV5 and probably mumps have been shown to encode small (64 and 44 amino acids), hydrophobic, type 2 transmembrane proteins of unknown function. The pneumovirus protein has been found in cell and virion membranes while the SV5 protein only in plasma membranes. The respiratory syncytial virus SH protein has been shown to enhance membrane fusion.

Nucleocapsid proteins

These proteins, which range in size from 391 to 553 amino acids, tightly bind both genomic and antigenomic RNAs along their entire length, conferring RNAase resistance to the RNA. Binding of the RNA is essential for transcription mediated by the L and P proteins. Soluble nucleocapsid protein, associated with the P protein, is essential for replication of the genome. The nucleocapsid protein also associates with the M protein during assembly.

P proteins/P gene-encoded proteins

The P gene encodes the P protein as well as V and sometimes C, W, I, X and D proteins, utilizing different reading frames on the same mRNA or alternative transcripts that result from a novel transcription mechanism involving the insertion of one or two nontemplated G residues. The strategies for encoding the various products of this gene vary with the genus. The P protein, a phosphoprotein, is essential for RNA synthesis. The C proteins, present only in paramyxoviruses and morbilliviruses, are small basic proteins encoded in a different reading frame from P. Their role in infection is not well-characterized but it has been shown that they inhibit primary transcription. The role of the V proteins, found in most members of Paramyxovirinae, are also not well-characterized, but it has been shown that they can inhibit replication. These proteins share the same N-terminal sequence as the P protein, but because of a shift in reading frame, they contain a unique, cysteine-rich C-terminus. The roles of the other P gene-associated proteins are unknown.

L proteins

These are large, 2200 amino acid, poorly characterized proteins which are probably the actual polymerase, their sequences sharing some motifs common to many RNA polymerases. They are also responsible for the capping and methylation of mRNAs.

Infectious cycle

Infection begins when the virion-attachment proteins bind receptors on cell surfaces (Figure 5, step 1). The distribution of these receptors in an animal clearly represents one determinant of the host range of these viruses. The receptors for paramyxoviruses and rubulaviruses are sialic acid-containing molecules. Sendai virus binds to gangliosides. Several different molecules have been reported to be the measles virus receptor, but CD46 has most definitively been demonstrated as the receptor. The receptors for pneumoviruses are unknown.

Subsequent to attachment, the fusion protein, probably activated in some way by the attachment protein, mediates the fusion of viral membranes with the host cell plasma membrane (step 2). As a result of this fusion, the virion interior becomes contiguous with the cytoplasm of the cell and, therefore, accessible to precursors required for transcription. How the RNP becomes disassociated with the virion M protein, which serves to inhibit transcription, has not been characterized (step 3). The genomic RNA is fully transcribed by virion-associated L and P proteins to produce monocistronic mRNAs in a process termed primary transcription (step 4). After translation of this mRNA (steps 5 and 6), replication of the genomic RNA ensues. Replication is accomplished by producing a precise, full-length, plus-stranded copy of the genome (step 7), which, in turn, serves as template for generation of progeny genomes (step 8). These newly made genomes serve to amplify infection by functioning as template for further transcription in a process called secondary transcription (step 9) or as template for the synthesis of more antigenomic RNA (step 10).

The mechanisms responsible for the synthesis of subgenomic mRNA and full-length antigenomic RNAs have been the subject of investigation over many years both in this system and the closely related rhabdovirus system. Current models include the following observations: 1) The L-P protein complex begins synthesis of positive-stranded RNA at the 3' end of the genome, synthesizing the positive-stranded leader RNA. 2) In the absence of sufficient concentrations of soluble NP protein, the polymerase copies the genome by a start-stop mechanism generating monocistronic RNA. Poly-A sequences at the 3' end of each mRNA are generated by a slippage mechanism on a sequence of 5-6 U residues in the genomic RNA at the end of each gene. 3) Later in infection, when concentrations of nucleocapsid protein increase, soluble N protein plays a role in initiation of replication by serving as an antiterminator of RNA synthesis at the intragenic regions. The

Figure 5 Paramyxovirus infectious cycle. Schematic representation of the steps in infection. Step 1, attachment; step 2, fusion of viral and host cell plasma membranes; step 3, penetration or uncoating (detachment of ribonucleocapsid from M protein); step 4, primary transcription; step 5, translation of nucleocapsid, M protein, P protein, and L protein on cytoplasmic ribosomes; step 6, translation of transmembrane proteins on membrane bound ribosomes; step 7, synthesis of antigenomic (+) full length RNA; step 8, synthesis of genomic (-) RNA; step 9, secondary transcription (transcription using progeny genomes as template); step 10, amplification of replication using progeny genomes as template; step 11, transport of transmembrane proteins through the membrane systems of the cell; step 12, insertion of transmembrane proteins into the plasma membrane; step 13, association of M protein and ribonucleocapsids with patches of plasma membrane containing glycoproteins; step 14, budding and release of progeny genomes.

V and C proteins (and perhaps other P gene-encoded proteins) may also play roles in regulating the levels of transcription and replication at various stages of infection.

Final assembly of progeny virions occurs at the host cell plasma membrane. The viral glycoproteins are inserted into the rough endoplasmic reticulum membrane during synthesis (step 6) and are processed through the membrane systems of cells (step 11) utilizing resident cellular chaperones and modifying enzymes. As are host cell plasma membrane proteins, the viral glycoproteins are inserted into the host cell plasma membrane (step 12). Thus viral glycoproteins serve to modify the antigenicity of the infected cell. The M protein associates with the cytoplasmic tails of the glycoproteins as well as the assembled RNP and the regions of plasma membrane containing all these components bud from the mem-

brane in poorly understood processes (steps 13 and 14). In polarized cells such as respiratory epithelium, paramyxoviruses bud from apical cell surfaces. This directed budding probably plays an important role in the pathogenesis of these viruses.

Effect of paramyxoviruses on host cells

Because of the presence of viral glycoproteins at the cell surface and because paramyxovirus fusion occurs at neutral pH, infected cells can fuse with adjacent uninfected cells, forming syncytia or multinucleated cells, a classic cytopathic effect of this family of viruses. The ability to form syncytia may also serve as an alternative mechanism to spread infection through an organ system.

Infection by many members of this family of viruses ultimately results in cell death. However,

the precise mechanisms involved remain poorly understood.

Immune responses of the host

In systems that have been studied, infection stimulates serum antibody as well as cell-mediated immune responses, both of which play roles in protection as well as recovery from disease although the relative importance of each varies with the virus. Secretory antibody production has also been characterized in many of the respiratory infections caused by some members of this family of viruses. Animal studies suggest that secretory antibody has an important role in protection in some infections although this antibody is only partially protective in some respiratory tract infections such as respiratory syncytial virus infections.

Serum antibody against all virion-encoded proteins can usually be detected after infection, although levels vary and antibodies against the M protein and F protein are often at low levels. While antinucleocapsid antibody is usually in the highest titers, only the antibody against the attachment protein and the fusion protein are neutralizing and, therefore, protective. Indeed, vaccination with vaccinia vectors expressing the F or HN proteins or both has shown that antibody against either protein is protective although expression of both antigens results in the most protective immune response.

Murine monoclonal antibodies have been raised against the attachment protein and the F protein in several systems. The attachment proteins of human parainfluenza virus 3 (HPIV3), Sendai virus, Newcastle disease virus, measles virus, and respiratory syncytial virus (RSV) have from 4 to 6 sites. Antibodies to some of the sites inhibit hemagglutination and, therefore, attachment, while antibodies to other sites are non-neutralizing. Similarly, F proteins have been shown to have 4–7 sites. Antibodies to some sites inhibit hemolysis, an assay generally thought to reflect the fusion activity of the protein, and are neutralizing.

The cell-mediated immune responses to these infections are generally less well characterized. Sendai virus infection of one strain of mice yielded CD8⁺ T cells with reactivity to a single sequence in the NP protein. After HPIV3 infections of humans, cytotoxic T lymphocytes (CTLs) with specificity to HN, P, and NP have been demonstrated. After RSV infection, CTLs with multiple reactivities have been demonstrated. CD4⁺ T cells have been demonstrated in some systems.

Evasive strategies by paramyxoviruses

Of the many ways viruses can evade host immune responses, there are two well-documented strategies employed by some members of the Paramyxoviridae family. First, best exemplified by measles virus, is modulation of the immune response of the host. It has been long recognized that measles virus infection results in a nonspecific suppression of cell-mediated immune responses during both acute and convalescent stages of the disease. Suppression may be related to measles infection of monocytes and macrophages. This suppression has also been recently linked to the binding of the measles virus H protein to the CD46 receptor. This binding signals a downregulation of the expression of interleukin 12 (IL-12) production which could account for a general suppression of cell-mediated immunity.

Sendai virus and bovine parainfluenza virus have been shown to infect alveolar macrophages, which may account for decreased resistance of infected animals to bacterial pulmonary infections.

A second evasive mechanism employed by some paramyxoviruses is the establishment of persistent infection. Again this phenomenon is perhaps best studied with measles virus since the disease SSPE (subacute sclerosing panencephalitis), a rare fatal neurological disease that is a sequela of acute measles infection, is the result of measles virus persistent infections. The establishment of persistent infections by these normally lytic viruses is probably due to incompletely understood cellular as well as viral factors as well as virus-specific antibody. Viruses present in persistently infected cells are usually mutants of the wild-type virus responsible for acute infections. Mutations most frequently associated with persistence seen in SSPE are in the attachment protein, the fusion protein, or the M protein, although alterations which result in decreased expression of these proteins are also associated with persistent viruses. Expression of these proteins at infected cell surfaces as well as virus budding are usually considerably reduced or absent. Infection in immunologically privileged sites may also account for the persistence of the virus.

Paramyxoviruses, typical of RNA viruses, are replicated by an RNA-dependent RNA polymerase which has no proofreading mechanism. Thus the frequency of mutation is high, allowing for variants in a population which may be less reactive to immune responses. However, for reasons that are not entirely clear, the antigenic drift observed in some other RNA viruses such as influenza viruses does not appear to play nearly as significant a role in the epidemiology of paramyxoviruses.

Vaccines

Vaccines against measles virus, mumps virus, Newcastle disease virus, canine distemper virus, and rhinderpest virus are currently in use. These vaccines are all live attenuated viruses. In most cases, attenuation was accomplished by growth of the virulent virus in tissue culture. In the case of Newcastle disease virus, naturally occurring avirulent strains of the virus are used as vaccine. Development of attenuated vaccine viruses for some other members of the family are currently underway.

Attempts to develop inactivated vaccines for measles virus and RSV have met with unfortunate results. Formalin-inactivated measles virus was tested as a vaccine and resulted in neutralizing antibody which rapidly declined in titer. More importantly, vaccinated individuals upon infection with live virus developed atypical measles, a much more severe form of the disease. The reason for the enhanced disease is unclear but has been attributed to alteration of F protein antigenicity by formalin and failure to develop antibodies to the F and NP proteins.

Similarly, formalin-inactivated respiratory syncytial virus was used in trials and also resulted in enhanced, life-threatening disease when the vaccinated individuals encountered the virulent virus. Animal studies suggest that enhanced disease was due to an imbalanced cell-mediated immune response to the inactivated virus and perhaps a failure of the vaccine to stimulate neutralizing antibodies to the F protein.

Inactivated virus vaccines against Newcastle disease virus and mumps virus have been used with some success and without reports of enhanced disease. Inactivated vaccines against parainfluenza 1, 2 and 3 administered intradermally have elicited an antibody response but no protection, a result thought to be due to the absence of stimulation of secretory antibody important for control of respiratory tract infections.

Conclusions

While the molecular characterization of the structure and function of the viral proteins is extensive, numerous questions remain concerning the mechanisms of virion entry, uncoating, replication, transcription and assembly. By comparison, there is less information about the immune response of hosts to infection, particularly the cell-mediated immune response. Further information in these areas will be important to the development of effective vaccines particularly for the respiratory tract infections.

PARASITES, IMMUNITY TO

Frank EG Cox, Immunology Section, Division of Life Sciences, King's College London, London, UK

The term parasitism describes any relationship between two organisms in which one lives at the expense of the other and thus includes infections caused by prions, viruses, bacteria, fungi, protozoa and helminth worms. The word parasite, however,

is traditionally reserved for the eukaryotes, protozoa and helminths. Protozoa are small single-celled microparasites, mostly measuring 1–10 µm, which multiply within their definitive hosts in the same way as viruses and bacteria. Helminth worms, on the

other hand, are macroparasites; they are much larger multicellular organisms, measuring 100 μm to 1000 μm or more, and do not multiply within their definitive hosts. Parasites are found in every kind of invertebrate and vertebrate and individual hosts often harbor several different species, sometimes in massive numbers.

Humans, partly because of our lifestyles and habits, seem to be particularly susceptible to infections with parasites and over 50 species of protozoa belonging to 20 genera, and over 340 species of helminths belonging to about 50 genera have been recorded. These parasites of humans have attracted considerable attention because they cause some of the most widespread human diseases such as malaria, which affects 350–500 million people, schistosomiasis, which affects 200 million people, and ascariasis, which affects some 250 million people worldwide. In Africa, the presence of the parasitic protozoan responsible for trypanosomiasis prevents the use of over 10 million km^2 of land in the sub-Saharan region for cattle rearing. Parasites of domestic animals are also of increasing importance; coccidiosis, for example, is a major threat to battery fowl, particularly in industrialized countries.

Parasitic diseases are difficult to control because they often produce intractable conditions, largely as a result of the inability of the immune system to keep them in check.

Immune strategies in protozoal and helminth infections

The strategies required for a successful immune response are different for protozoa and helminths. Because protozoa multiply in their vertebrate host with a rapid but variable doubling time the host must mount an immune response against the rapidly fulminating infection which presents an immediate threat. In contrast, in helminth infections, in which the parasites do not normally multiply within their vertebrate host, the parasite load is limited by the number of exposures to infection so a rapid immune response to an initial infection is not essential. In spite of the differences between protozoa and helminths, the infections they cause have many common features, including being very long lasting, often several years or even lifetimes, and inducing immunopathological changes which may be more dangerous than the infection itself. This is because most parasites, having been recognized as foreign and having elicited an apparently appropriate immune response, are capable of escaping from the consequences of the response because they have life cycles involving sev-

eral discrete stages. These stages are often antigenically different, and occupy different sites.

All parasites have also evolved mechanisms for evading the immune response. Schistosomes, for example, disguise themselves with host antigens; the African trypanosomes undergo antigenic variation; *Leishmania* and *Toxoplasma* survive in macrophages; *Trypanosoma cruzi*, the protozoan that causes Chagas' disease, mimics host antigens; and many parasites express irrelevant antigens which either deflect the immune response from more vulnerable targets or are shed as they become cross-linked by antibodies.

The net result is partial control but not total elimination of the parasite so the host continues to mount increasingly complex and ineffective immune responses and, unless the host eventually kills the parasite, the parasite kills the host or there is an uneasy compromise which is the most common outcome. Parasitic infections, therefore, tend to be long and chronic; Chagas disease, African trypanosomiasis and some forms of leishmaniasis cause life-long infections, some malarias last for 60 years or more and the duration of most helminth infections can be measured in terms of 5–10 years – about the natural lifespans of the parasites. Whatever the outcome, there is usually some immunopathological damage, often caused by inappropriate immune responses which occur in the wrong place, at the wrong time or for the wrong duration.

Immune responses to parasites

Because of the long-lasting nature of parasitic infections it was widely believed until comparatively recently that there were very few effective immune responses against most parasites. However, it is now clear that immunity is the rule. The evidence for this comes from a number of sources. First, there is the epidemiological evidence: in endemic areas the majority of people develop clinical immunity to parasitic infections, the prevalence of infection falls with age while immunological parameters increase and some immunity to reinfection occurs. Second, there is the experimental evidence: in every animal model investigated some degree of immunity can be demonstrated and it can be argued that there is no reason why humans should be any different. However, immunity is seldom complete and tends to be unstable and individuals suffering from concurrent infections or undergoing immunosuppressive therapy often suffer recrudescences of their dormant infections.

The immune response to any parasite, as with other infectious agents, begins when the host

becomes infected and the parasite is recognized as foreign. In order for this to occur, the parasite must come into contact with the cells of the immune system and if it does not, then no immune response will be initiated. Intestinal parasites, such as the nematode worm *Enterobius vermicularis* and the non-pathogenic strains of the amoeba, *Entamoeba histolytica*, that do not breach the integrity of the gut wall cannot and do not initiate any immune response.

Most parasitic infections, however, do come in contact with the cells of the immune system and are recognized as foreign. The actual events involved in recognition are complex and much of what we know about them is concerned with protein antigens and, in the context of parasitic infections, little is known about what happens to carbohydrate antigens. In parasitic infections macrophages seem to be the cells usually involved as antigen-presenting cells and the effector cells of the immune system, as in all other infections, are cytotoxic T lymphocytes (CTLs), natural killer (NK) cells, activated macrophages and B lymphocytes. Each of these has its own specific role and can act concurrently or sequentially to bring about the immobilization or destruction of the invading parasite.

Parasites, particularly helminths, represent large targets and are antigenically very complex but the immune response is normally only able to recognize a limited number of surface antigens, not all of which are involved in protection and some are even able to deflect the immune response away from more vulnerable targets. A great deal of research has been devoted to the identification and characterization of protective antigens in order to try to understand the mechanism of immunity to parasites and to target vaccines to relevant molecules. Much research has also been directed towards the identification of antigens that are irrelevant to protection, or are even counterprotective, those involved in the evasion of the immune response and those which may possibly contribute to pathology. The antigens that drive the cytokine response towards protection or pathology have only recently begun to receive any attention (see below).

What is known is that the totality of the immune responses to any particular parasite is complex but individual components are relatively simple and there is nothing unique or special about them. CTLs are frequently involved in viral infections but are seldom implicated in parasitic infections, the most important exception being *Theileria parva* in cattle in which CTLs predominate in protective immune responses, particularly in vaccinated animals. However, there is increasing experimental evidence for the involvement of CTLs against a number of intracellu-

lar protozoa, including malaria parasites. NK cells are also being increasingly implicated in protection against parasites. Activated macrophages are among the most important cells involved in protection against parasites and can kill parasites either intracellularly or extracellularly. If small, the target cell can be phagocytosed and destroyed in the phagolysosome via a number of pathways such as proteolytic enzymes and directly or indirectly by other toxic molecules, including reactive oxygen intermediates (ROI) and nitric oxide (NO), either on their own or together with other molecules. One of the key features of macrophage-mediated killing is that the toxic molecules produced are released not only into the phagolysosome but also extracellularly and are thus able to destroy cells in the close vicinity of the activated macrophage, including helminths, especially if the macrophage is closely bound to the target cell via an antibody bridge. These toxic molecules, however, can also damage host cells and their release in an inappropriate place or in excess is a major cause of immunopathology in parasitic infections.

Antibodies are effective against parasites in a number of ways including neutralization, agglutination, complement activation, opsonization and antibody-dependent cellular cytotoxicity (ADCC). The main function of immunoglobulin A (IgA) is the inhibition of invasion of the mucosa, either by agglutinating the parasites or blocking attachment to host cells, and this class of antibody is mainly concerned with defense against intestinal protozoa. IgG and IgM initiate complement-mediated lysis of parasites while both IgG and IgE bind to effector cells, activated macrophages or eosinophils respectively, and thus facilitate the destruction of the target cell via ADCC. Antibodies are also involved in ADCC by NK cells.

T cell subsets and immunity to parasites

The discovery of two subsets of CD4⁺ T helper cells (T_H1 and T_H2) by Mosmann and Coffman in 1986 has revolutionized our understanding of immunity to parasitic infections. These two subsets control the cell-mediated and antibody-mediated arms of the immune response respectively and this control is exerted by the cytokines produced. T_H1 cells characteristically produce interleukin 2 (IL-2) and interferon γ (IFN γ) and are responsible for the activation of cytotoxic T cells, NK cells and macrophages, while T_H2 cells produce IL-4 and IL-5 and are responsible for the induction of B cells to produce antibody and the activation of eosinophils. There is a considerable degree of cross-regulation between T_H1 and T_H2 cells; IFN γ inhibits antibody production

while IL-4 inhibits the production of IFN γ . These discoveries have enabled parasitologists to understand what is happening in parasitic infections and the paradigm of such studies is the protozoan parasite *Leishmania major* in mice. Briefly, what happens is that the *Leishmania* parasites live and divide in macrophages and the protective immune response involves IFN γ -activated macrophages which kill the intracellular parasites. However, this immune response is inhibited by IL-4 (and IL-10) which prevent the production of IFN γ . The net result is uncontrolled growth of the lesions and massive amounts of antibody that has no protective effect.

In many helminth infections the situation is different; T_H2 cells control the production of eosinophils and IgE and are protective whereas T_H1 cells are responsible for inflammation and pathology. By the early 1990s a general pattern had emerged, largely based on studies of parasites in mice, which suggested that in the majority of protozoal infections T_H1 cells were protective and T_H2 cells were counter-protective, whereas in helminth infections the reverse was the case. Since then the situation has changed dramatically and it is now known that CD8⁺ cells are also involved in cytokine production, NK cells are involved in the immune response, IL-12 plays an important role, the nature of the response is determined by the presence of particular cytokines and NO is probably the most important molecule involved in protection and pathology. It is now also known that human T cell subsets are basically similar to murine ones and, as far as immunity to parasitic infections is concerned, the significance of these discoveries is that the main features of the immune response can be analyzed against a background of the functional T cell dichotomy, which is similar in humans and mice and also in sheep and cattle.

An important point is that, whereas it had previously been assumed that CD8⁺ cells were essentially effector cells involved in major histocompatibility complex (MHC)-restricted target cell killing, we now know that they are also involved in the control of the immune response and are therefore presumably involved in immunity to parasitic infections.

Recent studies have also shown that NK cells are able to activate CD8⁺ T cells and are also important producers of IFN γ and thus they also strongly influence the outcome of the immune response. NK cells are activated by IL-12, which now occupies a central role in our understanding of immunity to parasitic infections. IL-12, produced by macrophages, is responsible for the activation of NK cells and is also involved in the regulation of IFN γ production and the growth and differentiation of T_H1 cells. IL-12 and NK cells, therefore, play a major role in T_H1-

type responses which determine the outcome of parasitic infections now thought to be determined by cross-regulation between T_H1 and T_H2 cells. Thus the immune response is controlled by a network of cytokines, some driving the immune response one way and some driving it the other.

It is only in the past few years that the role of NO in immunity to infection has been understood, largely as a result of studies on parasitic infections. NO is a powerful antimicrobial compound and is known to kill a range of organisms from bacteria and protozoa to helminth worms by acting on iron sulfur clusters in macromolecules, repressing DNA synthesis and inhibiting iron-containing enzymes, including those involved in respiration. NO activity is upregulated by IFN γ and tumor necrosis factor α (TNF α) and is downregulated by IL-4 and IL-10. Thus nitric oxide is a key molecule in the immune response against parasites and its production and activity are favored by T_H1 responses and inhibited by T_H2 responses.

The interrelationships between T cell subsets, cytokines and NO are now being actively investigated in many parasitic infections. There is, however, a major problem and this is that the protective cytokine profile can alter during the course of an infection, as appears to happen in experimental murine malaria and in a number of helminth infections, making it very difficult to draw any hard and fast conclusions about exactly what the pattern of cytokine activation actually is in any particular infection.

Immunopathology

The immune responses evoked by parasites are not unusual and are essentially the same as those involved in immunity to other infectious organisms but what is different is their complexity in response to diverse antigens expressed by different stages of complicated life cycles, often in different situations in the host. This leads to a plethora of antibody-independent and antibody-dependent responses which, over a period of time, can give rise to misdirected immune responses leading to pathological changes instead of protection. For example, during the course of many infections, parasite-derived molecules are deposited on host tissues and elicit autoimmune responses which contribute to the pathology of the infection. Some parasites, such as *T. cruzi*, evade the immune response by mimicking host molecules and, if effective, this is very successful but, if unsuccessful, can also initiate autoimmune reactions. Typically, parasitic infections are accompanied by periods of immunodepression as the host switches off what is becoming an ineffective or dangerous immune

response, rendering the host susceptible to concurrent infections as happens in malaria and African trypanosomiasis. During the course of long, chronic infections various aspects of the cytokine network are activated and the effector molecules produced are not necessarily beneficial. For example, in malaria the production of TNF α is beneficial but in excess is detrimental, and in schistosomiasis potentially protective cytokine-mediated immune responses lead to granulomas around nonthreatening eggs deposited in tissues. For these reasons, current interest in immunity to parasites is being concentrated on an understanding of the overall control of the immune response which is brought about by the interactions of the various cytokines involved in the cytokine network.

Immunity to specific parasitic infections

Our interpretations of the immune response to parasites as it appeared only a few years ago now seems very simplistic and the new discoveries have called for a reinterpretation of many of the facts observed. On the other hand, these new discoveries have enabled us to understand many of the phenomena observed much more clearly and it is easiest to illustrate these points by reference to a selected number of parasitic infections and to interpret these in terms of the human diseases.

In murine cutaneous leishmaniasis, the fundamental observations that protection is afforded by T_H1 cells and that T_H2 responses are counterprotective still stand; the effector molecule responsible for parasite killing is NO and the production of NO can be enhanced by the presence of IFN γ and other T_H1 cell-promoting cytokines. This information is being used as the basis for experimental vaccines. In humans, there is now abundant evidence that the pattern of cytokine activation is similar. Patients with localized cutaneous lesions tend to have high levels of IFN γ , whereas those with disseminated infections or mucocutaneous leishmaniasis tend to have high levels of IL-4. These cytokines are also predictive of the outcome of the cutaneous forms of leishmaniasis, patients with high levels of IFN γ tend to have a better prognosis than those with high levels of IL-4. However, the situation is not so simple in the case of visceral leishmaniasis where levels of IFN γ and IL-10, normally antagonistic, are both elevated. Overall, it seems as if the outcome of leishmaniasis infections in humans, as in mice, depends on a balance between those factors promoting a T_H1 response and those promoting a T_H2 response.

Toxoplasma gondii is also a parasite of macrophages and, like *Leishmania*, is killed by IFN γ -acti-

vated macrophages. Recently it has also been shown that TNF α synergizes with IFN γ in this killing. Interestingly, both CD4⁺ and CD8⁺ cells contribute to the production of IFN γ , but in mice without CD8⁺ cells, NK cells take over this role. *T. gondii* itself is able to stimulate the production of IL-12, which in turn stimulates NK cells which produce IFN γ and the actual parasite killing involves NO.

Malaria is a complex infection and immunity seems to involve both T_H1 and T_H2 responses and, in some murine models, there is a switch between early T_H1 and later T_H2 responses. Parasite killing involves NO but it is not at all clear how this gets into the infected red cell. One of the most interesting aspects of the role of NO in malaria is as a possible cause of the coma associated with cerebral malaria. This suggests that cerebral malaria might be prevented by inhibiting NO synthesis and there is evidence that this can be done by treating comatose children with anti-TNF α as TNF α is one of the costimulators of NO production. Malaria also demonstrates one of the fundamental problems in trying to control parasitic infections, getting the balance between protection and counterprotection right.

In schistosomiasis, protection involves ADCC comprising IgE and eosinophils, thus it would appear to be a T_H2-type response. However, parasite killing also seems to involve NO and there is now evidence that the initial protective response is a mixture of T_H1 and T_H2 responses with IFN γ being contributed by CD8⁺ cells and NK cells and IL-4 by basophils. The pathology associated with the granulomatous response to schistosome eggs has also had to be reinterpreted. These granulomas have long been considered to be due to a T_H1-mediated delayed-type hypersensitivity (DTH) response but it is now known that most of the inflammatory cells involved are eosinophils and that the development of granulomas is inhibited by the T_H1-activating cytokine IL-12.

Parasitic infections and human immunodeficiency virus (HIV)

The spread of HIV has had a major impact on parasitic infections and is responsible for more severe parasitic infections, the recrudescence of latent infections and even the occurrence of previously unknown parasites. The impact is greatest among the protozoan parasites and leishmaniasis, toxoplasmosis, Chagas disease, giardiasis, cryptosporidiosis, microsporidiosis and pneumocystosis are among the parasitic infections now associated with the acquired immune deficiency syndrome (AIDS). Of these, leishmaniasis-AIDS has emerged as a particularly formidable combination and pneumocystosis is a frequent

cause of death in AIDS patients. Several species of microsporidians have only been identified from AIDS patients. Virtually nothing is known about the immune responses to these more unusual parasites. There is no evidence of any interactions between HIV and malaria. Hyperinfections of the nematode worm *Strongyloides stercoralis* occurs in immunosuppressed patients but there is no evidence that this infection is a serious concomitant of AIDS.

Vaccination

There are no commercially available vaccines against any human parasitic diseases and only a few against parasites of veterinary importance. This is largely due to the fact that immune responses against parasites are so complex and that parasites themselves have evolved so many ways of evading the immune response. A number of vaccines based on living attenuated parasites have been developed. The most widely available commercially produced vaccine against any helminth worm is one based on the irradiated larvae of the lungworms *Dictyocaulus viviparus* in cattle and *D. filaria* in sheep, but a similar vaccine developed against the dog hookworm *Ancylostoma caninum* was abandoned in favor of chemotherapy. An attenuated vaccine based on infected blood has been in use for many years and is effective against cattle babesiosis; cultured attenuated parasites are widely used as vaccines against Mediterranean theileriosis caused by *Theileria annulata*; and a vaccine based on an avirulent strain of *Toxoplasma gondii* is being used in limited trials to control toxoplasmosis in sheep. Controlled low-level infections have also been used to immunize battery fowl against coccidiosis.

Immunization against East Coast fever (African theileriosis) caused by *Theileria parva* can be achieved by an infection-cure procedure which is very successful but time-consuming and expensive. A number of experimental vaccines based on attenuated larval stages of helminth worms, including *Haemonchus contortus* in sheep and *Schistosoma bovis* in cattle, have been encouraging but have not been developed commercially. A number of more defined vaccines are currently undergoing trials and these include recombinant vaccines against the tapeworm *Taenia ovis* and the nematode *H. contortus* in sheep.

Attenuated vaccines are unlikely to be widely acceptable for use in humans although there have been successes with such a vaccine against human cutaneous leishmaniasis both in the Middle East and in South America. A potentially useful synthetic vaccine against malaria, SPf66 developed in Colombia,

is currently undergoing clinical trials in several parts of the world but in spite of encouraging results in South America the vaccine has proved to be less effective in areas of endemic malaria in Africa. Other vaccines against human malaria, leishmaniasis and schistosomiasis are currently being developed under the auspices of the World Health Organization (WHO). Preliminary results have been encouraging and the hope is that vaccines may be able to produce better immunity than natural infections. In this context, there is considerable interest in the development of vaccines that manipulate the cytokine response so that the vaccine can work under the most favorable circumstances.

Summary and conclusions

This overview of immunity to parasites has emphasized the importance of the cytokine network in parasitic infections. We are gradually untangling this network and the hope is that by doing so it will be possible to devise new ways to combat these infections. There have already been successful attempts to drive the immune response in the desired direction by the incorporation of cytokines into a vaccine against leishmaniasis and similar experiments with IL-12 have prevented granuloma formation in schistosomiasis. However, the main problem will be to ensure protection while reducing the possibilities of counter-protection. There is also the need to discover exactly what is happening in humans before the theory based on experimental studies can be put into practice. Our interest now is not so much in determining whether or not an immune response occurs but instead is largely concerned with unravelling the complex interplay between invader and invaded which results in either protection or pathology or a combination of both. The practical aim on one hand is to determine what is actually responsible for protection and how this can be induced artificially and, on the other hand, to determine what causes pathology and how this can be ameliorated.

PARVOVIRUS, INFECTION AND IMMUNITY

N Frickhofen, Department of Hematology/Oncology, Clinical Center Wiesbaden (HSK), Wiesbaden, Germany

NS Young, Clinical Hematology Branch, National Heart, Lung, and Blood Institute, Bethesda, Maryland, USA

Parvoviruses infect many animals including humans, and almost every species has its own parvovirus pathogen. Epidemics in dogs, swine, geese and mink are major practical concerns of veterinarians. Because of the requirement for actively proliferating cells, the developing fetus and the newborn are at highest risk of disease following parvovirus infection. Infection can lead to fetal death, congenital malformations or predominant damage to single organs that may not be manifest until weeks after birth, such as the cerebellar ataxia that follows *in utero* feline parvovirus infection. Parvovirus infection of young animals can be clinically severe, with manifestations of encephalopathy, hepatitis or myocarditis. Parvoviruses cause a variety of diseases in adult animals, including gastroenteritis in cats, dogs and mink, leukopenia in cats, and immune complex glomerulonephritis in mink persistently infected with Aleutian disease virus.

The human parvovirus B19 was discovered by Yvonne Cossart while investigating tests for hepatitis B. A serum labeled 'B19' gave anomalous results but ultimately was shown to contain 23 nm particles resembling parvovirus. Six years later, B19 was demonstrated to be associated with transient aplastic crises in sickle cell patients and only a decade after

its discovery the major manifestation of B19 infection, fifth disease, was described. Today, B19 is known as a virus that infects most humans early in life without any major clinical sequelae. Significant disease only develops in people who cannot tolerate even transient damage to the target tissue of B19, the erythroid compartment of the bone marrow, and in those with an inappropriate immune response to the virus.

Parvovirus B19 biology

B19 belongs to the Parvoviridae family, which has been divided into the subfamilies of insect parvoviruses (Densovirinae) and vertebrate parvoviruses (Parvovirinae). The Parvovirinae are further divided into three genera, of which one (*Dependovirus*) requires coinfection of target cells with a herpes virus, whereas the other two (*Parvovirus* and *Erythrovirus*) replicate autonomously. B19 and the recently discovered simian parvovirus (SPV) belong to the newly formed genus *Erythrovirus*.

B19 is a nonenveloped DNA virus with a single-stranded genome of 5.6 kb. The genomic organization is typical for all parvoviruses: two capsid proteins are encoded by the right side of the genome and

a large nonstructural protein is encoded by the left side. The capsid proteins, by convention denoted VP1 and VP2, are derived from overlapping reading frames. VP1 differs from VP2 only by an additional 227 amino acids at the N-terminus. More than 95% of the capsid of the mature virion is composed of VP2, the smaller protein, whereas only about 5% represent VP1, the larger protein. The nonstructural protein contains sequences which are highly conserved among parvoviruses, consistent with an essential role in the life cycle of the virus. The protein binds DNA and mediates apoptotic death of the host cell.

The target of parvovirus B19 infection is the erythroid progenitor cell of the bone marrow. *In vitro*, B19 productively infects erythroid cells in human bone marrow cultures, leading to depletion of differentiated erythroid progeny and to complete suppression of erythroid colony formation in progenitor assays. The cytopathic evidence of parvovirus B19 infection, the 'giant pronormoblast', is seen both after tissue culture inoculation and in the bone marrow of infected patients. Parvovirus B19 is extremely tropic for erythroid cells and has only been propagated in bone marrow, fetal liver (which is the site of red blood cell production *in utero*), and cells lines with erythroid features.

The molecular basis for the extreme tropism of B19 for erythroid cells was clarified by the identification of the receptor for B19 as globoside, a neutral glycosphingolipid predominantly expressed on erythroid cells, where it is known as blood group P antigen. The great majority of the population expresses P antigen and is thus susceptible to B19 infection. Amish individuals who genetically lack P antigen are not susceptible to B19 infection. None showed serologic evidence of previous infection and their bone marrow could not be infected with B19 *in vitro*.

P antigen is also found in endothelium, kidney cortex, myocardial cells of the fetus, and placenta. However, expression of the receptor is probably essential but not sufficient for productive infection. *In vitro*, viral replication depends on active erythropoiesis and erythropoietin, suggesting a requirement for erythroid-specific in addition to S-phase factors. Permissive cells allow full-length transcription of the viral genome, whereas there is an apparent block in mRNA synthesis in nonerythroid cells. Replication of the viral genome is not required for viral cytotoxicity. Transcription of the nonstructural protein without DNA replication can kill cells, which may explain why B19 can damage cells nonpermissive to productive infection such as megakaryocytes.

Natural infection and immune response to parvovirus B19

The natural course of parvovirus B19 infection has been evaluated by experimental infection of normal volunteers and in a prospective study of a major epidemic. After intranasal inoculation of normal persons, the virus infects and replicates in erythroid bone marrow cells. Viremia is first detected by day 6 and can reach peak levels $>10^{14}$ ml⁻¹ serum. Infection kills the host cells, so that at the peak of infection, almost no erythroid cells except for a few virtually pathognomonic giant pronormoblasts can be detected in a bone marrow aspirate. Specific immunoglobulin M (IgM) followed by IgG antibodies appear during the second week postinoculation and effectively terminate the infection.

Antibody to parvovirus can be detected using indirect capture immunoassays employing genetically engineered capsid preparations for antigen. Capture techniques to detect viral antigen in sera have been supplanted by DNA hybridization using either ³²P-labeled or biotinylated DNA or RNA probes. The most sensitive technique for detection of virus is DNA amplification by polymerase chain reaction. Small amounts of viral DNA can be detected for many weeks after acute infection; the biological significance of this finding is unknown.

IgM antibody is usually present in the first specimen obtained after the onset of illness: in one study, 78% of sera were positive 0–2 days and 93% were positive 3–7 days after the onset of symptoms. The peak in IgM titer occurs at 2–3 weeks and IgM has been detected in sera obtained months after the onset of symptoms. Specific IgG antibodies can be demonstrated in 42% of persons at 0–2 days and in 90% at 3–7 days.

VP2 is the primary target of antibodies induced by first exposure to the virus. As the antibody response matures, specificity against VP1 epitopes develops. Linear epitopes, clustered in the VP1-unique region, are essential for an effective, neutralizing immune response. Using standard dot blot analysis, virus is rarely detected in sera beyond day 15 after inoculation, but when evaluated by polymerase chain reaction, low level viremia can still be demonstrated in some patients for more than 2 months after natural infection.

IgG antibodies persist for life in most individuals, probably boosted with re-exposure. Anti-B19 IgG has been found in 36% of children by the age of 10, in 50–60% of adults aged 16–40 and more than 85% in individuals more than 70 years old. B19 infections occur worldwide and throughout the year, with a seasonal peak in spring. They frequently occur

in epidemics of about 3 year periodicity, but also as sporadic cases. B19 parvovirus is probably transmitted by the respiratory route. High levels of virus in saliva and heat stability of the virus combine to make parvovirus infection very contagious. B19 has also been transmitted by blood products and seems to resist pasteurization and solvent detergent treatment.

Acute parvovirus B19 infection in humans

Parvovirus B19 diseases arise either from direct viral toxicity for specific target cells or as a result of the host immune response (Table 1). Direct viral infection leads to destruction of marrow erythroid cells in normal individuals, but cessation of red cell production is short-lived due to rapid immune clearance of virus, and the long lifespan of erythrocytes precludes the development of anemia.

In many persons, B19 infection is asymptomatic. Fifth disease in children presents typically with a 'slapped cheek' appearance and a lacy, evanescent maculopapular cutaneous eruption. Adults more often present with a polyarthralgia/polyarthritis syndrome. Rash and arthropathy are usually transient but may recur for several weeks or months; some women have had a relapsing chronic rheumatic syndrome that resembled rheumatoid arthritis. Normal volunteer studies showed that both the rash and arthropathy develop concomitantly with the rise in antiviral antibodies, and in patients with community-acquired fifth disease who have circulating specific IgM antibody, parvovirus is difficult to recover. These results suggest that fifth disease is immune complex-mediated.

In contrast, direct viral toxicity dominates the clinical picture in individuals with a shortened red cell life span, usually as a consequence of inherited

hemolytic anemia such as sickle cell disease or hereditary spherocytosis. In these patients, cessation of red cell production causes an abrupt, occasionally fatal worsening of chronic anemia called transient aplastic crisis (TAC). The self-limited character of the illness is due to the development of neutralizing antibodies which terminate the infection. TAC is rarely followed by fifth disease symptoms, perhaps because the large amount of virus produced by the expanded erythroid bone marrow is unfavorable for antibody-antigen lattice formation and immune complex deposition. Variations in the antibody response may also account for the lack of symptoms in about 25% of normal persons with acute parvovirus infection.

Both the normal volunteer and epidemiologic investigations demonstrated that the same virus was responsible for different clinical syndromes. Virus variability is probably not important pathophysiologically, since multiple isolates have been shown to be very similar at the nucleotide level and as antigens, and minor differences on restriction enzyme mapping have not been correlated with different clinical syndromes.

Persistent disease in immunodeficient patients

Parvovirus B19 can persist in immunodeficient persons who are unable to mount an adequate antibody response. Persistent parvovirus infection has been documented in three patient groups:

1. people with congenital immunodeficiency;
2. children with acute lymphocytic leukemia in remission, and adults with lymphoma and Hodgkin's disease treated with chemotherapy (our unpublished cases) and patients after bone marrow transplantation; and
3. patients with the acquired immune deficiency

Table 1 Diseases caused by parvovirus B19

<i>Diseases</i>	<i>Patients</i>	<i>Mechanism</i>
<i>Immunocompetent host</i>		
Fifth disease	Hematologically normal children	Immune complex vasculitis and arthritis
Polyarthropathy syndrome acute and chronic	Hematologically normal adults	"
Transient aplastic crisis	Patients with shortened red cell life span, e.g. hemolysis	"
<i>Immunocompromised host</i>		
Chronic pure red cell aplasia $\pm$ neutropenia, $\pm$ thrombocytopenia	Patients with congenital and acquired immunodeficiency	Aplasia of erythroid progenitor cells due to viral cytotoxicity (induced autoimmunity in congenital anemia?)
Fetal disease	Fetuses of normal, nonimmune women	"

syndrome (AIDS) due to infection with the human immunodeficiency virus type 1 (HIV-1).

Persistent parvovirus B19 infection results in severe, transfusion-dependent anemia due to suppression of bone marrow erythropoiesis. The anemia of persistent parvovirus infection may be indistinguishable from the hematologic disease pure red cell aplasia. The anemia may occur in combination with some degree of neutropenia or thrombocytopenia. Serology is misleading in immunodeficient patients who do not produce antibodies; the diagnosis of B19 infection in those patients can only be established by the demonstration of viral antigen or DNA.

In most cases of persistent parvovirus infection, virus has been present in serial blood specimens for months and, in at least one case, for many years. Levels of viremia in persistent infection are often lower than in acute infection, 10^6 – 10^8 genome copies ml^{-1} , possibly due to depletion over time of the erythroid target cell pool. Virus has been demonstrated in the bone marrow of persistently infected patients by molecular and immunologic techniques, including Southern analysis to show replicative intermediate DNA forms. Viremia and anemia may spontaneously remit, possibly the result of temporary target cell exhaustion or transient antibody production. In the absence of antibody production, immune complex formation does not occur and patients do not experience fifth disease symptoms.

The fetus has to be considered an immunodeficient individual with ideal target tissue because of the high proliferative state. Intrauterine parvovirus B19 infection is usually asymptomatic but it can have serious adverse consequences. The virus has been demonstrated in hepatic erythroid precursor cells of aborted fetuses by immunofluorescence, *in situ* hybridization and electron microscopy. Death in nonimmune hydrops fetalis is secondary to congestive heart failure due to severe anemia, perhaps in combination with viral myocarditis.

The time during pregnancy in which maternal infection occurs is a critical variable in determining fetal outcome. Infection during the first trimester can result in spontaneous abortion which is not recognized as a viral sequela. However, fetal loss after B19 infection in the first trimester does not occur more often compared to noninfected women. During the last trimester, transplacental passage of protective maternal IgG antibody usually prevents development of disease of the almost mature fetus. The second trimester is the critical period with significantly increased fetal death compared to controls.

A peculiar syndrome of congenital anemia associa-

ted with parvovirus B19 has recently been described in three infants. All had been treated by blood transfusion *in utero* or at birth because of hydrops fetalis. After delivery the infants had hypogammaglobulinemia. In all three, sera lacked B19 but viral DNA was found in bone marrow. All were treated with immunoglobulin. One child died despite therapy and B19 was detected in bone marrow and at lower levels in other tissues. In the other two cases, virus could no longer be detected after therapy but the patients remain persistently anemic. These observations suggest a 'hit and run' mechanism, perhaps with virus-induced autoimmune-mediated suppression of erythropoiesis rather than direct viral cytotoxicity.

The immune deficit in persistent parvovirus infection and its treatment

In persistent human infections, two patterns of antibody production have been observed. In children receiving chemotherapy and in most patients with AIDS, no antibody to virus is detectable by either capture immunoassay or immunoblot. In patients with congenital immunodeficiency, antibody has been detected by capture assays, but reactivity on immunoblot was low or undetectable. Sera from these patients poorly neutralize virus infectivity *in vitro*. In one case, the pattern of antibody response (high IgM and anti-VP2 IgG alone) suggested a defect in class switching and confirmed the importance of VP1-specific antibodies for definitely controlling parvovirus B19 infection. Although CD4^+ T cells must be key players in the development of an effective IgG antibody response, only one group has reported a proliferative *in vitro* response of human lymphocytes to parvovirus antigen.

Commercial immunoglobulin preparations are a good source of neutralizing antibody to parvovirus B19. Commercial IgG has been successfully employed in the treatment of persistent parvovirus infection, its administration leading to an immediate reduction in the titer of circulating virus (about 10^6 -fold) followed by reticulocytosis and return of hemoglobin to preinfection values. Fifth disease symptoms may occur with the infusion of immunoglobulin.

In some patients with congenital immunodeficiency and acute leukemia during chemotherapy, IgG therapy seemed to be curative for parvovirus infection. In patients treated with chemotherapy, this can be explained by regained immunocompetence when treatment is discontinued. Modulation of the antibody network secondary to IgG has been hypothesized in patients with congenital immunodeficiency. In patients with irreversible immunodeficiency, as in HIV infection, relapse of parvovirus infection often

occurs 3–7 months after initial therapy and requires retreatment with immunoglobulin. In AIDS patients, low titers of parvovirus are detectable by polymerase chain reaction in remission of the infection, and circulating DNA rises prior to clinical relapse of parvovirus infection.

Summary and perspective

Parvovirus B19 infection is an excellent example of determination of the outcome of a viral infection by the immune system (Table 1). In immunocompetent individuals, timely antibody production prealters clinical symptoms due to direct viral cytotoxicity. Infected people are either asymptomatic or they experience mild and usually transient manifestations of immune complex-mediated symptoms such as rash or arthralgia. Rarely, the immune response is significantly pathogenic, as in the few patients with prolonged or relapsing arthropathy. In contrast, immunodeficient patients unable to produce neutralizing antibodies develop severe anemia due to suppression of erythropoiesis by the virus.

Viral diseases can be prevented and even eliminated by vaccination. Empty parvovirus capsids enriched for VP1 epitopes elicit effective antibody responses in animals. A recombinant formulation has entered clinical trials in normal volunteers, in whom it appears safe. Vaccination would be desirable for nonimmune women before pregnancy (similar to rubella vaccination), for seronegative patients before and during immunosuppressive treatment and in AIDS patients. A program of universal vaccination might be considered if B19 can be convincingly linked to other serious diseases such as myocarditis and vasculitis.

Vaccine development may be easier in the future due to the recent description of the first animal model for parvovirus B19. In 1992, simian parvovirus (SPV) was identified as the agent causing anemia in a group of cynomolgus monkeys of an animal facility. There is about 50% overall sequence homology of SPV with B19 but little homology with members of the genera *Parvovirus* and *Dependovirus*. *In vitro*, SPV selectively infects erythroid progenitor cells and the major clinical manifestation is anemia. Similar to B19, SPV infection is common and mostly subclinical. Significant anemia only develops in immunosuppressed monkeys such as those coinfecting with a retrovirus. All these observations suggest a close evolutionary relationship of SPV and B19.

PASTEURELLA, INFECTION AND IMMUNITY

Richard B Rimler, Avian and Swine Respiratory Diseases Research Unit, USDA/Agricultural Research Service/National Animal Disease Center, Ames, Iowa, USA

Pasteurella multocida is primarily a veterinary pathogen that produces septicemic or respiratory diseases in both domesticated and wild mammals and birds. The organism can occur as a commensal in the nasopharyngeal region of apparently healthy animals. Uncomplicated diseases in which *P. multocida* is the primary etiologic agent are hemorrhagic septicemia of cattle and water buffalo, fowl cholera of poultry and free-flying birds, and rhinitis (snuffles) and pneumonia of rabbits. Diseases in which *P. multocida* is a complicating or secondary pathogen are atrophic rhinitis and pneumonia of swine, and shipping fever and pneumonia of cattle. In humans, most *P. multocida* infections arise from pet animal bites, particularly cats and dogs.

Characteristics of the organism and its antigens

P. multocida is a nonmotile gram-negative bacterium. Virulent strains are usually capsulated. When grown on transparent agar medium, colonies made up of capsulated cells appear iridescent in oblique transmitted light, whereas colonies made up of non-capsulated cells appear blue. *P. multocida* is a heterogeneous species consisting of different capsular serogroups and somatic serotypes. There are five distinct capsular serogroups lettered A, B, D, E and F. Mucopolysaccharides are associated with the capsules of serogroups A, D and F, rendering them inagglutinable in homologous, high-titered antisera. Specific mucopolysaccharidases which depolymerize the capsules can be used for presumptive identification of these serogroups (Table 1). Colonies of serogroup A, which contain hyaluronic acid, tend to be more mucoid and larger than those of the other serogroups. Fresh serogroup A isolates from the respiratory tract, particularly those from cattle, have a watery mucoid consistency similar to *Pseudomonas*

Table 1 Depolymerization of *Pasteurella multocida* capsules by specific enzymes

Enzyme	Serogroup				
	A	B	D	E	F
Hyaluronidase ^a	+	–	–	–	–
Heparinase III ^b	–	–	+	–	–
Chondroitinase AC ^b	+	–	+	–	+

^b From *Flavobacterium heparium*.

aeruginosa strains isolated from human cases of cystic fibrosis. The specific-polysaccharide capsule antigens are distinguished by indirect hemagglutination tests using antisera made in pasteurella-free rabbits. These heat-stable antigens readily adsorb to washed erythrocytes, are nontoxigenic, and can sometimes be demonstrated in cell-free tissue fluids of naturally and experimentally infected animals.

Sixteen somatic serotypes (numbered 1–16) have been distinguished. Serotyping is done by a gel diffusion precipitin test using heat extracts of formalinized bacteria versus antiserum made in chickens. Somatic serotype specificities are determined by lipopolysaccharide (LPS), structural components of the cell wall. The LPS of *P. multocida* has a chemical composition similar to that of typical members of the family Enterobacteriaceae. It contains lipid A, 2-keto-3-deoxyoctonate (KDO), heptose, and various neutral and amino sugars. Four LPS chemotypes have been described. The *P. multocida* LPS appears similar to R-type LPS of *Salmonella* sp. Biological reactions produced by *P. multocida* LPS are similar to those produced by endotoxins from typical gram-negative bacteria (i.e. pyrogenicity, Schwartzman reaction, endotoxic shock). Certain serotypes of the organism tend to be associated with specific diseases (Table 2) and virulence for certain animals.

Table 2 Association of *Pasteurella multocida* serogroups with specific diseases in domesticated animals

Disease	Serogroup ^a	Predominant somatic types ^b
Hemorrhagic septicemia	B , E ^c	2
Atrophic rhinitis	D , A	3, 12
Fowl cholera	A , F	1, 3, 4
Rhinitis (snuffles)	A, D	3, 12
Shipping fever	A , D	3
Pneumonia	A , D	3

^a Bold font indicates predominant serogroup associated with the disease.

^b Other somatic serotypes may occur.

^c Serogroup E has been isolated only from animals in Africa.

Some strains belonging to serogroups A and D produce a lethal protein toxin that can cause hemorrhage and necrosis when inoculated intradermally into experimental animals. Toxigenicity of a strain is not related to specific somatic serotype or animal of origin, and toxin from both serogroups is antigenically the same. Inoculation of purified toxin by a parenteral or nasal mucosal route will produce turbinate atrophy in swine.

A number of soluble and membrane-associated protein antigens are common to the various serotypes, and epitopes may be shared with closely related gram-negative bacteria. Also, common epitopes can occur between *P. multocida* and red blood cells of mammals and birds.

Immune responses of the host

Protection against *P. multocida* in mammals and birds appears to be primarily humoral mediated. However, cell-mediated immune responses have been demonstrated. Naturally acquired immunity to *P. multocida* can occur in unvaccinated mammalian species and is demonstrated by serum passive protection of mice. This immunity is particularly evident in cattle and water buffalo from geographic areas where hemorrhagic septicemia is endemic. Bactericidal reactions can occur with polyclonal antibodies or monoclonal antibodies made against *P. multocida* provided a complement source is available. Antibody-opsonized *P. multocida* are readily phagocytosed by monocytes, macrophages and polymorphonuclear neutrophils.

Most antigens in the bacterium probably exist as complexes (i.e. LPS-protein complexes). Protein antigens are presumed to be the major immunogens responsible for protection. However, except for the toxin found in some serogroup A and D strains, a protein purified to homogeneity has not been shown

to produce protective immunity. Antibodies against the protein toxin neutralize its toxic effects and protect mice and pigs against toxin-induced turbinate atrophy.

Cattle, buffalo and poultry vaccinated with bacterins of *P. multocida* produce antibody reactions to LPS. Also, antibodies to LPS are sometimes found in sera from animals with naturally acquired immunity. Adsorption of vaccinated-cattle antiserum with LPS will remove some protection in the mouse passive protection test. Purified LPS has produced little or no active immune protection of mice. In poultry, LPS from some serotypes will produce a moderate active immune protection. Complexes of LPS and basic protein or ribosomes from a heterogeneous source produce a better serological response and active immune protection. However, this protection is somatic serotype specific. The similarity of *P. multocida* LPS to the R-type LPS of enterobacteria, particularly with regard to molecular size, probably accounts for the poor immunogenicity of purified preparations.

Capsule antigens have been suspected to be responsible for immune protection, particularly in cattle and buffalo. Antibodies to these antigens have been found in sera from those animals vaccinated with bacterins as well as those with naturally acquired immunity. Adsorption of the sera with purified polysaccharide can remove some protection in the mouse passive protection test.

Evasive strategies by the organism

The presence of a capsule contributes significantly to virulence of *P. multocida* and its survival in a host. Little or no phagocytosis occurs with nonopsonized capsulated strains of any serogroup. In contrast, noncapsulated strains and strains whose capsules are enzymatically depolymerized are more readily phagocytosed. The nonantigenic mucopolysaccharides associated with capsules of serogroup A, D and F strains are chemically similar or identical to mucopolysaccharides produced by their hosts. The mucopolysaccharides may provide a mechanism for bacterial attachment to host cell receptors as well as protecting them from ingestion by phagocytic cells. Resistance to the bactericidal effect of normal serum has been associated with the capsule and virulent strains of the organism. Additionally, an antiphagocytic membrane protein has been described in an avian strain. The older literature describes aggressins produced by strains of *P. multocida* that cause hemorrhagic septicemia.

Vaccines

Bacterins and live-attenuated vaccines are used to control diseases caused by *P. multocida*. Bacterins usually consist of formalin-killed organisms in a water-in-oil emulsion; they produce a longer duration of protection than bacterins without adjuvant. Aluminum hydroxide is occasionally substituted as adjuvant. Protection produced by bacterins is largely serotype specific, whereas live-attenuated vaccines can protect against a variety of serotypes.

PERFORIN

Jürg Tschopp, Institute of Biochemistry, University of Lausanne, Epalinges, Switzerland

The perforin model of lymphocyte-mediated cytotoxicity has its origin in the electron microscopic examination of target cells lysed by cytotoxic lymphocytes. In 1980, Dourmashkin detected circular lesions (designated polyperforins) of up to 16 nm inner diameter resembling the complement pores (Figure 1), which suggested a functional and mechanistic relationship between complement- and lymphocyte-mediated cytotoxicity. Of the two pathways implicated in target cell damage by cytotoxic T lymphocytes, perforin-dependent lysis seems to dominate in antiviral immunity, whereas the Fas pathway may regulate immune responses.

Molecular properties of perforin

The lymphocyte-generated pores are assembled from monomeric perforin (alternative names include pore-forming protein, cytolytic protein and C9-related protein)

which is stored in electron-dense cytoplasmic granules. These granules also harbor several serine proteases, designated granzymes, and proteoglycans of the chondroitin sulfate A type. Purified perforin has a potent lytic activity and lyses most tumor targets in a nonspecific manner.

Cytoplasmic granules are a common feature of both activated cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells. Upon T cell receptor-mediated binding of the target cell, granules selectively localize to the contact site, eventually fuse with the plasma membrane and release their contents, including perforin, into the microenvironment between the effector and target cells. It is generally accepted that perforin monomers, upon their release from granules, bind to phosphorylcholine moieties and insert into target cell membranes (Figure 2). This process is strictly Ca^{2+} -dependent. Individual proteins subsequently undergo a conformational change,

Figure 1 Pores formed by perforin (A) and complement C9 (B).

insert into the target membrane, and polymerize in the plane of the membrane, leading to transmembrane channel formation. The internal diameters of perforin pores vary from 5 to 20 nm depending on the number of oligomerized perforins (2–18).

The mature perforin exhibits a molecular weight of 65–75 kDa and has a pI of 6.44. The mouse, rat and human cDNAs coding for perforin have been sequenced, predicting a protein of 534 amino acids (mouse). The central portion of perforin, containing the membrane interaction site, shows sequence

homology with C9. This central segment is likely to be responsible for the structural and functional similarities between the two proteins, in particular the capacity to polymerize into similar tubules and to insert into the membrane. The C-terminal portion of perforin includes a C2 domain initially characterized in protein kinase C. C2 domains are thought to be involved in calcium-dependent phospholipid binding.

Perforin-mediated lysis

Initially, perforin was considered as the only lytic mediator required for target cell death. Significantly, mice with a defective perforin gene have severely impaired cytolytic activity of CTLs and NK cells. However, several lines of evidence implicate the serine proteases, granzymes, as an additional component in target cell damage. Purified perforin induces lysis of target cells without DNA fragmentation, whereas the addition of granzyme A or B to intact cells restores the apoptotic activity. Granzyme B cleaves after aspartate, a rare substrate specificity shared only with the cysteine proteinases of the interleukin 1 β -converting enzyme (ICE) family which are key molecules of apoptosis. Since ICE members require processing at aspartate, it has been speculated that during CTL attack, ICE precursors may be activated by granzyme B and accelerate cell death. Indeed, CTLs from granzyme B knockout mice were found to have impaired apoptotic activity.

Figure 2 Structural organization of human perforin and the terminal complement component C9 and lipid insertion of perforin. Monomeric perforin binds to phosphatidylcholine (PC) headgroups of lipid membranes. This interaction is strictly Ca^{2+} -dependent and reversible. At physiological temperature, perforin undergoes a drastic conformational change and inserts into the lipid bilayer. Polymerization of the perforin protomers ensues. Cylindrical polymers of up to 18 monomers are formed. The largest tubules have an inner diameter of >10 nm. The inset above shows the arrangement of the various structural motifs present in perforin and C9: TS, thrombospondin module; L, LDL receptor class A module; EGF, EGF receptor module; MB, candidate lipid-binding domain.

PHAGE DISPLAY OF ANTIBODIES

John de Kruif and **Ton Logtenberg**, Department of Immunology, University Hospital Utrecht, Utrecht, The Netherlands

Antigenic stimulation of the humoral arm of the immune system results in the production of specific antibodies with high affinity for the inciting antigen. This process involves a series of highly regulated genetic and cellular events, beginning with the generation of antibody diversity by somatic recombination of germline gene segments encoding immunoglobulin receptors in B lineage cells, and culminating in hypermutation of immunoglobulin receptors and clonal expansion and selection of B lymphocytes that express high-affinity receptors for antigen. It has recently been shown that the hallmarks of the humoral immune system may be mimicked entirely *in vitro* by phage display technology and antibody engineering. The construction of very large libraries of antibody fragments displayed on the surface of bacteriophage particles, the selection and multiplication of phages expressing desirable antibody specificities and the increase of antibody affinity by introduction and selection of favorable mutations in the genes encoding a selected antibody specificity represent the molecular biologists' solutions in an attempt to copy the immune system's impressive capacity to mount an immune response to a virtually unlimited number of antigens.

Antibody phage display technology

An important aspect of antibody phage display technology is the expression of fragments of antibody molecules on the surface of filamentous phage particles. The expressed antibody fragments may take various formats, including Fab fragments, single-chain (sc) Fv fragments and fragments composed of

disulfide bridged variable regions. A good example of a vector system that directs the production of phages bearing antibody fragments upon introduction in bacteria is a system based on phagemid vector pHEN1 (Figure 1). In phagemid pHEN1, an scFv antibody fragment is fused with the N-terminus of the M13 phage minor coat protein g3p. Constructs are placed under control of the lacZ promoter and directed to the periplasmic space of bacteria by a pelB leader peptide. A peptide tag for detection and purification is fused to the C-terminus of the scFv

Figure 1 Phagemid pHEN1 (A), a phage antibody (B) and a soluble scFv fragment (C). P/O, lacZ promoter/operator; L, pelB leader; V_H + V_L, scFv encoding gene; M, Myc tag; A, amber codon; g3, gene3; colE1 ori, *E. coli* origin of replication; AMP^R, ampicillin resistance gene; M13 ori, phage intergenic region; g3p, coat protein 3.

fragment. The phagemid harbors an amber stop codon preceding the gene encoding g3p. As a consequence, in SupE suppressor strains of *Escherichia coli*, the amber codon is read as a glutamine and the antibody is displayed on the phage via a g3p anchor. In nonsuppressor strains, the amber codon is read as a stop codon, and soluble antibody fragments are secreted from the bacteria. Inclusion of the M13 phage intergenic region in the vector allows for replication and packaging of single-stranded phagemid DNA with the aid of helper phage. Because the filamentous particles contain a copy of the pHEN1 phagemid, selections based on the functional properties of the displayed antibody also result in selection of the genes encoding these antibodies. Phage displayed antibodies may be of any animal species including human, depending on the source of antibody variable (V) regions used for cloning.

Phage display libraries

A major goal of antibody phage display technology is to develop phage repertoires of large size and diversity to facilitate isolation of high-affinity antibodies of every conceivable specificity. Large libraries are constructed by molecular cloning of large numbers of immunoglobulin H and L chain genes and randomly combining H and L chain genes in the phage or phagemid vector. An important determinant of the composition and diversity of these *in vitro* immune systems is the source of antibody genes used as building blocks to construct the library. Libraries may be assembled from the V regions expressed by the B lymphocytes of an individual known to have mounted a particular immune response as a result of immunization, exposure to an infectious agent or as a result of an autoimmune response (Figure 2A). The pool of B lymphocytes in lymphoid organs of these individuals is enriched for antigen-specific B cells and plasma cells that have undergone clonal expansion and antigen affinity maturation. The likelihood of selecting high-affinity antibody fragments from the eventual 'immunized' phage library is increased as a consequence of the increased frequency of the desired immunoglobulin H and L chain genes used to construct the library. In principle, to further enrich for lymphocytes that bear the outward signs of antigenic contact, these libraries are constructed from the V genes expressed by B cells that have switched from expressing an immunoglobulin M (IgM) receptor to a receptor of one of the other immunoglobulin isotypes. Such libraries contain a high proportion of somatically mutated V regions.

Phage antibody display libraries may also be con-

Figure 2 Constructing antibody phage display libraries. Immunized libraries are constructed from the B lymphocytes of an immunized individual (A) whereas nonimmunized repertoires are obtained from the B cells of an individual not undergoing an immune response (B). The lymphocytes are used to prepare RNA and cDNA from which the V_H and V_L genes are polymerase chain reaction (PCR) amplified using specific oligonucleotides. In a synthetic library (C), previously cloned V_H segments are used to construct functional V_H genes by adding randomized CDR3 sequences to the immunoglobulin genes by PCR. Completed scFv genes are cloned in phagemid vectors which are used to produce the phage antibody particles.

structed from the V regions expressed by the B cells of 'nonimmunized' individuals in an attempt to recruit all the diversity present in the pool of IgM-bearing B cells (Figure 2B). These so-called 'naive' antibody phage display libraries harbor a high proportion of germline V regions and are expected to encode a different collection of antibodies as compared to the immunized libraries. A third approach to create diverse libraries exploits the use of large collections of cloned V gene segments to which randomized CDR3 and J_H regions are fused *in vitro* by the polymerase chain reaction (Figure 2C). It may be anticipated that such semisynthetic libraries contain

'novel' specificities not present in the actual antibody repertoires of humans. Phage antibody display libraries of various sizes, constructed according to the above-mentioned strategies have been described. As a general rule, it appears that large-sized libraries ($>10^{10}$ clones) permit the direct selection of high-affinity antibodies, even from naive or semi-synthetic repertoires.

Phage selection strategies

Phages expressing antibody specificities of interest are selected from libraries in a four-step procedure (Figure 3): 1) binding of phages to the target antigen, 2) removal of nonbound phages by washing, 3) elu-

tion of bound phages and 4) infection and propagation of eluted phages in *E. coli* bacteria. Phage selections have been extensively performed on purified antigens coated to plastic surfaces. Although the antibodies obtained through this procedure perform well in ELISA, their effectiveness in other assays with antigens in their native conformation is usually limited. Presumably the coating procedure leads to the partial destruction of the conformational integrity of the antigen and the subsequent selection of phages against neo-epitopes.

Phage antibodies may also be selected using intact eukaryotic cells in suspension or cells growing in monolayers as targets. Selection procedures on eukaryotic target cells may be extended by an absorption step in which the library is incubated with absorber cells to remove undesired specificities. For example, selection of phages for binding to malignant melanoma cells followed by absorption of eluted phages on normal melanocytes yielded antibodies that exclusively recognized the melanoma cells. Along this line, the combination of flow cytometry and phage display library technology has proven to be a successful approach for isolating antibodies directed against surface markers present on subpopulations of cells in a heterogeneous mixture. In this procedure, the phage library is incubated with the heterogeneous population of cells, the subpopulation of interest is subsequently stained with fluorochrome-labeled monoclonal antibodies, and sorted from the heterogeneous mixture by fluorescence activated cell sorting. The nonselected cells in the mixture act as an absorber population.

Preparation of cells for phage selections may require treatment of tissues with proteolytic enzymes and/or cell culture, potentially resulting in the loss of phenotypic characteristics of the target cells. To circumvent this problem, intact fragments of tissues can be used as targets for phage selection. In this manner, scFv antibodies have been obtained binding to either membrane-bound or intracellular proteins.

Constructing antibody derivatives

The antibody fragments obtained from phage display libraries are monovalent, whereas in many *in vitro* and *in vivo* applications, multivalency is a desirable property. In addition, linking two or more binding sites efficiently increases the functional avidity of antibody molecules. Multivalent (and multispecific) scFv and Fab fragments have been successfully produced by association of antibody fragments through flexible linker polypeptides, chemical cross-linking and fusion to transcription factor-derived multimerization domains. For instance, scFv antibody frag-

Figure 3 Schematic outline of the basic selection procedure. The antibody phage display repertoire is grown in *E. coli* bacteria (A) and purified from the medium (B). The phage antibodies are allowed to bind to the antigen, which may be either coated to a solid surface or expressed on a cell surface (C). Nonbinding phages are removed by washing (D) after which the remaining phage antibodies are eluted (E), propagated in bacteria and used for a next round of selection.

ments can be converted to dimers by genetic fusion of the scFv moiety to peptides derived from Fos and Jun or to tetramers by fusion to GCN4 protein interaction domains. Thus modified scFv fragments spontaneously multimerize to bivalent (scFv)₂ or tetravalent (scFv)₄ fragments in the bacterial periplasm. ScFv antibodies from phage display libraries have also been converted to complete immunoglobulin molecules by insertion of the variable region genes in eukaryotic expression constructs containing the constant region genes encoding each human immunoglobulin isotype. These 'natural' monoclonal antibodies can be produced in eukaryotic cells, retain the specificity of the original scFv and perform effector functions associated with the immunoglobulin Fc portion.

ScFv fragments may be incorporated into liposomes to create immunoliposomes with specific cellular or tissue-targeting properties. Addition of the *E. coli* lipoprotein signal sequence to scFv fragments results in the *in vivo* biosynthetic lipid modification of scFv, efficiently anchoring the scFv fragments to membrane encapsulated vesicles while retaining their specificity.

Conclusions

Phage display technology permits the selection of antibody fragments from large libraries constructed from the B lymphocytes of individuals or assembled *in vitro* from the genetic elements encoding antibodies. The procedure is rapid and independent of the immunogenicity of the target antigen, a drawback associated with conventional hybridoma technology. An array of selection procedures on whole eukaryotic cells and intact tissues facilitates the isolation of antibodies against membrane molecules and epitopes, even when the target cells are extremely rare or lose phenotypic characteristics upon preparation. These characteristics render this technology

a valuable research tool in searches for novel cell surface molecules, including tumor-specific antigens. Engineering steps allow the tailoring of antibody fragments to meet specific needs in terms of avidity, pharmacokinetic properties and biological effector functions. Monoclonal antibodies from phage display libraries constructed from human V regions represent a class of molecules particularly suitable for immunotherapy in humans.

PHAGOCYTOSIS

Phagocytosis by phagocytic cells is a crucial part of the host defense against invading microorganisms once the outer epithelial surface of the body has been breached (Figures 1 and 2). The most important cell types involved are polymorphonuclear leukocytes (PMNs) and mononuclear phagocytes (MNs; monocytes and macrophages), both of which are derived from precursor cells in the bone marrow. PMNs are released into the circulation in vast numbers in a fully differentiated state, with a half-life in the bloodstream of only about 6 h. The turnover rate of these cells is enormous; each day about 10^{11} PMNs disappear from the bloodstream to be replaced by equal numbers from the bone marrow. Monocytes are capable of further differentiation. After migration from the blood to tissues (diapedesis), they become macrophages of the mononuclear phagocytic system. These fixed macrophages are strategically placed to defend the body against invading microorganisms by lining blood sinusoids in the liver, spleen, bone marrow, adrenals, etc.

After invasion of the tissues by microorganisms, circulating PMNs become activated. This process is triggered by bacterial cell wall products (e.g. lipopolysaccharides, peptidoglycan, etc.), cytokines (e.g. interleukin 1, IL-1) and many other molecules (e.g. platelet-activating factor). Activated PMNs leave the bloodstream by adhering to endothelial cells and moving through the endothelial barrier to the site of the infection. This process of migration is called chemotaxis and is defined as cell movement in one direction in response to an agent (chemoattractant) (Figure 3).

Neutrophil chemotaxis requires the binding of chemoattractants to specific membrane receptors. Chemoattractants include bacterial products, activated complement factors (C5a), arachidonic acid metabolites (LTB₄), and cytokines such as IL-1, IL-8. These bind to G proteins of PMNs, leading to signal transmission to the interior of the cell which in turn leads to activation of the PMN and thus expression of adhesion molecules.

The first event during chemotaxis is the slowing or margination of the circulating leukocytes within the venule where the white cells are loosely tethered to the vessel wall and roll along the surface of the endothelium. After rolling, many neutrophils firmly adhere to the endothelial cell surface and become

Figure 1 Polymorphonuclear leukocyte in the process of phagocytosing *Escherichia coli*.

Figure 2 Processes involved in phagocytosis of bacteria by polymorphonuclear leukocytes. (Reproduced with permission from Verhoef and Visser (1993) In: Abramson and Wheeler (eds) *The Neutrophil* pp 109–137. Oxford: IRL Press.)

activated, changing from a spherical configuration to a flattened shape (Figure 3). During tethering, a family of three lectin-like carbohydrate-binding molecules called L-selectin, E-selectin and P-selectin are activated. L-selectins are expressed on most leukocytes, while E- and P-selectins are expressed by endothelial cells. Selectins promote leukocyte rolling and recognize specific carbohydrates on either leukocytes

Figure 3 Process of chemotaxis. Neutrophils (PMN) are activated, adhere to the endothelial surface, roll over the surface, spread and move through the endothelial cell layer. (Reproduced with permission from Verhoef and Visser (1993) In: Abramson and Wheeler (eds) *The Neutrophil*, pp 109–137. Oxford: IRL Press.)

or the endothelium (L-selectin), which leads to tethering of the leukocytes. Adhesion by selectins is not strong enough to stop the flow of leukocytes completely. Adhesion molecules called integrins are responsible for the firm adhesion of leukocytes to endothelium. Activation of the integrins stops the flow of leukocytes.

Many of the activators (triggers) needed for the adhesion of PMNs to endothelial cells and subsequent chemotaxis are produced by the endothelial cells themselves, and by monocytes, bacteria, etc. There is growing evidence that the neutrophil itself is also able to produce chemotactic factors and activators.

Opsonization

Generally, microorganisms are only phagocytosed after they have been properly opsonized; that is, loaded with activated C3 and immunoglobulin (IgG) (Figure 4). PMNs have receptors specifically designed to bind to the Fc fragment of the IgG molecule present on the surface of the opsonized bacteria and other receptors designed to bind to the activated complement factors. Opsonization through activation of complement is primarily a function of C3b and iC3b. The PMN receptor that recognizes C3b is CR1, while the receptor that recognizes iC3b is CR3. For most opsonized particles the iC3b–CR3 interac-

Figure 4 Opsonization of bacteria.

tion enhances attachment of the particle to PMN but not its ingestion. Ingestion only occurs in the presence of antibodies. Antibodies bind to specific antigens on the cell wall of bacteria; these antibody molecules also serve as ligands for the attachment of bacteria to the PMN.

Many bacteria have developed a defense against opsonophagocytosis and are thus able to escape phagocytosis by PMNs. The most important anti-phagocytic defense of bacteria is an enveloping capsule (Figure 5). These capsules protect the microbes against PMNs by interfering with opsonization. For example, *Haemophilus influenzae*, *Neisseria meningitidis*, *Escherichia coli*, *Streptococcus pneumoniae*, *Klebsiella pneumoniae* and group B streptococci have polysaccharide capsules on their surface. Non-encapsulated derivatives of these organisms are less virulent.

Some other cell wall components that help microbes to evade the phagocytic defense of the host

Figure 5 Encapsulated bacteria are resistant to phagocytosis because (A) opsonic antibodies cannot reach epitopes in the cell wall and therefore complement is not activated, and (B) antibodies and C3b are bound to cell wall epitopes but binding to PMNs is hindered by the capsule. (Reproduced with permission from Verhoef and Visser (1993) In: Abramson and Wheeler (eds) *The Neutrophil*, pp 109–137. Oxford: IRL Press.)

are peptidoglycans, protein A (*Staphylococcus aureus*), and protein M (group A streptococci). Some bacteria are able to adhere to PMNs in the absence of antibodies and/or complement. *E. coli* adhesins, for example, are important components that may mediate adherence of *E. coli* directly to PMNs without antibodies and complement.

In plasma there is a high molecular weight glycoprotein called fibronectin that aids the reticuloendothelial system in clearing the host of microorganisms and helps to maintain vascular stability. Several bacteria, for example, *S. aureus* and groups A, B, C and G streptococci, have receptors for fibronectin. Because PMNs can also bind fibronectin, it is possible that this glycoprotein acts as a bridge between PMNs and the bacteria and therefore facilitates phagocytosis in the absence of specific opsonins.

Phagocytosis

Phagocytosis is the process that leads to ingestion of the particle. It involves both attachment to receptors and subsequent engulfment. After engulfment, phagosomes are formed that surround the microbe, followed by fusion of secretory granules (lysosomes) with phagosomes to form phagolysosomes. Killing and digestion of the microorganisms take place within these phagolysosomes.

The process of receptor-mediated ingestion involves two steps: binding and ingestion. During binding, the receptor interacts with its ligand (opsonin) to bring the target particle in close contact with the phagocyte. For ingestion, the receptor has to deliver a signal to the cell to form pseudopodia around the target particle. The most important membrane receptors involved in the process of attachment are Fc receptors (FcγRs) and complement receptors (CRs). Human phagocytic cells bear at least three distinct types of FcR: FcγRI (CD64), FcγRIIa (CD32) and FcγRIIb (CD16). FcγRI is a 72 kDa glycoprotein with a high avidity for monomeric IgG. It is found mainly on monocytes and macrophages and contains three Ig domains in its extracytoplasmic portion and a short charged cytoplasmic tail. This receptor is upregulated by interferon γ. FcγRII is not a single receptor, but a family of closely related 40 kDa transmembrane glycoproteins with low avidity for monomeric IgG. FcγRIII is a glycoprotein that runs as a broad band between 50 and 80 kDa on SDS-PAGE gels. It is a receptor with low affinity for monomeric IgG that preferentially binds immune complexes. Human IgG1 and IgG3 subclasses interact with all FcγR classes. Human IgG2 is bound solely to FcγRII2a. Thus, uptake of bacteria by PMNs is determined by the subclass and allotype of

the opsonic IgG and the phenotype of the Fc receptor in the membrane of the PMN molecule.

Complement receptors

After opsonization, iC3b and C3b are recognized by different receptors: CR3 (CD11b/CD18) found on almost all phagocytes; and CR4 (CD11c/CD18) or gp150,95 found on some lymphocytes and phagocytes. CR1 (CD35), a glycoprotein with a molecular weight that varies between 160 and 250 kDa, only binds C3b with high affinity.

Resting PMNs have a low capacity to bind C3b-opsonized particles, but the binding capacity of PMN is rapidly upregulated during activation. The receptor-ligand interaction activates the engine of the ingestion phase: actin, myosin and actin-binding proteins. The actin microfilaments in the cytoplasm underlying the site of particle attachment polymerize and the membrane starts crawling around the particle. Pseudopodia are thus produced and surround the particle, producing a phagocytic vacuole (phagosome). Granules in the cytoplasm then fuse with the phagosome membrane to form a phagolysosome.

Uptake without opsonization

Phagocytic cell membranes contain various other receptors. One of these is the scavenger receptor, which was initially described as being involved in the removal of damaged erythrocytes and in the uptake by phagocytes of lipoprotein-proteoglycan complexes from human atherosclerotic lesions. It is now clear that these receptors also bind bacterial antigens and may be involved in binding and phagocytosis of unopsonized bacteria.

Killing

PMNs are able to kill microorganisms by two distinct mechanisms, one of which is oxygen dependent, while the other is oxygen-independent.

Oxygen-dependent events

The oxygen-dependent antimicrobial mechanisms are set in motion when PMNs undergo a 'respiratory burst'. How the interaction between PMNs and opsonized bacteria leads to a respiratory burst is not yet known. Much of our knowledge of the signal transduction that leads to enhanced oxidative metabolism after activation of the receptors for opsonins comes from studies with soluble chemoattractants. During signal transduction G proteins serve as intermediates between cell surface receptors and effector enzymes responsible for generating second

messengers. The interaction with G proteins leads to changes in conformation of the S protein and activation of adenylcyclase or phospholipase. Activation of phospholipase results in the activation of second messengers such as cAMP, inositol triphosphate, Ca^{2+} , arachidonic acid, etc. High levels of Ca^{2+} leads to activation of protein kinase A (PKA) and protein kinase C (PKC). It is likely that PKC and PKA and, possibly other kinases, play a role directly or indirectly in the activation of NADPH oxidase in the cell membrane, which reduces O_2 to superoxide (O_2^-).

Reduction of O_2 is the first step in a series of reactions that produce toxic oxygen species during the respiratory burst: $2\text{O}_2 + \text{NADPH} \rightarrow 2\text{O}_2^- + \text{NADP}^+ + \text{H}^+$. Next, O_2^- dismutates to hydrogen peroxide (H_2O_2) and the azurophil granule enzyme myeloperoxidase (MPO) catalyzes the oxidation of Cl^- by H_2O_2 to yield hypochlorous acid (HOCl):

H_2O_2 is a powerful oxidant; however, it reacts sluggishly with biological materials. H_2O_2 and O_2^- can give rise to more potent agents in the presence of ferric ion or Fe^{3+} chelates. O_2^- reduces Fe^{3+} while Fe^{3+} chelates to Fe^{2+} . The reaction of H_2O_2 with Fe^{2+} chelates yields iron-oxygen complexes that react directly with microbial components or that release hydroxyl radicals ($\text{OH}^\cdot$, Haber-Weiss reaction): $\text{O}_2^- + \text{H}_2\text{O}_2 \rightarrow \text{O}_2 + \text{OH}^- + \text{OH}^\cdot$. Because $\text{OH}^\cdot$ reacts rapidly with chemical bonds of all kinds, it causes damage only in the direct vicinity of where it is produced.

HOCl is a potent microbial agent and it is unlikely that it acts directly in phagolysosomes. HOCl reacts rapidly with ammonium (NH_4^+) to yield monochloramine (NH_2Cl) and with amines to yield mono- and dichloramines (RNHCl and RNCl_2). Because the concentration of nitrogen compounds is very high *in vivo*, HOCl has little opportunity to react directly with target cells. It is likely that toxicity of the $\text{MPO}/\text{H}_2\text{O}_2/\text{Cl}^-$ system is mediated by chloramines. There is some (still controversial) evidence that human neutrophils produce $\text{NO}^\cdot$, although the effectiveness of this radical in killing staphylococci is unclear.

Oxygen-independent events

PMN cytoplasmic granules contain additional antimicrobial agents that are released into phagolysosomes and do not require the production of oxidants for activity. These agents include proteases, other

hydrolytic enzymes, such as phospholipases, glycosidases and lysozymes, and other proteins and peptides that disrupt microbial functions or structural components. It is likely that these agents must bind to the microbial cell surface to have antimicrobial activity. But activity of each agent is limited to certain microorganisms. Three well-characterized granule components, B/PI (bactericidal/permeability-increasing protein), CLCP (chymotrypsin-like cationic protein; cathepsin G) and defensins, have such microbicidal activity *in vitro*.

B/PI This 58 kDa protein of the primary (azurophil) granules may contribute to the ability of neutrophils to kill mainly gram-negative bacteria. Within 15 s of exposure to B/PI *Escherichia coli* no longer form colonies. Loss of viability is caused by an increase in outer membrane permeability to hydrophobic molecules and by activation of enzymes that are able to degrade peptidoglycan and outer membrane phospholipids. The specificity of B/PI for gram-negative bacteria is due to the interactions between B/PI and lipopolysaccharides. Both antibacterial and endotoxin-neutralizing activities reside in the N-terminal 23 kDa portion. A recombinant N-terminal 23 kDa fragment (rBPI₂₃) has been synthesized. Unexpectedly, this rBPI also exhibits gram-positive bactericidal activity and enhances the susceptibility of *S. aureus* to antibiotics.

CLCP Azurophil granules of human PMNs contain three immunologically cross-reactive cationic proteins that have both antibacterial and chymotrypsin-like neutral protease activity *in vitro*. Exposure of *S. aureus* or *E. coli* to CLCP causes inhibition of multiplication due to inhibition of macromolecular (protein, RNA, DNA) synthesis. The ability of CLCP to kill *S. aureus* and *E. coli* *in vitro* is markedly inhibited by altering the incubation conditions, e.g. by adding millimolar concentrations of calcium or magnesium ions or by increasing ionic strength or acidity. The antimicrobial activity of CLCP persists when protease activity is abolished by heat or by active-site inhibitors. Therefore, the microbicidal activity of CLCP does not depend on a primary proteolytic activity. CLCP has also been shown to act synergistically with PMN elastase against *E. coli* and *S. aureus*.

Defensins The cytoplasmic granules of PMNs contain a variety of antimicrobial cationic proteins with potent antimicrobial activity, called defensins. These peptides are small (3.5 kDa), cysteine-rich, only moderately cationic, and identical except in their N-terminal residues. They are also remarkably

abundant, comprising up to 5–7% of the total protein of human PMNs and 30–50% of the total protein of the primary (azurophil) granules. They have a broad spectrum of activity *in vitro* against gram-positive and gram-negative bacteria, fungi (including *Candida* species and *Cryptococcus neoformans*), and certain enveloped viruses. Human PMN defensins only kill metabolically active bacteria and induce loss of outer and inner membrane integrity.

Other granular agents that contribute to bactericidal activity of the PMN are, for example, elastase and lactoferrin. Lactoferrin binds iron and produces an iron-free milieu in the PMN. It is bacteriostatic because most bacteria do not multiply in the absence of iron. Lactoferrin also alters the cell wall of bacteria so that they become more accessible to lysozymes. Thus, lactoferrin and lysozyme act synergistically.

Lactoferrin has a high degree of homology with transferrin. At sites of inflammation, such as occurs at infected sites in the body, unsaturated lactoferrin is released by the specific granules of neutrophils into the extracellular environment. At the acidic pH often found at sites of inflammation, free iron is present because transferrin is unable to bind and hold iron under acidic conditions. Lactoferrin, on the other hand, has a high affinity for iron under acidic conditions and is thus able to bind this free iron instead, rendering it unavailable to pathogenic microorganisms. Iron–lactoferrin is then taken up by mononuclear phagocytes via receptors with a specificity for lactoferrin. By this mechanism, lactoferrin contributes to a localized hypoferrinemia at sites of infection.

The release of iron from lactoferrin within the mononuclear phagocyte appears to involve a different mechanism than that from transferrin. In the case of transferrin, endocytosed iron–transferrin enters a distinct, mildly acidic endosomal compartment within the cell where iron is released and then recycled back to the cell surface. Iron–lactoferrin also cycles through a mildly acidic endosomal compartment, but lactoferrin does not release iron under this condition. Iron is released from lactoferrin when a portion of the endocytosed lactoferrin enters the lysosomal compartment and is degraded. Thus, there is a potential indirect role for PMN in infections where mononuclear phagocytes play the major role, with the PMN providing lactoferrin and thereby enabling the monocyte macrophage to inhibit intracellular multiplication.

Digestion

Most of the microorganisms are digested after being killed and bacterial components are rapidly degraded by the numerous granule-associated degradative enzymes. The degree of digestion of the engulfed bacteria depends on the structure of the bacterial cell wall and on the presence of digestive enzymes in the phagocyte.

PHORBOL ESTERS

Gerald A Evans, Intramural Research Support Program, Scientific Applications International Corporation Frederick, NCI-FCRDC, Frederick, MD, USA

William L Farrar, Cytokine Molecular Mechanisms Section, Laboratory of Molecular Immunoregulation, NCI-FCRDC, Frederick, MD, USA

Phorbol esters and protein kinase C

Phorbol esters are natural products derived from plants of the family Euphorbiaceae. Much interest in the phorbol esters arose from experimental results which demonstrated potent activity as skin tumor promoters in mice. Subsequently, phorbol esters were shown to have profound effects on a wide variety of biological systems *in vitro*. Some of these included effects on cellular differentiation, mimicry in normal cells of the transformed phenotype, stimulation of secretory responses and modulation of membrane activities.

Studies using radioactively labeled phorbol esters (Figure 1), PDBu (phorbol 12,13-dibutyrate) and PMA (phorbol 12-myristate, 13-acetate) identified specific phorbol ester receptors in a wide variety of cells and tissues. Interestingly, studies of these receptors and further characterization showed that they shared marked similarities with a serine/threonine protein kinase activity referred to as protein kinase C (PKC). Results from a number of laboratories confirmed that PKC was the major phorbol ester receptor. Nishizuka's group at Kobe University in Japan demonstrated, under appropriate conditions with limiting amounts of calcium and phospholipid, the required cofactors for PKC, that the phorbol esters were able to stimulate PKC activity. In addition, sev-

eral laboratories demonstrated that PKC enzymatic activity and phorbol ester binding activity copurified to homogeneity.

The identification of a kinase which is stimulated by phorbol ester provided a critical link in understanding the signal transduction pathways which are utilized by a number of hormones and growth factors. For a large class of these cellular effectors, the initial action, upon receptor occupancy, is the activation of phospholipase C. Activation of phospholipase C leads to the degradation of a specific phospholipid, phosphatidylinositol 4,5-bisphosphate, generating two products, inositol 1,4,5-trisphosphate and diacylglycerol. Inositol 1,4,5-trisphosphate acts to elevate intracellular calcium resulting in the activation of calcium-dependent protein kinases. Nishizuka's group demonstrated that diacylglycerol (Figure 1), like the phorbol esters, is able to activate PKC, implying that PKC may be intimately involved in signal transduction for a large number of cellular stimuli, including hormones, neurotransmitters, antigens and growth factors.

The observation that diacylglycerol can substitute for phorbol ester in the *in vitro* activation of PKC suggested that it may be the natural analog mediating phorbol ester-like effects *in vivo*. A number of approaches were used to verify that assumption, including direct treatment of cells with synthetic diacylglycerols and bacterial phospholipase C to pro-

Figure 1 Structure of phorbol, phorbol esters and diacylglycerol. Phorbol, the nontumorigenic parent molecule to the phorbol esters, is shown with carbon atoms numbered in the standard format. The tumorigenic property of the phorbol esters is associated with the addition of hydrophobic moieties at carbons 12 and 13, thus forming molecules with a structure similar to diacylglycerol, a natural activator of protein kinase C.

mote cell surface phospholipid breakdown to diacylglycerol. Both these approaches showed that diacylglycerol can mimic some, but not all, of the effects associated with phorbol ester treatment. Furthermore, it was also observed that different phorbol esters could provoke different biological responses and under certain circumstances different concentrations of the same phorbol ester could produce a different effect. Although the evidence that PKC is the major phorbol ester receptor is very strong, it is clear that phorbol ester or diacylglycerol modulated effects are not exclusively mediated through a simple cellular pool of PKC.

The PKC isozyme family

Studies of phorbol ester effects mediated by PKC have revealed a number of mechanisms which may lead to the observed heterogeneity in the biological responses. Using oligonucleotide probes generated from the partial amino acid sequence of purified bov-

ine brain PKC, studies revealed that PKC exists as a family of closely related enzymes. Four subspecies (α , β I, β II and γ) emerged from the initial screening of a variety of cDNA libraries. Additionally, three other species (δ , ϵ , ζ) were identified from rat and rabbit cDNA libraries using a mixture of α , β II, and γ cDNAs as probes. In addition to certain structural differences, members of the PKC family differ in substrate specificity, ability to be activated by phospholipid, calcium, diacylglycerol and arachidonic acid. Members of this family also differ in tissue distribution and intracellular localization. While there is little evidence relating a specific function for each PKC family member, each subspecies may have a distinct role in the modulation of a variety of cellular responses, thus leading to the observed heterogeneity in PKC-mediated effects.

The primary structure of members of the PKC family consists of a single polypeptide chain (68–83 kDa) containing a regulatory and catalytic domain connected by a trypsin-sensitive hinge region

Figure 2 The structure of the PKC family. Regions which are relatively constant (C) among the subspecies are dark, while variable (V) regions are light. The major difference between the $\alpha, \beta I, \beta II, \gamma$ group and the group containing δ, ϵ and ζ is the loss of constant region 2 (C₂) in the latter. Regulatory and catalytic domains as well as the proteolytic cleavage and ATP-binding site are shown.

(Figure 2). It has been shown that limited proteolysis by calpain results in cleavage of PKC into a regulatory and fully catalytically active form (called protein kinase M). The *in vivo* implications of this observation are not completely understood; however, it appears that calpain activity is increased in the presence of phosphatidylserine plus diacylglycerol or PMA, implying that the activated form of PKC is the target for calpain action. Upon phorbol ester treatment, PKC is translocated from the cytosol to the membrane followed by subsequent depletion, termed downregulation of PKC. Thus, it appears that mechanisms exist which may lead to the rapid degradation of PKC upon activation.

Major questions regarding the role of PKC isozymes in biological signaling remain unanswered and are the focus of much research. Areas of investigation include: 1) specific isozyme coupling to recep-

tor activation; 2) alternative PKC activation pathways; and 3) identity and functional consequences of PKC substrate phosphorylation. Nevertheless, the PKC isozymes clearly appear to be an important kinase family involved in biological signal transduction.

PHOTOIMMUNOLOGY

Stephen E Ullrich and **Margaret L Kripke**, Department of Immunology, M.D. Anderson Cancer Center, The University of Texas, Houston, Texas, USA

Photoimmunology is the study of the effects of photons on the immune system. Although this field of study can be traced to ancient times, when sunlight was used to treat skin diseases, its origins as a scientific discipline stem largely from studies on ultraviolet (UV) radiation-induced skin cancers in experimental animals and from investigations of the cutaneous immune system. The skin is an important component of photoimmunology because all of the known effects of photons on the immune system are initiated in the skin, either from a direct interaction of UV radiation with immune cells in the skin or from indirect effects of UV radiation on other components of the skin that secondarily affect immune cells.

The photons of primary interest in photoimmunology are those with wavelengths in the UV region of

the solar spectrum, particularly the mid-UV or UVB (290–320 nm) region. UVB radiation is responsible for much of the biological activity associated with sunlight exposure, including tanning, sunburn, skin cancer and immune alterations. Wavelengths in the short UV or UVC (200–290 nm) region of the spectrum, are also immunologically active, but they receive much less attention because of their absence from natural sunlight. Long-wave UV, or UVA (320–400 nm) radiation is important because it triggers photoallergic reactions in humans and it is used in combination with photosensitizing drugs for the treatment of a variety of skin diseases, such as psoriasis and cutaneous T cell lymphoma. Recent findings have suggested that UVA may cooperate with UVB in the induction of skin cancers in mice,

cause skin aging, and contribute to immune suppression in humans.

In addition to its medical importance, interest in photoimmunology has been stimulated recently by environmental concerns. A decrease in the concentration of stratospheric ozone due to increasing concentrations of ozone-depleting chlorofluorocarbon compounds in the upper atmosphere has resulted in an increase in the amount of solar UVB radiation reaching the earth's surface. Thus, concerns about ozone depletion have focused attention on the potential health consequences of UVB exposure. The finding that UVB irradiation can suppress the immune responses of experimental animals to various antigens, including those of infectious microorganisms, has raised the question of whether increases in the amount of UVB radiation in sunlight might increase the incidence or severity of infectious diseases. UV radiation has also been a useful tool for understanding immune regulation, particularly with respect to the question of how the suppressor pathway of the immune system is activated, and for investigating the role of the immune system in cutaneous carcinogenesis.

The immunology of photocarcinogenesis

The first indication that UV radiation could produce systemic immunological alterations came from studies on UV-induced skin cancers in mice. These cancers are highly antigenic and are generally immunologically rejected upon transplantation into genetically identical mice. This unusual property of UV-induced tumors prompted studies to determine how such highly antigenic tumors could survive and grow progressively in the original host. Such studies demonstrated that the UV radiation-induced tumors were able to grow progressively when transplanted into mice that had been exposed to a short course of UV irradiation but had not yet developed primary skin cancers. Because the tumors would grow when transplanted into tissues not directly exposed to UV radiation, these studies demonstrated that UV exposure produced a systemic effect on the host that interfered with its ability to reject these highly antigenic skin cancers.

The systemic effect was immunological because it could be transferred to normal syngeneic mice by injecting them with T lymphocytes from UV-irradiated donors. Thus, repeated exposure of mice to UVB radiation induced ($CD3^+CD4^+CD8^-$) suppressor T cells, that inhibited immunological rejection of the UV radiation-induced skin cancers. These suppressor T lymphocytes also interfered with immune surveillance against the development of skin

cancers in the primary host. The conclusion drawn from these studies was that carcinogenesis by UV radiation involves at least three distinct effects of UV radiation: neoplastic transformation of cells within the skin, the formation of antigens in the UV-irradiated skin, and the induction of suppressor T cells directed against these antigens.

Alterations of immune responses by UV radiation

One of the most intriguing questions raised by studies of the immunology of photocarcinogenesis is how UVB irradiation brings about systemic alterations of immune function. It is not at all obvious how exposing the skin to UV rays brings about activation of the suppressor cell pathway in response to tumor-associated antigens. Clues for answering this question have come mainly from studies of the effect of UV irradiation on other immune reactions, particularly on the suppression of delayed and contact hypersensitivity reactions.

A crucial link between UV irradiation and the induction of suppressor T cells originated from studies on the role of epidermal Langerhans cells in the induction of contact hypersensitivity. Exposing mouse skin to suberythral doses of UV radiation brings about changes in the morphology and function of Langerhans cells. Application of a contact sensitizer to UV-irradiated skin fails to induce contact hypersensitivity, but rather induces hapten-specific tolerance and hapten-specific suppressor T lymphocytes in certain UV-susceptible strains of mice. The same phenomenon has been demonstrated in humans. The mechanism may involve an alteration in the ability of UV-irradiated Langerhans cells to stimulate different T cell subsets. Although normal Langerhans cells can present antigen to both T_H1 and T_H2 T cells *in vitro*, UV-irradiated Langerhans cells fail to activate T_H1 cells, but retain their ability to present antigen to T_H2 cells. Furthermore, the T_H1 cells are rendered tolerant by interaction with UV-irradiated Langerhans cells *in vitro*. Because the induction of tolerance was blocked by coculturing the UV-irradiated Langerhans cells with third-party allogeneic cells, it was suggested that UV may be inhibiting a costimulatory function of the antigen-presenting cells. The observation that UV exposure downregulates the expression of CD80 (B7.1) and CD86 (B7.2) on Langerhans cells supports this hypothesis. UV irradiation of antigen-presenting cells also decreases expression of class II major histocompatibility complex (MHC) molecules; however, loss of function can occur at UV doses where class II expression is unaffected, indicating that other mech-

anisms are probably responsible for their loss of function. Thus, one consequence of UV irradiation is to change the signal presented by Langerhans cells from one that activates T_{H1} cells, to one that tolerizes T_{H1} cell function.

Cytokines produced by UV-irradiated keratinocytes can also affect antigen presentation by Langerhans cells. Following UV irradiation, keratinocytes are activated to produce and secrete a wide variety of immunoregulatory cytokines. Among these, tumor necrosis factor α (TNF α) appears to contribute to the downregulation of contact hypersensitivity responses initiated within UV-irradiated skin. In addition, dendritic cells with altered antigen-presenting activity appear in both dermis and epidermis at the site of UV irradiation. Thus, alterations in Langerhans cells, local cytokine production, and a cellular infiltrate all appear to contribute to the modification of T cell-mediated immune responses induced at the site of irradiation.

In mice, UV irradiation also alters delayed and contact hypersensitivity responses initiated at sites distant from the irradiation and impairs the activity of splenic antigen-presenting cells. Generally, higher doses of UV are required than those needed to modify immune responses within the UV-irradiated site. This effect is thought to be due to the production of soluble mediators by UV-irradiated skin. Of particular importance in suppression of delayed hypersensitivity responses is interleukin 10 (IL-10), which is secreted by UV-irradiated keratinocytes and found in the serum of UV-irradiated animals. This cytokine blocks antigen presentation by macrophages and dendritic cells and suppresses the secretion of T_{H1} -associated cytokines (e.g. interferon γ), thereby blocking the induction of inflammatory immune reactions. Injecting UV-irradiated mice with monoclonal antibody to IL-10 blocks the UV-induced suppression of delayed-type hypersensitivity and reverses the impairment of splenic antigen presenting cell function. IL-10 also appears to alter antigen presentation to T_{H1} and T_{H2} cells. Whereas spleen cells from normal mice presented antigen equally well to T_{H1} and T_{H2} clones, spleen cells from UV-irradiated mice failed to present antigen to T_{H1} cells; injection of the UV-irradiated mice with IL-10-specific antibody reversed this effect. In contrast, antigen-presenting cells from UV-irradiated mice caused greater activation of T_{H2} cells than those from unirradiated mice, and injecting the UV-irradiated mice with anti-IL-10 blocked the enhanced activation of T_{H2} cells. These data suggest that one consequence of UV exposure is a shift from the activation of T_{H1} to T_{H2} cells, and induction of anergy in the T_{H1} cell population. Because IL-10 downregulates CD80

expression on antigen-presenting cells and coculturing the IL-10-treated Langerhans cells with allogeneic spleen cells overcomes the induction of tolerance, the mechanism may involve modulation of costimulatory molecules by IL-10.

In cell transfer experiments, antibodies to IL-4 and IL-10 were shown to interfere with the activity of the UV-induced suppressor cells, suggesting that these cells are indeed T_{H2} cells. Injection of IL-12 also reversed UV-induced immune suppression and blocked the induction of suppressor cells. Since this cytokine promotes the activation of T_{H1} cells, suppresses the activation and differentiation of T_{H2} cells, and interferes with the biological activities of IL-10, this finding also supports the concept that UV irradiation shifts the balance from a T_{H1} - to a T_{H2} -type of response.

One needs to keep in mind, however, that in addition to IL-10, UV-irradiated keratinocytes produce a wide variety of immunomodulatory cytokines and soluble factors, many of which have been implicated in the induction of systemic immune suppression. Prostaglandin E_2 (PGE $_2$), urocanic acid, IL-1, TNF α , and α -melanocyte-stimulating hormone are all produced following UV irradiation and all have been suggested to play a role in immune suppression. PGE $_2$ and IL-1 have been shown to inhibit the production of T_{H1} -like cytokines and favor a shift to T_{H2} cell activation. *cis*-Urocanic acid and TNF α have been shown to alter antigen-presenting cell function. Antibody against *cis*-urocanic acid prevents UV-induced suppression of certain delayed-type hypersensitivity responses, and anti-TNF α inhibits UV-induced suppression of contact hypersensitivity. Furthermore, *cis*-urocanic acid and α -melanocyte-stimulating hormone have been shown to upregulate serum prostaglandin E_2 levels, which in turn induces blood monocytes to secrete IL-10 and suppress IL-12 production. Thus, it is likely that several different mediators are involved in the induction of immune suppression following UV-irradiation. It is likely, however, that a key regulatory effect of many of these factors is an alteration of antigen-presenting cell function and upregulation of IL-10, which contribute to a shift toward an immune response dominated by T_{H2} cells.

Molecular targets of UV radiation within the skin

DNA absorbs UV radiation and is a primary molecular target of UV radiation in the skin. Mutagenesis, cellular transformation, and cell death all result from UV-induced DNA damage. DNA damage also appears to be an essential initiating event for many

forms of UV-induced immune suppression. Three experimental approaches were used to establish this finding. In the first, opossums (*Monodelphis domestica*) were exposed to UV radiation. Marsupial cells contain an enzyme that is activated by visible light and repairs UV-induced pyrimidine dimers. When the opossums were first exposed to UV and then to visible light, immune suppression was blocked. No inhibition was observed when the visible light was applied before UV, a situation that does not activate the enzyme to repair pyrimidine dimers. In the second series of experiments, a DNA repair enzyme (T4 endonuclease V) was encapsulated in liposomes and delivered to the skin of UV-irradiated mice. Here also, repair of pyrimidine dimer formation by the applied enzyme blocked the induction of immune suppression. No inhibition of immune suppression was observed when liposomes containing heat-inactivated enzyme were used. In addition, the production of IL-10 by keratinocytes was suppressed by applying liposomes containing the DNA repair enzymes to UV-irradiated skin or to keratinocytes *in vitro*. In the final approach, liposomes containing a restriction endonuclease (*HindIII*) were applied to mouse skin. Not only did applying the liposome-encapsulated enzyme damage epidermal DNA, as measured by the induction of DNA strand breaks, but it also upregulated IL-10 production and suppressed the induction of delayed and contact hypersensitivity. Thus, these experiments indicate that immune suppression can be initiated by DNA damage and reversed by repairing the pyrimidine dimers formed following UV irradiation of the skin. The implication of these findings is that DNA is a photoreceptor and that DNA damage is an essential initiating event for the induction of some forms of UV-induced immune suppression.

Other photoreceptors for UV radiation have been proposed. Most prominent is urocanic acid. *trans*-Urocanic acid is found naturally in the outermost layer of the skin and, upon exposure to UV radiation, isomerizes to the *cis*-form. Based on a comparison of the action spectra for the isomerization of urocanic acid and UV-induced immune suppression, urocanic acid was proposed to be the photoreceptor. Data from many laboratories showing that *cis*-urocanic acid has immunosuppressive effects support this hypothesis. It should be noted, however, that wavelengths in the UVA region of the solar spectrum, which are not immunosuppressive by themselves, are very efficient at forming *cis*-urocanic acid *in situ*, leading some to question the suggestion that urocanic acid is the sole photoreceptor for the induction of immune suppression. Recent studies in which

mice are treated with an antibody against *cis*-urocanic acid after UV irradiation suggest that this molecule is an essential mediator for suppression of some, but not all delayed hypersensitivity responses. Thus, some immunosuppressive effects of UV irradiation appear to be mediated by DNA damage and others by isomerization of urocanic acid.

Photoimmunology in humans

Although most of our information about photoimmunology comes from studies of laboratory animals, evidence of immunological effects of sunlight and UV exposure on humans is beginning to accumulate. Exposing human skin to sunlight or artificial sources of UV radiation causes the same types of alterations to human Langerhans cells as previously described in mice. Furthermore, human keratinocytes secrete a variety of immune modulatory factors following UV exposure, including IL-1, IL-6, IL-10, TNF α and PGE $_2$. Sensitization of humans with contact allergens through the UV-irradiated skin also suppresses the contact hypersensitivity reaction. Interestingly, although the UV-induced suppression of contact hypersensitivity was evident in approximately 40–50% of irradiated normal human volunteers, almost 100% of skin cancer patients were susceptible to the suppressive effects of UV radiation. These findings not only suggest that there is a genetic component that influences the sensitivity of humans to UV-induced immune suppression, similar to that in mice, but also that the UV-induced suppression of immune reactivity may be an additional risk factor in the induction of human skin cancer.

One question of considerable importance concerns the potential of UV-induced immune suppression to alter the immune response to pathogenic microorganisms. While animal studies have clearly shown that UV exposure can suppress the immune response to a variety of infectious agents and increase the incidence, severity and duration of infection, it is not clear whether photoimmunosuppression similarly affects the immune response to infectious agents in humans. Some evidence suggests that the ability of sunlight to trigger recrudescence of herpes simplex virus infection is due to the immunosuppressive activity of UV radiation. In addition, UV irradiation of the site of elicitation of a delayed hypersensitivity reaction to leprosy antigens in healthy, immune subjects reduced the granulomatous reaction and decreased the number of CD4 $^+$ T cells in the reaction site. Thus, UV radiation seems to have the ability to modify the immune responses of humans to infectious agents, but whether this translates into an

increase in the pathogenesis of infectious diseases remains unclear.

Conclusions

Photoimmunology is contributing to our understanding of basic immunological mechanisms, especially the role of antigen presentation in the activation of immunosuppressive T cells subsets and the identity of T cells with immunosuppressive activity. Its importance for cutaneous carcinogenesis has been clearly established in animal models, and data generated in a few studies with human skin cancer patients suggest that UV-induced immune suppression may play a similar role in human skin cancer induction. It is clear that exposure of mice to UV radiation can have systemic effects on the immune system and can suppress the immune reaction against infectious agents, but the role of photoimmunology in the pathogenesis of human diseases other than skin cancer remains to be elucidated.

PHYLOGENY OF THE IMMUNE RESPONSE

Norman A Ratcliffe, Biomedical and Physiological Research Group,
School of Biological Sciences, University of Wales, Swansea, UK

In comparison with vertebrates, the immune response of invertebrates is extremely limited. Specific antibody produced by interactive lymphocyte subpopulations together with extremely finely tuned discrimination of self from nonself and a high degree of memory are confined to the vertebrates, and yet, invertebrates comprise over 95% of all known species of animals. Clearly, the invertebrate immune system is not defective in any way so why have the vertebrates developed such sophisticated immune processes? Examination of the phylogeny of immunity and consideration of possible evolutionary and environmental pressures favoring its development may help to answer this question. As a preliminary, however, it is essential for a brief consideration to be made of the phylogeny of the main animal groups together with a basic description of the invertebrate and vertebrate immune systems.

Phylogeny of animals

Figure 1 presents the so-called monophyletic and polyphyletic origins of the main groups of animals. In the monophyletic scheme, the animal kingdom is divided into deuterostome and protostome groups according to whether the mouth and anus originate from a single opening (protostomes) or separately (deuterostomes). With the polyphyletic scheme, the major phyla of multicellular animals arose independently from ancestral metazoans. The implication of these two schemes, as far as evolution of the immune system is concerned, is that with a polyphyletic origin, the blood cells and humoral factors may have had a common ancestor and, with the exception of the vertebrates, evolved independently within each phylum. The branch leading to the vertebrates would have followed a sequential evolution passing from echinoderms, protochordates to the vertebrates, just as in the deuterostome branch of the monophyletic

Figure 1 The phylogenetic relationships of animals. (A) monophyletic scheme; (B) polyphyletic scheme. (Reproduced with permission from Miller DA and Ratcliffe NA (1989). The evolution of blood cells: facts and enigmas. In: *Endeavour* 13: 72-77).

scheme. In this latter system, the animal kingdom bifurcates at the coelenterate level into the proto-stomes and deuterostomes with a separate evolution of the immune system in each of the groups.

In both of these evolutionary schemes, it is most probable that the ancestors of vertebrate immunity arose in the echinoderms, hemichordates and protochordates since these groups eventually led to the vertebrates. Similar structures in animals in these groups would be homologous, while any similarities with the protostomes would be purely analogous, having arisen by convergent evolution. The echinoderms and tunicates (urochordates) have been particularly studied (see below) in attempts to find the precursors of vertebrate immunity. A major barrier in tracing the evolutionary origin of the vertebrate immune system is that not only is there disagreement as to the exact origin of the vertebrates but the immediate ancestors of vertebrates are extinct. Thus, any conclusions drawn will be speculative and

assume that comparisons with living species are valid.

Invertebrate immunity

Like vertebrates, invertebrates have efficient physico-chemical barriers to infection. For example, the mucus surrounding the body of many coelenterates, annelids, molluscs and protochordates entraps and kills potential invaders. The tough exoskeleton of the coelenterates, molluscs, arthropods, echinoderms and protochordates also forms an effective barrier to infection.

Most higher invertebrates have a circulatory system containing white, but not usually red, blood cells which are termed hemocytes or coelomocytes, depending upon the nature of the body cavity. Due to the diversity of invertebrate species, and in contrast to most vertebrates, it is impossible to categorize the blood cells on the basis of staining or

morphology alone. Only a functional scheme is relevant to all the invertebrate groups and this recognizes five main types of cells: progenitors, phagocytes, hemostatic, nutritive and pigmented cells. The phagocytic and hemostatic cells are the main cells involved in defense reactions, in which they may function interactively.

Regarding cellular and humoral immunity, these too are not isolated processes but are interactive in nature. The cellular defenses include wound repair, clotting and coagulation responses, phagocytosis and encapsulation reactions and these all involve contributions from the plasma. Ingestion of small numbers of invading microorganisms is mediated by circulating phagocytes, while larger numbers of microbes and metazoan parasites are encapsulated by hemostatic and phagocytic-type cells. In many invertebrates, lectin-like molecules are probably responsible for nonself recognition processes involved in these reactions, although in most arthropod groups, the cuticle-tanning enzyme cascade, the prophenoloxidase system, may also be important. The lectin- and prophenoloxidase-based recognition systems have recently been shown to interact.

Apart from the recognition molecules, the humoral defences include a range of naturally-occurring, antimicrobial factors of which lysozyme is the most common. A few groups, such as the crustaceans, insects and molluscs, are also capable of producing inducible antimicrobial proteins but these are very different to vertebrate immunoglobulin. There are, however, recent reports of inducible proteins and antibody-like molecules in an insect and an echinoderm species but detailed biochemical analyses are wanting.

Most of the above-mentioned immune reactions are nonspecific (innate) with no accelerated or heightened response following secondary challenge and no memory component involved. Transplantation studies and mixed leukocyte cultures have shown, however, that in sponges, coelenterates, annelids, echinoderms and tunicates, allogeneic and xenogeneic recognition are present and that short-term memory may occur. The significance of these latter observations is discussed below.

Vertebrate immunity

Vertebrates also rely extensively on the physicochemical barriers such as the skin and the mucus covering the gut, respiratory and reproductive systems for protection from would-be infectious agents. The white blood cells arise from pluripotent cells in the bone marrow or their equivalent in lower vertebrates. These stem cells pass either through

the myeloid lineage to produce the phagocytic monocytes and polymorphonuclear granulocytes (polymorphs) or mature through the lymphoid lineage to form the lymphocytes. The relative lack of diversity of vertebrates allows the identification of these main cell types in simple blood smears taken from all the representative groups.

The monocytes and polymorphs undertake phagocytosis of invading microorganisms utilizing either nonspecific cell surface receptors or specific receptors for the Fc portion of antibody and the C3b fragment of complement. The monocytes mature into the tissue macrophages which form a phagocytic network, the reticuloendothelial system, in many organs of the body. The polymorphs are important cellular components of inflammation following wounding and rapidly arrive at the site of infection. Specific acquired immunity is most important in the vertebrates and is mediated by interactive events, governed by the major histocompatibility complex (MHC) system, between antigen-presenting cells, including macrophages, and particular populations of lymphocytes, termed T cells. One set of T cells (the CD4⁺ cells) then assist another population of lymphocytes, the B cells, to produce specific antibody, whilst a second set of CD4⁺ T cells induce other T cells (CD8⁺ cells) to function as cytotoxic cells, which form an immunosurveillance system in the body, eliminating virus-infected as well as mutated cells. All these lymphocyte subpopulations are identified by the nature of specific cell surface markers stained with monoclonal antibodies. In contrast to the invertebrates, which have a diverse array of hematopoietic organs, vertebrates have discrete accumulations of lymphocytes and antigen-presenting cells termed lymphoid organs. In these organs, the T and B cells undergo differentiation and development.

As with invertebrates, cellular and humoral immunity interact intimately, and in vertebrates, at least, these processes are finely controlled by a complex of molecules termed cytokines produced by activated leukocytes and other cells. In vertebrates, nonself recognition factors include the MHC antigens and receptors as well as complement components and highly specific antibody molecules. Nonspecific immunity in vertebrates also involves lectin molecules (cf. invertebrates) which activate the complement system. The hallmark of vertebrate immunity, however, is the presence of a specific acquired or adaptive immune response characterized by a high degree of specificity and a long-term memory component. Possible reasons for the development of this finely tuned adaptive response are discussed below.

Origins and comparisons of blood cells

Even the most primitive invertebrates, the protozoans, possess cell surface receptors, are capable of distinguishing self from nonself and contain lysosomes. They thus have the potential to give rise to immunocytes. With the appearance of primitive multicellular organisms or metazoans, well-organized cell layers with division of functions are formed. In sponges, for example, which lack a blood system, food is trapped by the choanocytes and carried around the body by phagocytic amoebocytes. Simple diffusion of nutrients, excretory products and respiratory gases through the body wall serves the needs of the primitive coelenterates and flatworms but, once the third body layer, the mesoderm, evolved, a circulatory system was required to transport trophic substances and respiratory gases around the body. This latter evolutionary step would have freed the blood cells from their nutritional role so that they migrated from the connective tissue into the circulatory system to take up their defensive role. This evolutionary step can be seen in some advanced platyhelminthes in which the phagocytes migrate from the parenchymatous connective tissue into the hemolymph. Once the blood cells took on a purely defensive role then differentiation into other cell types would have occurred because of various environmental and internal pressures detailed below.

The phagocytic cell type has been conserved throughout phylogeny. In invertebrates, it has a food-gathering role but in higher forms it also phagocytoses and encapsulates invading agents. In the vertebrates, the phagocytic cell evolved into polymorphs, monocytes and macrophages which retained their phagocytic role. The macrophage also took on the function of presenting antigen to the lymphocytes during specific acquired immunity. Vertebrate phagocytes also bear surface receptors for Fc and C3b which, with the exception of one echinoderm, appear to be absent on invertebrate phagocytic cells.

Much research has attempted to detect the origin of the vertebrate lymphocyte and indeed cells resembling lymphocytes in morphology are present in many invertebrates. In most cases, these are immature progenitor cells although some workers believe that invertebrates possess cells homologous to vertebrate lymphocytes. In annelids, the presence of allograft and xenograft rejection with specificity and short-term memory, adoptive transfer, graft infiltration by lymphocyte-like cells and blastogenic responses towards transplantation and T cell mitogens, indicate that the blood cells involved may be analogous to vertebrate lymphocytes and have arisen by convergent evolution. Similar properties are

reported for lymphocyte-like cells in tunicates, but the strongest case for true homology is provided by the echinoderms. In the starfish, *Asterias rubens*, lymphocyte-like cells secrete an antibody-like substance as well as a lymphokine-like factor. These axial organ cells can also be fractionated by a method used to separate mammalian B and T cells and respond like these cells towards mitogens. Another echinoderm is also reported to have C3b-like receptors on the surface of its blood cells. The case for true homology, however, awaits detailed molecular evidence of the sort recently produced in studies on the evolution of the vertebrate immunoglobulins.

Evolution of recognition molecules

In the animal kingdom there are a number of protein molecules which have been shown to function during immune recognition. These factors include the MHC system, immunoglobulins, lectins and components of the complement cascade. Much research has been undertaken to trace the phylogenetic origins of these molecules and to identify the main steps in the evolution of the vertebrate immune complex. To date, circulating immunoglobulins of the sort found in vertebrates have yet to be found in invertebrates. Possible exceptions to this statement are the inducible antibody-like response of the axial organ cells of the starfish, *Asterias rubens*, and the inducible protein involved in secondary reactions in the cockroach, *Periplaneta americana*, which shows both specificity and memory. However, until further detailed data to the contrary become available, it appears that functional, circulating immunoglobulins (Ig) are an invention of the vertebrates in which they have undergone rapid evolutionary change from the mainly single Ig class of fishes to the multiple Ig classes of mammals.

In contrast, the presence of allogeneic recognition of transplants in sponges, coelenterates, annelids, echinoderms and tunicates with a short-term memory component, indicates the presence of an ancestral MHC system. Furthermore, the alloimmune rejection process often involves lymphocyte-like cells with cytotoxic properties killing the allogeneic cells. On the basis of these results, Hildemann proposed that the histocompatibility system of cell-mediated immunity arose to deal with the threat of colony fusion in aquatic invertebrates and that the MHC complex is ancestral and entirely separate from the immunoglobulin systems of vertebrates. Immunoglobulins may have been added at the vertebrate level to provide a more extensive and sensitive immunorecognition ability in these more complex animals. The integration of the MHC and immunoglobulin

systems in the higher vertebrates resulted in an exquisitely controlled immune system involving interactive T and B lymphocytes together with antigen-presenting cells. Without the evolution of the MHC system, the various T cell subpopulations would not have developed since their activities are governed by surface receptors for MHC-encoded proteins.

The question arises as to whether the MHC and immunoglobulin systems could be interrelated in some way. One possible linking molecule is a low molecular weight (12 kDa) protein called β_2 -microglobulin which is not encoded for in the MHC region genes. β_2 -Microglobulin is closely associated with class I antigens at the cell surface and shows significant sequence homology with class I heavy chains, class II β chains and immunoglobulin constant region domains. It also shares homology with Thy-1, a differentiation antigen of thymocytes and T lymphocytes which is also found in the brain of an advanced mollusc, the squid, and is a member of the immunoglobulin superfamily. This family of molecules shares some structural and genetic homology with the immunoglobulins without necessarily having an immune function. Also of significance is the discovery of β_2 -microglobulin-like molecules in earthworms, crayfish, lobsters and *Drosophila*. Thus, some immunologists believe that the β_2 -microglobulin gene may have given rise to the immunoglobulin superfamily and the MHC antigens by gene duplication and adaptive selection. Marchalonis and his colleagues have, however, compared amino acid sequences of members of the immunoglobulin superfamily and question the idea that MHC antigens and Thy-1 share a common ancestry with immunoglobulins.

Other evolutionary ancient recognition molecules include the lectins, which identify nonself in at least the molluscs, insects, tunicates and vertebrates. Horseshoe crabs contain a lectin called limulin, which has been compared with immunoglobulin by Marchalonis and colleagues, although no sequence homology was found. Also of significance is the fact that limulin has considerable sequence homology with the pentraxins (C reactive protein family). This result was interpreted not as evidence of evolutionary homology but rather as convergent evolution of molecules binding the same ligand (phosphorylcholine), and having a similar geometry and charge distribution. Alternatively, 'mini gene insertion' of small segments of DNA ('diversity segments') occurred into molecules of diverse and unrelated genetic background. Thus, any similarity between invertebrate lectins, the pentraxins and immunoglobulin is probably analogous rather than homologous.

Another area of intense study by Clem, Du Pasquier, Litman, Marchalonis, Reynaud, Shambloott, Warr and many others has been of the immunoglobulin gene rearrangements to produce antibody diversity which occur in the various vertebrate groups. These studies have shown, amongst other things, that different patterns of gene organization and mechanisms of diversification occur in the immunoglobulin genes of the different vertebrate groups. In addition, since both light and heavy genes are organized similarly, then they probably arose by molecular coevolution. In vertebrates, there appears to have been a major change in organization of the immunoglobulin gene complex at a point in evolution when the cartilaginous and bony fish separated. Thus in teleosts, the V_H locus is similar to that of higher vertebrates, including mammals, in that gene clusters are no longer found but instead gene segments are arranged tandemly and different gene families exist in the V_H genes. Elasmobranchs are characterized by a cluster-type gene arrangement and a single family of V_H genes.

Yet another group of recognition molecules present in the animal kingdom are the complement components generated in the vertebrates. The C3 component, in particular, functions in immunorecognition with receptors for this molecule present on vertebrate phagocytes. Components of a complement-like system have been detected in insects, horseshoe crabs and echinoderms and may indicate an early evolution of this system as an immunorecognition and effector complex. Comparisons are also made of the arthropod prophenoloxidase and clotting systems and the complement cascade. Recently, however, the structural requirements for complement activation by lipid A (an active endotoxin component) have been shown to be quite different from those activating the clotting reaction in *Limulus*.

The role of evolutionary and environmental pressures

What possible pressures on the vertebrates necessitated the imposition of acquired or adaptive immunity on the very effective immune defenses of the invertebrates? After all, the invertebrates evolved successfully over several hundreds of millions of years to occupy every habitat and niche and to comprise of 95% of all animal species, without the need of a sophisticated vertebrate-type immune system. A possible explanation may involve the common occurrence of somatic mutations in vertebrates which, unless removed by a surveillance system, would develop into cancer. The increased size, longevity

Table 1 Evolutionary steps of possible significance in the phylogeny of blood cells and the immune system

<i>Evolutionary step/pressure</i>	<i>Immunological implications</i>
1. Protozoa	Recognition and discrimination
2. Metazoa including colonial forms	Histocompatibility system, allogeneic recognition, and short-term memory
3. Mesoderm and circulatory system; nutrition and defense as separate functions	Freely circulating and more diverse blood cell types; cellular immunity and erythrocytes
4. Cancer associated with increasing complexity and longevity	Immunosurveillance
5. Ancestral protovertebrate	Increased recognition and discriminatory powers?
6. Lower vertebrates with increased body size, longer lifespan, and reduced reproductive potential	True lymphocytes, lymphoid tissue, and antibody production (IgM); longer term memory
7. Emergence on to land, exposure to irradiation, and development of high-pressure blood vascular systems	Bone marrow, additional antibody classes, T and B lymphocytes, lymphoid organs with increased complexity, gut-associated lymphoid tissue (GALT)
8. Amniotes (reptiles, birds, mammals) with loss of free-living larval form	Advanced differentiation of immunocompetent cells allowing increased diversity and efficiency of immune system
9. Homoiothermy with more favorable environment for pathogens	Increased efficiency of immune system, integrated cellular and humoral responses, germinal centers in secondary lymphoid organs, lymph nodes
10. Viviparity with maternal-fetal interactions	Additional fine-tuning of immune system

Modified with permission from Ratcliffe NA and Miller DA (1988). Comparative aspects and possible phylogenetic affinities of vertebrate and invertebrate blood cells. In: Rowley AF and Ratcliffe NA (eds) *Vertebrate Blood Cells*, pp 1–17. Cambridge: Cambridge University Press.

and complexity of the vertebrates would increase the risks of somatic mutations occurring and developing into cancer. Such malignancies, if commonly occurring during the reproductive phase, would be disastrous. Adaptive immunity may thus have arisen to deal with threats developing from within the animal and would have been based on the recognition by patrolling effector cells of 'foreign' (i.e. mutated) antigens on the surface of malignant cells. This system would need to be extremely sensitive to distinguish normal self from abnormal self cells. Furthermore, since it involved circulating cytotoxic cells in surface recognition phenomena, then evolutionary pressure would favor the development and retention of the MHC system to present these antigens, and cellular rather than humoral immunity.

Recently, it has also been proposed that viral infection may impose evolutionary pressures to increase the efficiency of the MHC-based surveillance system of vertebrates. Cytotoxic T cells recognize not only mutated cells but also cells infected by viruses. In order to survive, pressure will be on the viruses to constantly modify their antigens to avoid inducing a vigorous response in association with the MHC antigens. Likewise, the immune system will be pressurized to produce MHC antigens which, in combination with the viral antigens, will be recognized by the cytotoxic T cells. This constant game of cat and mouse of the immune system in pursuit of the viral antigens will favor polymorphism of the MHC system in order to ensure that at least a few individuals can recognize the constantly changing patho-

gens. If viral infection imparts such important evolutionary pressure on the development of polymorphism in the MHC system in vertebrates then the question of why this has not also occurred in invertebrates is not easily answered.

Finally, Table 1, modified from Ratcliffe and Miller (1988), which has been compiled from the work of Burnet, Cone, Cooper, Hildemann, Manning, Marchalonis, Turner, Warr and colleagues, summarizes much of the above and also provides an outline of additional evolutionary pressures, which are self-explanatory, and which would have influenced the development of the vertebrate immune system.

PHYTOHEMAGGLUTININ (PHA)

Tom Geppert, Department of Internal Medicine, The University of Texas, Southwestern Medical School, Texas, USA

Phytohemagglutinin (PHA) is an extract from the red kidney bean (*Phaseolus vulgaris*) that contains potent cell-agglutinating and mitogenic properties. PHA played an important role in the development of cellular immunology. It was the first polyclonal mitogen discovered. Prior to the development of PHA, it was difficult to induce lymphocyte activation *in vitro*. The discovery of PHA allowed investigators to activate lymphocytes in *in vitro* cultures and to study the subsequent events such as growth and lymphokine production.

PHA is a mixture of five tetrameric glycoproteins. Each glycoprotein is composed of two different subunits, E and L, that have molecular weights of 33 kDa and 31.6 kDa, respectively. These subunits are combined into five possible tetrameric proteins termed E₄, E₃L₁, E₂L₂, E₁L₃ and L₄. The nomenclature E and L is derived from the observations that the E subunit appears to be the most effective subunit for inducing erythroagglutination, whereas the L subunit is a more effective lymphocyte mitogen and leukagglutinator. Thus, the E₄ protein is more than three orders of magnitude more potent an erythroagglutinator than L₄, whereas L₄ is approximately two orders of magnitude more potent a T cell mitogen than E₄. More recently studies have demonstrated that both E₄ and L₄ are effective lymphocyte mitogens, but that E₄ binds to a larger number of serum proteins. Therefore, the mitogenic capacity of E₄ is diminished more than the mitogenic capacity of L₄ under conditions in which serum is present. PHA-P is the protein form of PHA prior to separation into leucoagglutinin and erythroagglutinin.

Both E₄ and L₄ bind to glycoproteins. The carbohydrate specificity of L₄ lies within asparagine-linked oligosaccharides. The minimal structural unit required for binding appears to be GlcNAcβ1→2Man. Additions to this basic oligosaccharide greatly alters its affinity for PHA. E₄ has been shown to bind to a similar asparagine-linked oligosaccharide, although the minimal structure unit appears to be Gal1→4GlcNAc1→2Man.

PHA stimulates the proliferation of peripheral blood mononuclear cells. T cells are the responding cell within peripheral blood mononuclear cells, but responses are dependent on the presence of peripheral blood monocytes that function as accessory cells. B cells do not proliferate in response to PHA even in the presence of accessory cells. A variety of other cell types can function as accessory cells for PHA-induced T cell activation, including fibroblasts and endothelial cells.

PHA binds to a variety of glycoproteins on the surface of T cells. The specific glycoprotein(s) that is responsible for triggering T cell activation upon binding to PHA is not yet known. It is clear that PHA binds to the T cell antigen receptor. In addition, PHA binds to a member of the CD3 complex that is noncovalently associated with the T cell antigen receptor. Finally, PHA has been shown to bind to the sheep erythrocyte receptor termed CD2. Monoclonal antibodies to each of these determinants have the capacity to trigger T cell activation under certain circumstances. Thus, it appears likely that at least a portion of the activation signal is related to its ability to bind these determinants. Since PHA is a multi-

valent lectin, it is expected that PHA would not only bind T cell surface glycoproteins, but that it would cross-link these molecules as well. It has been demonstrated the CD3 must be cross-linked to generate an activation signal. Thus, the multivalent nature of PHA is likely to play an important role in its ability to trigger T cell activation. Recently, several studies have demonstrated that cross-linking CD3 together with a variety of other T cell surface molecules, including CD2, CD4, CD8, CD11a/CD18 (LFA-1), and class I major histocompatibility complex (MHC) molecules, generates an activation signal that is more potent than simply cross-linking CD3. The data suggest that the mechanism whereby PHA stimulates T cell activation is by engaging and cross-linking cell antigen receptor complex together with other T cell surface molecules.

The role of accessory cells in PHA-induced T cell activation is not clear. It has been suggested that one function of accessory cells is to bind PHA via surface glycoproteins and provide a matrix whereby PHA cross-links various T cell surface molecules. A similar function for accessory cells has been described for T cell activation induced by monoclonal antibodies to the T cell antigen receptor complex. This provision of a cellular matrix whereby PHA might cross-link various T cell surface molecules cannot completely explain the role of accessory cells, however, and other mechanisms have been proposed. These include a putative role for additional signals provided by direct contact between accessory cells and T cells and for soluble factors secreted by accessory cells such as interleukin 1 or tumor necrosis factor.

PHA remains an important investigative tool in immunology today. It is one of the most potent T cell mitogens. Moreover, it stimulates T cells in a manner that promotes their long-term growth. Thus, T cells can be cloned with nearly 100% cloning efficiency from the peripheral blood using PHA as the stimulus and these cell lines can be maintained for months with repeated stimulation. This technique

has recently been utilized to clone T cells from inflammatory tissue sites with a similar cloning efficiency. These techniques should facilitate the study of T cells that are involved in the pathogenesis of inflammatory diseases.

PICORNAVIRUS, INFECTION AND IMMUNITY

Nicholas J Knowles, Institute for Animal Health, Pirbright Laboratory, Woking, Surrey, UK

Trevor Collen, Institute for Animal Health, Compton Laboratory, Newbury, Berkshire, UK

Characteristics of the organism and its antigens

Picornaviruses are small icosahedral viruses with a diameter of 30 nm. They lack a lipid envelope and

comprise a 7–9 kb, single-stranded, monopartite RNA genome surrounded by a 35–70 Å thick protein shell. This capsid comprises 60 copies each of three major polypeptides (1B, 1C and 1D, alternatively named VP2, VP3 and VP1, respectively) and one

minor polypeptide (1A or VP4). The virus genome contains a single open reading frame coding for a polyprotein of approximately 240–250 kDa (Figure 1). The polyprotein is commonly described in an L-4-3-4 format in which an optional leader (L) polypeptide is followed by the four structural proteins (P1 region) and seven nonstructural proteins (P2 and P3 regions). Primary cleavages are between these units and are mediated by virus-encoded proteases. The polyprotein coding region is flanked on both sides by untranslated regions (UTRs). The 5' UTR is exceptionally long (approximately 600–1200 bases) and contains structures important for replication and cap-independent translation; in some members of the family a long poly-C tract separates these domains. The 5' end of the genome is uncapped; however, a small virus-encoded protein (VPg) is covalently attached. The 3' end of the genome is polyadenylated. Virion properties such as heat and acid stability can vary greatly.

The picornaviruses of vertebrates are divided into five genera: *Enterovirus*, *Rhinovirus*, *Cardiovirus*, *Aphthovirus* and *Hepatovirus*, based on their physicochemical and biological properties (Table 1). Recent analyses of complete genome sequences have shown that a number of picornaviruses require reclassification; 1) echovirus types 22 and 23 represent two species within a new genus, provisionally named *Parechovirus*; 2) equine rhinovirus type 1 is a possible new member of the *Aphthovirus* genus; and 3) equine rhinovirus type 2 should probably be classified as a new genus.

Within each genus there exist between two and >100 species which normally equate to serotypes. Generally, there is little cross-protection by viruses of different species, even within the same genus or subgroup.

The antigenic sites of picornaviruses are located on the exterior of the capsid and comprise a small number of amino acids derived either from a linear seg-

ment of polypeptide or, more generally, by the folding together of different regions of one or more of the three major structural proteins to form a discontinuous epitope. A number of epitopes have been defined and studied extensively in poliovirus (PV), human rhinovirus (HRV), mengovirus (a strain of encephalomyocarditis virus, EMCV), Theiler's murine encephalomyelitis virus (TMEV), and foot-and-mouth disease virus (FMDV) by the use of monoclonal antibody-resistant mutant viruses. Some picornaviruses show extreme antigenic variability (e.g. HRV and FMDV), whereas others are more stable (e.g. PV and HAV).

Picornavirus infections and vaccination using attenuated or chemically inactivated intact virus induce serological responses to some or all of the nonstructural proteins. The presence and specificity of serum antibody to nonstructural polypeptides is diagnostic for exposure to virus (anti-3D) and to distinguish responses elicited by infection from those of inactivated virus vaccination (anti-2C/3A).

Picornaviruses replicate in the cytoplasm of cells and entry is effected by receptor-mediated endocytosis. After replication, the progeny virus is released by lysis of the cell. The cellular receptors for HRV and PV have been cloned and sequenced (Table 2). The receptor for the major HRV group is ICAM-1 and for PV it is an unidentified member of the integrin/immunoglobulin supergene family. In the entero- and rhinoviruses a deep 'canyon' runs around the fivefold axis of the virus capsid. The cellular receptor is able to penetrate and bind to amino acids within this canyon; however, antibody molecules are too large to fit and thus cannot be directed against this conserved structure. Recently receptors for many other human enteroviruses (DAF, VLA-2, $\alpha_v\beta_3$ -integrin) and the minor HRV group (LDLR and $\alpha 2\text{MR/LRP}$) have been described. The cardioviruses appear to have a series of depressions

Figure 1 Generalized picornavirus genome map. The leader polypeptide is present in cardioviruses, aphthoviruses and equine rhinoviruses, however, it is a protease only in the latter two. A poly-C tract is present in aphthovirus, equine rhinoviruses and some cardioviruses. The P1/P2 cleavage occurs at the N-terminal end of 2A in entero- and rhinoviruses and at the C-terminal end in all other genera. Aphthoviruses have three VPg (3B) genes as tandem repeats.

Table 1 The picornaviruses

<i>Genus</i>	<i>Subgroup (serotype = species)</i>	<i>Examples of diseases associated with each group</i>
<i>Enterovirus</i>	Human poliovirus types 1–3	Acute anterior poliomyelitis
	Human coxsackievirus group A types 1–22, 24	Herpangina; paralytic disease; aseptic meningitis; encephalitis, ataxia; hand, foot and mouth disease; acute hemorrhagic conjunctivitis
	Human coxsackievirus group B types 1–6	Epidemic pleurodynia; aseptic meningitis; paralytic disease; encephalitis; myocarditis; hand, foot and mouth disease; swine vesicular disease
	Human echovirus types 1–7, 11–21, 24–27, 29–33	Aseptic meningitis; encephalitis; ataxia; paralytic disease; diarrhea
	Human enterovirus types 68–71	Hand, foot and mouth disease; acute hemorrhagic conjunctivitis; paralytic disease
	Simian enterovirus types 1–18	Neurological disease (?)
	Porcine enterovirus types 1–13+	Infectious porcine encephalomyelitis (Teschen disease); diarrhea; reproductive failure
<i>Rhinovirus</i>	Bovine enterovirus types 1–2	
	Human rhinovirus types 1–100	Common cold
<i>Cardiovirus</i>	Bovine rhinovirus types 1–3	Respiratory disease
	Encephalomyocarditis virus	Myocarditis; reproductive failure
	Theiler's murine encephalomyelitis virus	Paralysis; chronic demyelinating disease
<i>Aphthovirus</i> (proposed member)	Vilyuisk human encephalomyelitis virus	Encephalomyelitis
	Foot-and-mouth disease virus (7 types)	Food-and-mouth disease; myocarditis
<i>Hepatovirus</i>	Equine rhinovirus type 1	Upper respiratory tract illness
	Human hepatitis A virus	Infectious hepatitis
<i>Parechovirus</i> 'possible genus'	Simian hepatitis A virus	Infectious hepatitis
	Human echovirus types 22 and 23	Diarrhea
Unclassified/candidate picornaviruses	Equine rhinovirus type 2	Upper respiratory tract illness
	Equine rhinovirus type 3	Upper respiratory tract illness
	Acid-stable equine picornavirus	Upper respiratory tract illness
	Avian encephalomyelitis virus	Encephalomyelitis (epidemic tremors)
	Duck virus hepatitis types I and III	Hepatitis
	Picorna-like virus of harbor seals	
	Avian nephritis virus (3 types)	Nephritis
	Avian picorna-like viruses (~12)	Runting syndrome, hepatitis, pancreatitis, enteritis
	Fish picorna-like viruses	Encephalomyelitis
	Insect picorna-like viruses (at least 30 types)	Paralysis

or pits surrounding the fivefold axis and these may be involved in receptor binding. At least one receptor, VCAM-1, has been identified on susceptible cells. In the case of FMDV, which lacks the pit or canyon, a different mechanism for receptor binding has been postulated. This involves the binding of a flexible loop, containing an Arg-Gly-Asp (RGD) tripeptide, to the vitronectin receptor, $\alpha_v\beta_3$ -integrin. Other similar integrins are also thought to be candidate receptors for FMD viruses. Amino acid sequences surrounding the RGD tend to be variable, allowing immune evasion. The involvement of heparan sulfate in the initial binding of FMDV to cells has also been reported.

Most picornaviruses infect via the mouth or nose, although direct infection of target tissue such as skin (e.g. foot-and-mouth disease and swine vesicular disease) or the eye (e.g. acute hemorrhagic conjunctivitis) can also occur. Some picornaviruses replicate in the pharynx (rhinoviruses and aphthoviruses), whereas others traverse the alimentary tract to infect the gut (enteroviruses and cardioviruses). Viremia may occur, thus allowing transport of the virus to other target organs or tissues such as the central nervous system (e.g. polioviruses) or liver (hepatitis viruses).

Table 2 Cell surface receptors used by picornaviruses

Genus	Virus	Receptor
<i>Enterovirus</i>	PV-1, PV-2, PV-3	PVR (first domain) CD44 ^a
	CV-A13, CV-A15, CV-A18, CV-A21	ICAM-1 (first domain)
	CV-A2, CV-A5	Not known
	CV-A9	$\alpha_v\beta_3$ (VNR) and a second unknown ^b
	CV-B1 to B6	Not known (46–49 kDa)
	CV-B1, CV-B3, CV-B5	DAF (CD55) and $\alpha_v\beta_6$ ^c
	EV-1, EV-8	VLA-2 (α_2 chain)
	EV-3, EV-6, EV-7, EV-11, EV-12, EV-20, EV-21	DAF (CD55)
	Enterovirus 70	DAF (CD55)
<i>Rhinovirus</i>	HRV-major receptor group (90 species)	ICAM-1
	HRV-minor receptor group (9 species)	LDLR and α_2 MR/LRP
	HRV-87	Sialylated membrane protein
<i>Cardiovirus</i>	Encephalomyocarditis virus	VCAM-1
	Encephalomyocarditis virus	Sialoglycoprotein(s) (70 kDa)
	Encephalomyocarditis virus	Glycophorin A ^d
	Theiler's murine encephalomyelitis virus	Not known (34 kDa and 90 kDa)
<i>Aphthovirus</i>	Foot-and-mouth disease virus (7 species)	$\alpha_v\beta_3$ (possibly others) ^e
	(Proposed member) Equine rhinovirus 1	2 polypeptides (>200 kDa)
<i>Hepatovirus</i>	Hepatitis A virus	α_2 -Macroglobulin
	Hepatitis A virus	HAVcr-1
<i>Parechovirus</i>	EV-22, EV-23	Integrin (possibly $\alpha_7\beta_1$ or $\alpha_7\beta_3$)
Unclassified	Equine rhinovirus 2	Not known (100–150 kDa)

^aCD44 (lymphocyte homing receptor) is a possible cofactor in poliovirus attachment.

^bCV-A9 has an extension to the C-terminal end of VP1 containing an integrin-binding RGD tripeptide; this extension can be removed by enzymatic cleavage. In some cells cleaved virus is able to use an alternative receptor which presumably attaches to another site (the canyon?) on the virus surface.

^cThe integrin $\alpha_v\beta_6$ is a possible cofactor.

^dOn human erythrocytes.

^eInvolvement of heparan sulfate in binding has been reported for FMDV-O.

PV, poliovirus; CV, coxsackievirus; EV, echovirus; HRV, human rhinovirus; PVR, poliovirus receptor (possibly NCAM-like); LDLR, low density lipoprotein receptor; α_2 MR/LRP, α_2 -macroglobulin receptor/LDLR-related protein; VLA-2, very late antigen 2; VNR, vitronectin receptor; DAF, decay-accelerating factor (CD55; a glycosylphosphatidylinositol-anchored complement regulatory protein); ICAM-1, intercellular adhesion molecule 1; NCAM, neural cell adhesion molecule; VCAM-1, vascular cell adhesion molecule 1; HAVcr-1, hepatitis A virus cellular receptor 1 (mucin-like class I integral membrane glycoprotein).

Immune responses of the host

Neutralizing antibodies play an important role in protection against picornaviruses since passively transferred and vaccine-induced antibodies can abrogate virus replication and disease progression. The early immunoglobulin M (IgM) response is less specific than later IgG and IgA responses. Infection by a number of different serotypes of the same group of viruses can induce antibodies which cross-react between a wide range of serotypes. Equally, epitopes conserved between viruses of the same or different genera induce cross-reactive responses. Virus neutralization by antibody occurs via Fc receptor-mediated endocytosis (opsonization) and/or interactions which prevent virus penetration and uncoating or cause lethal RNA unpackaging (disablement). In some situations opsonization may actually promote infection of Fc receptor-positive cells although the virus yield and cell types involved are unlikely to be

sufficient to sustain clinically important productive infection.

The paradigm of antibody-mediated protection against picornavirus infection has now been challenged by the demonstration that adoptive transfer of CD4 T cells can protect from lethal cardiovirus-induced disease in the absence of any detectable antibody response. Picornavirus infections induce a wide range of cell-mediated immune responses (e.g. T cell help, delayed-type hypersensitivity (DTH), cytotoxic T lymphocyte (CTL) and natural killer (NK)-like activity) with concomitant production of cytokines (e.g. interferon γ (IFN γ), interleukin 2 (IL-2), IL-4, IL-5, IL-10, IL-12, tumor necrosis factor α/β (TNF α/β)) thereby regulating virus load, antibody responses, and the expression of accessory molecules such as major histocompatibility complex (MHC), immunoglobulin supergene family, integrin and virus receptor molecules. Epitopes recognized by CD4 and CD8 T cells have been identified in mice (e.g.

PV, poliovirus; CV, coxsackievirus; SVDV, swine vesicular disease virus; HAV, hepatitis A virus; EMCV, encephalomyocarditis virus; TMEV, Theiler's murine encephalomyelitis virus; FMDV, foot-and-mouth disease virus.

Adapted from Usherwood and Nash (1995).

CV-B3, HRV-2, PV-1, PV-3, EMCV, TMEV), humans (PV-1) and cattle (FMDV) (Table 3). In some picornavirus infections (e.g. CV-B, HAV, TMEV), T cell responses contribute to the immuno-

pathological sequelae such that depletion of T cell subsets can ameliorate clinical disease. The T cell receptor (TCR) repertoire of T cells infiltrating pathogenic lesions can show restricted V $_{\alpha}$ and V $_{\beta}$,

gene usage, suggesting that the target is a specific antigen.

Some picornaviruses can establish persistent infections in the throat (FMDV, equine rhinoviruses), CNS (TMEV), or muscles (enteroviruses). The role of the immune system in maintaining or controlling persistence is not yet understood. However, CD4 T cell-depleted mice infected with TMEV fail to produce antibody and to clear virus from the CNS. TMEV antigens have been used to induce split tolerance affecting the T_H1 subset function, suggesting that inappropriately regulated immune responses, which would include infection of cells in privileged sites, such as the eye and salivary glands, may contribute to the establishment of persistence.

Evasive strategies by the organism

Evasion of the immune system by picornaviruses is primarily by antigenic variation of neutralizing antibody epitopes but may also involve variation at T cell sites/MHC-binding motifs leading to compromised help for humoral immune responses and cell-mediated killing of infected cells. However, persistent infections may be another mechanism by which these viruses can survive in the presence of circulating antibody. Hepatitis A virus appears to be antigenically very stable and little is known about how this virus may evade the immune response. Antigenic epitopes lie on the surface of the virus and are generally located on the loops which join β sheets. These loops are less constrained in both amino acid type and length. Many of these epitopes have been mapped by sequence analysis of monoclonal antibody neutralization-resistant mutant viruses.

Vaccines

Vaccines against picornaviruses rely upon the induction of neutralizing antibodies in the host by the inoculation of either attenuated live virus or chemically inactivated intact virus. Successful inactivated (Salk) and attenuated (Sabin) cell culture vaccines have been used since the early 1950s against all three serotypes of poliovirus. Similar success has been achieved for avian diseases (duck virus hepatitis and avian encephalomyelitis). Inactivated FMDV vaccines are widely used but can sometimes be of limited value because of rapid antigenic variation within serotypes; attenuated FMDV vaccines have been of little use due to rapid reversion to virulence. A more extreme problem exists for HRV which numbers at least 100 serotypes and for which no vaccines are available.

Recent advances in the molecular biology of picor-

naviruses has led to the identification of many of the antigenic sites recognized by neutralizing antibodies. Short linear peptides representing some of these sites have been evaluated as subunit vaccine antigens for several picornaviruses. Protection using peptide antigens has proved elusive despite the capacity of the antigens to elicit neutralizing antibodies in model and natural hosts. It is now clear that in addition to antibody such antigens must also elicit CD4 and CD8 T cell effector responses and that the target antigens for these cells could be derived from non-structural or structural proteins. Furthermore, T cell epitopes will need to have promiscuous MHC binding to confer maximum efficacy in outbred species. Effective delivery of these sequences will also need to be solved. The use of poliovirus as a vector to carry small antigenic peptides of unrelated viruses (e.g. human immunodeficiency virus and human papillomavirus) either within their own natural antigenic sites or as extragenomic information has also been described. An effective vaccine has recently been developed for hepatitis A virus. Poliovirus vaccines have been improved by the specific introduction of additional attenuating mutations, although they are not currently in use.

Restricted TCR gene usage by infiltrating lymphocytes from some picornavirus disease lesions also introduces the possibility to prevent or treat T cell-mediated tissue damage (e.g. myocardium, pancreas) through specific immunotherapy.

Resolution of the three-dimensional structures of a number of human rhinoviruses has enabled the design of specific antiviral drugs which bind in a pocket beneath the canyon and inhibit viral uncoating; however, their use may be limited by the ease with which drug-resistant mutants are generated.

PLAQUE-FORMING CELL (PFC) ASSAYS

Hans-Michael Dosch, Departments of Pediatrics and Immunology, University of Toronto, The Hospital for Sick Children, Toronto, Ontario, Canada

Hemolytic plaque assay procedures

Developed in the early 1960s, hemolytic plaque assays are among the most sensitive biological measurement procedures. In principle, these assays resemble plaque techniques for the detection of bacterial viruses. Typically, agar-embedded (see below for variations) erythrocyte suspensions are mixed with lymphocyte populations which contain relevant B lineage cells. If these cells secrete antibody to antigenic determinants present on the surface of target red blood cells, the antibody will bind first to the nearest cells and then to erythrocytes further away. In the presence of a source of complement (usually rabbit or guinea pig serum), antibody-coated red cells lyse. Thus, after ~6–12 h incubation (1–3 h in the thin-/monolayer techniques, see below), the result is formation of clear zones where erythrocytes have been lysed, and in the center of the zone is the single antibody-producing cell.

To facilitate the lytic function of antibodies that are not able to or inefficient in complement fixation (e.g. immunoglobulin G, IgG), addition of a secondary (e.g. goat anti-IgG) antibody will 'develop' such 'indirect' plaque-forming cell (PFC) assays (Table 1). If only secondary (e.g. IgG/IgA) responses are to be evaluated, it is possible to prevent the formation of 'direct' (IgM-mediated) plaques by the inclusion of 2-mercaptoethanol in the assay mixture. An excellent and extensive review of PFC assay techniques used in rodent research has been written by its inventor, Niels Jerne, and updates have been published by colleagues in his institution (see Further reading).

Numerous antigens and haptens have been conjugated to various red cells to serve as specific antigen, and the assay lends itself to functional estimates of affinity through, for example, titration of the amount of free hapten required for blockade of 50% of PFCs. However, since such blocking procedures also titrate the amount of antibody, i.e. secretory rates, and

Table 1 Key words and terms

<i>Term</i>	<i>Definition</i>
PFC	Hemolytic plaque-forming cell: a B lineage cell which secretes antibody that binds to epitopes present on surrounding erythrocytes; if the antibody can fix complement added to the assay, a zone of hemolysis is formed around the secretory B cell.
Direct PFC	If the antibody produced by the PFC is of the IgM class, the added complement directly mediates lysis of surrounding red blood cells. Theoretically, a single, bound IgM molecule is sufficient for the lysis of a red cell.
Indirect PFC	If the antibody produced by the PFC is not of the IgM class (e.g. IgG, IgA) then a 'secondary' (or developing) antibody (e.g. goat anti-IgG, rabbit anti-IgA) is added late during the assay to achieve more efficient complement activation on target erythrocytes.
Fluid-phase PFC assays	Reduction of plaque assay volumes by omission of the agarose gel. The first of these assays ('Cunningham assay') uses hemocytometer chambers and coverslips to suspend appropriate mixtures of lymphocytes (i.e. PFCs) and target red blood cells. To avoid physical disturbance of these mixtures, another procedure uses red blood cell monolayers fixed to the bottoms of 96-well microtiter plates with poly-L-lysine. Relevant lymphocyte/complement mixtures are added to monolayers and close red cell/white cell contact can be achieved by gentle centrifugation.
Reverse PFC assays (rPFC)	Nonantigen-specific version of indirect plaque assays where the target red blood cells are conjugated with anti-Ig antibody (e.g. anti-IgG, anti-IgA or polyvalent antibody). One variation uses protein A instead of anti-Ig. A nearby B cell secreting an antibody of the relevant class becomes a plaque-forming cell as its Ig product is bound to the red blood cell surface. rPFC assays permit studies of polyclonal B cell activation. This assay can be modified to detect the secretion of molecules other than Ig.
ELISPOT assays	Reminiscent of rPFC. Replacement of conjugated erythrocytes with an enzymatic detection system typical of ELISA procedures allows enumeration of cells secreting molecules of interest such as specific cytokines. Instead of red cells, the primary (capture) antibody is coated to plastic and cells are incubated on top. Following addition of enzyme-conjugated secondary antibody and enzyme substrate, secretory cells are enumerated as dark spots surrounding a single lymphocyte.

since secretory rates can vary by orders of magnitude within a given immune response induced, results of hapten inhibition studies must be interpreted with caution.

The size of hemolytic zones is related to antibody affinity and secretory rate, but accurate measurements are cumbersome and have not been rigorously examined with cloned cell sources. Given that a single IgM molecule can fix one C1q complement molecule to the red cell surface and that this is sufficient for the formation of a lytic site, there is little doubt that hemolytic plaque assays are of exquisite sensitivity. The actual sensitivity is somewhat lower, probably due to antibody loss in the three-dimensional assay space, but cells secreting in the order of a few thousand antibody molecules per hour are clearly detectable.

Methodological variations of PFC assays

A number of variations of the original hemolysis-in-gel (agarose) procedure have been described with the goals to improve cell survival in the assay system, reduce the cell number and materials requirements and increase practical assay throughput and, perhaps, sensitivity. Agarose is still used extensively as

the plaquing medium but smaller assay vessels than standard Petri dishes (e.g. slides) are now being used more often. The development of efficient microcultures generated a need for micro-PFC assays. The first such modification was Cunningham's fluid phase assay that used red blood cell/lymphocyte mixtures suspended in hemocytometer chambers. In this procedure PFCs are read microscopically. It requires small cell numbers and eliminates the need for a solid carrier medium. One potential drawback of the procedure is the danger of accidental resuspension which, of course, obscures the round lytic zones.

Modified plaque assays were further developed under Cunningham's influence in Toronto, including a solid-phase procedure, and its micromodification which permitted fast (1 h) PFC assays in 96-well formats using very small numbers of cells (e.g. limiting dilution microcultures). In this procedure, monolayers of red blood cells, modified with haptens or unmodified, are immobilized on plastic surfaces with poly-L-lysine. To ensure intimate contact, lymphocytes are sedimented on to that monolayer by centrifugation. Small volumes of medium and complement are added with the lymphocyte preparation. Plaques in this system develop quickly but often are small

and a specific role of the poly-L-lysine itself modifying antibody release was suggested. A majority of experiments dealing with antigen-specific *in vitro* responses of human lymphocytes have used this system. Although successful in several laboratories these modifications were overall 'tender' techniques which are rarely used today.

Another, rather important development was the introduction of 'reverse' hemolytic PFC assays. This procedure is in essence the reverse of an indirect PFC technique where the secondary (developing) antibody becomes the primary reagent covalently coupled on to the surface of target erythrocytes. Any secretory B cell releasing an Ig bound by these anti-Ig-coated target red blood cells will now become a PFC. This is a rapid and elegant procedure for studies of polyclonal B cell activation, in particular in the human system where B cell activation has been less easily achieved and manipulated.

Reverse PFC assays have been further modified for the detection of cells secreting proteins other than Ig, broadening applications for this sensitive procedure beyond B lymphocyte studies. The latest of these modifications is a departure from the use of indicator erythrocytes and their replacement with an ELISA-type enzymatic read-out system. These ELISPOT assays are now increasingly used for the enumeration of T cells secreting T_H1 - or T_H2 -type cytokines. Reminiscent of rPFC assays, plastic dishes or plates are coated with an antibody specific for the cytokine of choice, T cells (fresh or stimulated) are added in culture medium, and the secreted cytokine is captured by the plastic-bound antibody. After some hours of incubation, the assays are developed through addition of enzyme-coupled secondary antibody to the cytokine. In the presence of relevant enzyme substrate, round areas of enzymatic activity (usually dark spots) are counted microscopically, each corresponding to one T cell producing the particular cytokine of interest.

Application of PFC assays

PFC procedures have long been a mainstay of cellular immunology research. Developed prior to the advent of high-sensitivity immunoassay procedures for secreted antibodies, the vast majority of early fundamental research into cellular aspects of humoral immune responses employed hemolytic plaque assays. PFC assay procedures turned out to be overall very robust, reproducible and practical. Although a high throughput screening method has been described (hemolytic drop procedure), the principal drawback of PFC assays is the need for visual inspection of each plaque. This reduces the number of vari-

ables that can be practically monitored and stands in some contrast to the now quite efficient tissue culture methods for multiple microcultures.

A computer-directed on-line literature search yielded over 3000 PFC papers published from 1970 to 1980. This number declined in the following decade to ~1000, with a majority published in the earlier 1980s. Besides the current expansion of molecular approaches towards cellular immunology research, this primarily reflects the development of more and more versatile and sensitive immunoassays which can easily be automated and require less experimental effort, in particular in processing larger sample numbers. The use of ELISPOT assays, however, is on the upswing.

The exquisite sensitivity of hemolytic plaque assays can become a drawback. For example, antibody present in serum or culture fluids and binding to leukocyte Fc receptors can easily be transferred to PFC assays. These Igs may be released to form a plaque; as well, small conglomerates of antibody-coated red cells used as antigen in preassay culture systems can be transferred to the assay system and produce small 'pseudoplaques' without a central leukocyte. Inclusion of controls such as cycloheximide (to block *de novo* protein synthesis) can point to such artifacts, since pseudoplaques obviously do not involve newly synthesized Ig. Fc receptor binding/release of Igs was exploited in the development of plaque assays for the characterization of Fc receptors on lymphoid and nonlymphoid cells.

PFC assays measure several aspects of the total cellular immune response induced in a given experiment, i.e. the product of clonal recruitment, clonal expansion and activation of enhanced antibody secretory rates. However, and in contrast to immunoassays of secreted immunoglobulin accumulation in supernatants, PFC assays detect only those cells which secrete their antibody *during the assay period*.

When combined with limiting dilution-type protocols, PFC precursor cell recruitment and clonal expansion can be distinguished and employed for estimates of response diversity. However, neither the PFC nor the immunoassay approach permit a complete analysis and understanding of a given immune response. For example, the induction of few, very high-rate Ig secretors may represent a 'large' secretory immune response, while enumerating the number of secretory cells in PFC assays would suggest a 'small' response – and vice versa.

This is illustrated in **Figure 1** which summarizes typical results of limiting dilution experiments with hapten carrier-stimulated human lymphocytes. When PFC assays were used in such experiments, it was

Figure 1 Measurements of B cell recruitment, clonal expression and activation of antibody secretion: cellular PFC and innoval (ELISA) assays generate different conclusions. Limiting dilution cultures of human blood or tonsil lymphocytes were stimulated with TNP-ovalbumin in the absence (■) or presence (□) of high-dose (100 µg ovalbumin per 24 h) primed, purified T cells. Cultures were assayed by hemolytic plaque assay for the frequency of TNP-specific PFC precursor cells and for the clone size present in positive cultures. A TNP-specific ELISA was used to measure specific antibody accumulated in supernatants over the 1-week culture period.

found that high-dose carrier (e.g. ovalbumin)-primed T cells appeared to actually reduce the optimal response of blood or tonsil cell cultures by 94–98% (Figure 1, columns 1 and 2, log scale). Closer analysis revealed that the few clones escaping this apparent suppression had much larger clone sizes (4–8-fold, columns 3 and 4). However, when immunoassays (e.g. ELISA) were used to measure specific antibodies secreted in these cultures, the suppressive effect of high-dose carrier-primed T cells was no longer apparent, since in addition to differential promotion of clonal expansion, these regulatory cells promoted higher secretory rates in these clones ($\sim 2\text{--}3 \times 10^4$ molecules cell⁻¹ h⁻¹). These latter two parameters are closely linked and vary concordantly during B cell maturation. Thus, depending on the assay system employed, such experiments may generate literally opposite conclusions.

It is therefore clear that the choice of assay system for immune responses can dramatically affect understanding and interpretations: in the given example, the apparent suppressor function following high-dose carrier priming identified in the PFC assay is not really reducing an immune response. Instead, these T cells recruit a clonally restricted portion of the hapten-specific B cell repertoire and promote its maturation more effectively. It is interesting to note that severe reduction of such apparent suppressor

cell function induced with high doses of protein antigen is typical for a number of autoimmune conditions.

PLASMA

Edward L Snyder, Yale University School of Medicine and Blood Bank/Apheresis Service, Yale-New Haven Hospital, New Haven, Connecticut, USA

Joan Judge, Department of Pathology, Norwalk Hospital, Norwalk, Connecticut, USA

Plasma is the noncellular fraction of blood which transports red cells, white cells and platelets. It is an aqueous solution of salts, proteins, lipids, sugars and various other substances serving a myriad of physiological functions. Plasma is obtained for clinical use either by centrifugation of anticoagulated whole blood and collection of the supernatant or as source plasma from a plasmapheresis program (see below). If plasma is allowed to clot, the residual liquid is called serum. Essentially, serum is plasma minus the clotting factors V, VIII and fibrinogen which are consumed during clot formation.

Plasma was first used as a treatment for shock in the 1930s after the development of sodium citrate anticoagulant made possible the separation of cellular blood components from plasma by centrifugation. After the development of lyophilization techniques, plasma from many donor units could be pooled and stored for an indefinite period at room temperature as a freeze-dried preparation to be reconstituted later with sterile water. Because pooled plasma was found to be associated with a high risk of viral transmission, in particular hepatitis B, this pooled lyophilized product is no longer used in current medical practice when plasma is needed. Rather, single donor units of fresh frozen plasma have become the standard therapeutic component. Given the small amount of some blood proteins in plasma, such as coagulation factors, obtaining commercial quantities of coagulation factor concentrates still

requires use of large pools of source plasma. These products, however, generally undergo one or more viral inactivation steps during processing.

In the early 1900s, serum was used medically as a source of immunoglobulins to treat infections including diphtheria, rabies, anthrax and tetanus. The first immune serums to be used were collected from naturally or artificially infected cattle or sheep; however, the frequency of anaphylactic reactions to these products, after the first injection, made them unsuitable for most human uses. Today, purified human immunoglobulins are available and serum is used mainly as a diagnostic laboratory reagent and in tissue culture media.

Plasma composition

Some of the normal constituents of human plasma are listed in Table 1. Proteins make up 6% of plasma weight; all other constituents make up 2%. Plasma serves as a vehicle for transportation and exchange of cells, nutrients and gases. Importantly, plasma is in dynamic equilibrium with the extravascular and intracellular spaces. Tissue oncotic pressure and capillary hydrostatic pressure, which tend to move fluid out of the intravascular space, are counterbalanced primarily by plasma protein oncotic pressure pulling fluid into the intravascular space. Albumin, a relatively small (60 kDa) globular protein manufactured by the liver, is the major plasma protein

Table 1 Some components of human plasma

Constituent	Normal concentration

Uric acid		5
Bilirubin		1

Total plasma volume: 3.2 litres (70 kg adult); 4.5% of body weight.

responsible for maintaining intravascular volume. Although it makes up only half of the protein mass, it provides 80% of the oncotic pressure. Patients with acquired hypoalbuminemia due to malnutrition, malabsorption, liver disease, protein-losing enteropathy or nephropathy, or burns develop peripheral edema when the albumin concentration falls to about half its normal value (<1.5 g dl⁻¹). Curiously, patients with congenital analbuminemia usually do not manifest this symptom, presumably because of a compensatory increase in other plasma proteins.

Immunoglobulins (Igs) as a class represent 15% of the total plasma proteins. They are produced by mature B lymphocytes, or plasma cells in a variety of molecular forms separable by electrophoresis and designated IgG, IgM, IgA, IgE and IgD. They are vital components of the immune system, being responsible for the recognition and opsonization of foreign antigens. Transport proteins, including albumin, transferrin and lipoproteins, are responsible for solubilizing hydrophobic moieties such as steroids and fats to permit their rapid distribution. They also serve to bind potentially toxic metabolites, such as

bilirubin, iron, exogenous drugs or poisons, thereby preventing peripheral tissue uptake and accelerating excretion.

That blood is able to remain liquid despite its ability to coagulate rapidly after damage to a blood vessel is due to a balance between opposing sets of plasma proteins: those initiating coagulation and those promoting fibrinolysis. The clotting factors (II, V, VII–XIII) form a cascade of activation that terminates in the precipitation of stable insoluble multimers of fibrin from its precursor fibrinogen. The fibrinolytic system degrades fibrin and interferes with several steps in the cascade. Together the two systems interact to produce normal hemostasis.

The major plasma electrolytes, listed in Table 1, serve to regulate total body water balance, maintain the transport and conduction properties of membranes, and mediate the resorption and reformation of bone. The pH of plasma is kept within a narrow range of about 7.35–7.45. This permits adequate binding with, and dissociation of oxygen from, hemoglobin, as well as optimizing many other pH-dependent physiologic reactions. Although overall acid–base balance is dependent on renal and pulmonary function, it is the buffering capacity of the plasma provided by bicarbonate and, to a lesser extent, by phosphate, sulfate and proteins, which stabilizes the system against transient fluctuations.

Plasma is responsible for the bulk transport of red cells and platelets, blood elements which function primarily within the vascular spaces. Plasma also carries white cells which are in transit between reticulo-endothelial and tissue sites. Plasma transports dissolved atmospheric gases such as oxygen, carbon dioxide and nitrogen, as well as anesthetic gases during surgery. Nutrients in the form of sugars, amino acids and fatty acids are transported from sites of absorption or storage to the tissues, and wastes such as urea and organic acids are carried to the excretory organs. Present in minute but critical amounts are the many blood-borne hormones, including those from the pituitary (gonadotropins, growth hormone, adrenocorticotrophic hormone, thyroid-stimulating hormone), the kidney (erythropoietin), the adrenals (aldosterone, epinephrine (adrenaline)), and the gonads (testosterone, estrogen, progesterone). In addition, there are literally hundreds of enzymes, interleukins, growth factors, biological response modifiers and a great number of as yet uncharacterized substances in the plasma. Although synthetic volume expanders exist (i.e. colloid solutions such as dextran and hydroxyethyl starch), the complexity of the nature and functions of plasma make it unlikely that a synthetic substitute which can truly mimic the

many functions of plasma will be developed in the foreseeable future.

Clinical uses

Fresh frozen plasma

A 'unit' of plasma is defined as that volume of plasma (180–270 ml) separated from a single unit (450 ml) of anticoagulated human whole blood. The therapeutic component fresh frozen plasma (FFP) is plasma separated from donated whole blood and frozen at -18°C within 8 hours of donation. When processed in this fashion, FFP maintains labile as well as stable coagulation factors in concentrations essentially equal to that of fresh whole blood for up to 1 year with proper storage (below -18°C). When plasma is stored in the liquid form at $1-6^{\circ}\text{C}$, the labile clotting factors V and VIII begin to deteriorate within hours; consequently liquid stored plasma is generally not used to treat clinical coagulopathies. Although individual factor concentrates are available, many clinical situations require the replacement of multiple clotting factors, thereby making FFP the therapeutic component of choice.

The primary indication for administration of FFP is to increase the level of coagulation factors in patients with a documented deficiency (i.e. prolonged prothrombin time (PT)/partial thromboplastin time (PTT)). FFP transfusion as replacement therapy may be indicated when there is a deficiency in a single factor for which a factor concentrate is not available, when a specific factor deficiency has not been determined, or when multiple factors have been depleted, as in hepatic failure or disseminated intravascular coagulation (DIC). Other indications for use of FFP include rapid reversal of warfarin sodium therapy, and as the replacement fluid during plasmapheresis for thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS). FFP should not be used as a volume expander, as a nutritional supplement, or prophylactically either for massive transfusion or following cardiopulmonary bypass. Aside from use in TTP or HUS, FFP is rarely indicated for use as a replacement fluid for plasmapheresis; 5% albumin in normal saline (0.9%) should be used instead. FFP dosage depends on which factors are depleted and the patient's plasma volume.

Cryoprecipitate

Cryoprecipitate is the cold-insoluble precipitate which is formed when a unit of FFP is thawed between 1 and 6°C . This precipitate is collected by centrifugation, refrozen and stored at -18°C for up

to 1 year. It contains predominantly factor VIII (80 units, with a unit of factor VIII being defined as that amount of factor contained in 1 ml normal plasma), fibrinogen (150 mg), factor XIII and von Willebrand factor. Consequently, cryoprecipitate is used as replacement therapy in patients deficient in these components (i.e. patients with classic hemophilia, or dysfibrinogenemia). As fibrinogen is depleted in DIC, cryoprecipitate may be used as a concentrated source of fibrinogen along with standard FFP therapy in the management of this coagulopathy. Use of cryoprecipitate alone in the management of DIC is inadequate, given the lack of factor V in this product.

Other uses of cryoprecipitate take advantage of the adhesive properties of fibrin. This adhesive action depends on the final stages of the coagulation cascade in which fibrinogen is converted to fibrin in the presence of thrombin, factor XIII, fibronectin and ionized calcium. In the USA, cryoprecipitate is often used in conjunction with topical thrombin (bovine or human) as a local hemostatic agent, referred to as 'fibrin glue' or 'fibrin sealant'. This 'glue' is felt by many to be the ideal operative sealant, with its primary use in cardiothoracic and general vascular surgery. It appears to have little tissue toxicity, promotes a fibrin seal in seconds to minutes, is reabsorbed in days and promotes local tissue growth and repair in general. Although commercially available in Europe, these commercial products are not yet licensed in the USA because the source of fibrinogen is pooled plasma, thereby introducing the theoretical risk of viral transmission. The American experience with fibrin sealant, therefore, is limited to that derived from individual units of cryoprecipitate based on methods which are cumbersome and variable in response.

In addition to infectious risks, other possible complications from the use of fibrin sealant include thrombosis, formation of antibodies to bovine thrombin, a bleeding diathesis due to an acquired factor V deficiency, adhesions and transient hypotension.

Coagulation factor concentrates and other products

Not all coagulation factors are available as individual concentrates. Concentrates are, however, available for the more common deficiency states i.e. factors VIII and IX. Lyophilized coagulant complexes containing factors II, VII, IX and X are also available. Factor concentrates are derived from either source plasma or recombinant technology. If prepared from pooled plasma, the concentrates are often highly purified. In addition, they undergo a variety of viral inactivation techniques (i.e. heat or

solvent/detergent treatment) aimed at destroying lipid-enveloped viruses. Although deemed to be safer, the risk of viral transmission continues to exist. In particular, outbreaks of nonlipid-enveloped viruses hepatitis A and parvovirus have been reported. For those patients who have developed inhibitors to factor VIII, other products are available which bypass factor VIII activity. These are presumed to act via factor VIIa, thus bypassing the need for factor VIII.

Albumin

Albumin, as used clinically today, is derived from plasma by a Cohn cold alcohol fractionation technique developed for large-scale plasma processing during World War II. The resulting product contains 96% albumin and 4% globulins and other proteins. During processing, the plasma is heated to 60°C for 10 hours, which serves to inactivate microorganisms, including hepatitis viruses and human immunodeficiency virus (HIV), thereby minimizing any infectious risk of this product. Albumin is used as a colloidal solution to provide an oncotic load and can serve to bind potentially toxic metabolites (i.e. bilirubin). Albumin is indicated as a replacement fluid during plasmapheresis and to support the blood pressure in shock. It is also used to reduce accumulated fluid, via an induced diuresis, in patients with ascites suffering from hypoproteinemic states (i.e. protein-losing nephropathy or enteropathy, liver disease or burns). Albumin is not a good nutritional source of protein because it lacks essential amino acids, is very slowly metabolized and is far more expensive than standard hyperalimentation products available with total parenteral nutrition (TPN) programs.

Immunoglobulins

A second major product of cold alcohol separation is the immunoglobulin fraction consisting of 95% IgG and 5% other proteins. When isolated by this technique, the IgG molecules tend to form multimers which, when injected intravenously, can activate complement, induce basophil degranulation and precipitate a severe anaphylactic reaction. Consequently, its use originally was limited to intramuscular preparations, which were painful and not ideal for patients requiring large doses or chronic therapy. Since the 1980s, however, treatment of immunoglobulin preparations with proteases or reducing agents, which serve to prevent these multimer formations without affecting the biological activity, have led to the availability of intravascular preparations as well. Intravascular administration of immunoglobulin has been used as prophylaxis against known viral and

bacterial infections in patients with either primary or secondary antibody deficiency syndromes. Intramuscular injection of immunoglobulin preparations containing antibodies to rhesus D (RhD) have been used since the middle 1960s to treat Rh-negative patients prophylactically to prevent Rh hemolytic disease of the newborn (erythroblastosis). A licensed intravenous Rh immune globulin is now available for that purpose, as well as for treatment of Rh-positive patients with idiopathic thrombocytopenic purpura (IPT). Intramuscular injections of hyperimmune serum globulins are still used for cases of acute antigen exposure in nonimmunized immunocompetent individuals. Hyperimmune serum globulins are pooled from donors with high specific antibody titers and are available with specificity for hepatitis B, herpes zoster, rabies, tetanus, vaccinia, mumps, pertussis and measles.

Serum

The therapeutic uses of whole human serum have been supplanted by plasma and its derivatives. As a reagent, however, serum is still important as a diagnostic tool in blood banking to detect specific red blood cell antigens. It is also used for the production of antihuman globulin, the basis of the direct antiglobulin (Coombs') test. Serum is also used in transplant medicine to determine the tissue (HLA) antigens of donors and recipients. Serum from humans or domestic animals continues to be an essential component of many tissue culture media because it contains many necessary but as yet undefined growth factors. Serum from animals immunized against human tissues provides the basis for immunohistochemical staining in both research and in surgical pathology.

Risks

The risks associated with the transfusion of plasma or its derivatives are similar to those encountered with any blood product. Allergic reactions to plasma-containing products are very common and occur in 1–3% of transfusions. Nonhemolytic febrile reactions may occur as well. Other risks include alloimmunization to plasma antigens, hypervolemia and viral disease transmission. Severe reactions include anaphylactic shock due to infusion of various allergens such as IgA transfused to IgA-deficient patients. Transfusion-related lung injury (TRALI), due to the transfusion of leukoagglutinins which activate complement, resulting in a pulmonary capillary leak syndrome causing acute noncardiogenic pulmonary edema, has also been reported. Some recent animal

studies suggest a deleterious effect of plasma transfusions in the setting of septic shock.

Many pathogenic microorganisms are known to be transmissible by plasma infusions including HIV-1/2, viral hepatitis types A, B and C, and, if not stored frozen, a variety of bacteria. The statistics on transfusion-transmitted disease risks from all transfused blood components, including plasma, are approximately as follows: hepatitis B 1:60 000 per unit transfused (50% of cases become symptomatic), hepatitis C 1:100 000 per unit transfused (50% of cases become chronic), human T-cell leukemia virus (HTLV) 1:600 000 per unit screened (4% lifetime risk of associated disease) and HIV 1:600 000 to 1:800 000 per unit transfused. Also of note is that, in the USA, all immunoglobulin preparations, both intramuscular and intravenous, must either undergo viral inactivation procedures or must be subjected to hepatitis C viral RNA testing.

A recent well-publicized theoretical risk of blood component use relates to the transmission of Creutzfeldt-Jakob disease (CJD). After the death of a frequent blood donor due to CJD in 1994, there was a voluntary market withdrawal of involved plasma-derived products pending further investigation of this issue. CJD is a rare neurologic disease believed by some to be caused by an abnormal proteinaceous infectious particle, the prion, which occurs in a sporadic fashion with an extremely low incidence. It has an inherited form (100 extended families identified) and an infectious form (80 cases identified). This disease has only been shown to be transmitted via direct inoculation of infected neural tissues, i.e. dura mater, cornea, human pituitary growth hormone and ingestion of infected brain. Although this disease has been transmitted to animals by direct intracerebral inoculation of the buffy coat of blood from a known infected human, there has never been a documented case of disease transmission via a blood or blood component transfusion, despite several retrospective studies of recipients of blood from donors who subsequently died of CJD. Nevertheless, because a theoretical risk of transmission via transfusion exists, new guidelines state that if a person has more than one family member who has succumbed to this disease, they will be permanently deferred from donating blood.

Attempts to eliminate the infectious risk of plasma products include various viral inactivation techniques. Solvent/detergent (S/D) treatment has been used in Europe since 1990. This technique involves the introduction/incubation of 1% tri-*n*-butyl phosphate and 1% octyl phenylpolyethylene glycol ether (Triton-X) with large pools of plasma (300–1250 litres from 1200–1500 donors). During incubation, the S/D strips the lipid envelope from viruses, thereby

inactivating them; it has no effect on nonlipid-enveloped viruses. The S/D reagents are then extracted/adsorbed from the plasma, which in turn is repackaged as a pooled product and frozen. Minimal residual S/D is present in treated products, but no detrimental effect on red cells or platelets has been shown. It has been documented that this process decreases procoagulant activity by 10–15%, decreases protein S and α_2 -antiplasmin and eliminates the presence of larger multimers of von Willebrand factor. Its main disadvantage lies in the need for large plasma pools, increasing the risk of transmission of known nonenveloped viruses as well as possible unknown infectious agents. Other technologies under investigation to reduce risk of disease transmission include use of pasteurized plasma and use of photochemically treated plasma, chaotropic agents, irradiation, chromatography, filtration or a combination of the above technologies. It is apparent, however, that absolute viral inactivation in plasma and plasma derivatives is difficult to obtain. The benefits of pooled processed plasma must be weighed against product yield, product function and cost.

After infection, the most common serious complication of plasma transfusion is circulatory overload. The risk depends on the volume infused, the rate of infusion and the cardiovascular status of the patient. Fluid overload is more likely to occur in the elderly and in infants. The overall incidence of transfusion-related pulmonary edema is very low, about 0.01%. This complication can often be avoided or controlled by a slow infusion or a simultaneous diuresis.

Plasmapheresis

Plasmapheresis is the selective removal of plasma from the blood, generally using automated machines, with the immediate return of the cellular components to the donor/patient. It is accomplished by removing anticoagulated whole blood via a closed system, sterile in-line centrifuge, and separating the collected plasma from the cellular components. The cellular components are resuspended with normal saline and/or albumin and reinfused back into the donor/patient. This technique is used to collect plasma (donated source plasma) for the manufacture of clotting factor concentrates as well as albumin or immunoglobulins. It is also used therapeutically for the removal of plasma containing toxins, antibodies and antigen-antibody complexes. Diseases treated by plasmapheresis include myasthenia gravis, Guillain-Barré syndrome, TTP/HUS and hyperglobulinemic conditions such as multiple myeloma and Waldenström's macroglobulinemia.

PLASMAPHERESIS

Terry Hamblin, Department of Hematology, Royal Bournemouth Hospital, Bournemouth, UK

Historical background

The word 'plasmapheresis' (meaning the withdrawal of plasma) was coined by Abel in 1914 to describe a process by which whole blood is withdrawn from the body and separated into its constitutive parts, the cells being returned to the body while the plasma is retained. It should be noted that the word has no etymological relationship to 'electrophoresis'. Between the two World Wars Whipple used the technique to evaluate the dynamic equilibria between tissue and plasma proteins, but during World War II it was appreciated that plasmapheresis could provide a method of taking frequent plasma donations so as to satisfy military needs without depleting the donor's red cells. This spurred Cohn to modify a Swedish cream separator to produce the first semi-continuous flow cell separator. Developments of this machine are the mainstay of plasma donation today.

In response to the need for white cells to transfuse into patients with leukemia a continuous flow cell

separator was developed jointly by IBM and the National Cancer Institute, and subsequently a large number of different machines have been produced. Most separate the blood by centrifugation, but a new generation of machines which work by membrane filtration has been developed. These machines have turned what would otherwise be a tedious and time-consuming process into an easily applied automated technique and opened up the possibility of physically manipulating the immune response by the removal of large volumes of antibody.

Pathophysiological basis of plasmapheresis

Anything that appears in the plasma may be removed by plasmapheresis according to the equation $Y_t = Y_o \cdot e^{-x}$, where Y_t is the final concentration of a plasma component, Y_o is the initial concentration and x is the number of plasma volumes exchanged. Because of the exponential nature of this curve it is

usual to limit the volume exchanged to a single plasma volume on each occasion.

As fluid is lost from the intravascular space there is a flow of protein-free fluid from the interstitial tissues into the blood vessels to restore blood volume. Thus, within minutes there is a dilutional effect on plasma proteins which persists for about 6 h before both albumin and immunoglobulin G (IgG) begin to return to the circulation from the interstitium via the thoracic duct and capillary pores. Increased synthesis of albumin does not begin for 2 days, but the synthetic rate may increase threefold under severe hypo-oncotic stimulation. A loss of the albumin from 1 liter of plasma per week can be replenished by resynthesis alone by a well nourished 70 kg man. It is usual to use 5% human albumin solution as a replacement fluid when undertaking repeated plasmaphereses.

For IgM, 76% of which is intravascular and for which the fractional synthetic rate is only 8%, plasmapheresis is an efficient means of clearing it from the body. On the other hand only 45% of IgG is intravascular and repeated and frequent plasmaphereses are necessary to make an impact on plasma levels. Falls in IgG levels diminish the fractional catabolic rate, and for this reason some advocate adding IgG to the replacement fluid. Effects on the synthesis of specific IgG molecules vary, but during an immune response fueled by persisting antigen it is likely that plasmapheresis will be followed by a rebound and overshoot of antibody levels.

Other plasma proteins such as complement components and coagulation factors are also removed by plasmapheresis, and their removal may play a part in the modulation of some diseases by this form of treatment.

In many diseases characterized by the presence of circulating immune complexes, a defect in the clearance of such complexes by the mononuclear phagocytic system can be detected. Plasmapheresis may be shown to improve the function of the cells of this system in a way that is not totally clear.

Therapeutic effects

For many years the only clinical use of plasmapheresis was to alleviate the hyperviscosity syndrome of Waldenström's macroglobulinemia. In 1976 three articles in the *Lancet* detailed its use in Goodpasture's syndrome, systemic lupus erythematosus and myasthenia gravis. Since then reports of its use in over 180 different conditions have appeared. In most of these diseases plasmapheresis has been shown to be ineffective or to offer no clear benefit over conventional treatment. In 1981 a report that plasmapher-

esis was an effective treatment of rheumatoid arthritis was threatening to add \$28 billion to the American health care budget. Controlled clinical trials have delineated only very few clinical conditions in which plasmapheresis is an effective component of treatment. These include Goodpasture's syndrome, the Guillain-Barré syndrome, Waldenström's macroglobulinemia, myasthenic crisis, cryoglobulinemia, thrombotic thrombocytopenic purpura, polyarteritis nodosa associated with hepatitis B virus, homozygous hypercholesterolemia and certain poisonings. A case can also be made for its use in certain other autoimmune diseases when they are refractory to conventional treatment.

Plasmapheresis undoubtedly exerts an immunosuppressive effect, but is seldom safe to use alone because of the tendency to produce rebound with overshoot of antibody levels. It is usually used together with immunosuppressive drugs. Some have suggested that these are synergistic but this is unproven. The great advantage of plasmapheresis is speed so that vulnerable end organs such as the kidney or nerve may be spared from the onslaught of circulating antibody while immunosuppressive drugs are switching off its production. Thus plasmapheresis confers no additional benefit to conventional immunosuppression in cases of rapidly progressive glomerulonephritis with independent renal function, but is of significant benefit for those patients who are already oliguric. In a similar way, plasmapheresis is effective in polyarteritis nodosa associated with hepatitis B virus when combined with antivirals such as vidarabine or interferon α which, in eliminating the antigen, reduce the generation of immune complexes.

The considerable placebo effect of connecting a patient to a whirring machine with flashing lights tended by an attentive nurse should not be underestimated and some have recommended that controlled clinical trials should include a sham apheresis arm. The role of plasmapheresis is becoming clearer as more controlled trials report. Even where a clear role has been previously established new and cheaper methods of immune manipulation may usurp its position. A good example is the use of intravenous immunoglobulin in the Guillain-Barré syndrome.

PLATELET-ACTIVATING FACTOR (PAF)

David Hosford and Pierre Braquet, Biol-Inova DNA Tech Corporation, Plaisir, France

Platelet-activating factor (PAF) is a potent autocoid mediator implicated in a diverse range of human pathologies including shock, ischemia, asthma, cardiac and systemic anaphylaxis, CNS and renal disorders, and a variety of inflammatory conditions. Originally isolated from antigen-stimulated rabbit basophils and characterized structurally as 1-O-alkyl-2(R)-acetyl-glycero-3-phosphocholine, the alkyl phospholipid is now known to be produced by, and act on, a variety of cell types including neutrophils, eosinophils, monocytes, macrophages, platelets and endothelial cells. Platelet-activating factor (PAF) acetylhydrolase is a physiological inhibitor of PAF which is widely distributed in plasma and tissues and inactivates PAF by removing the acetyl group at the sn-2 position. Studies on the pathophysiological role of PAF have been facilitated by a variety of compounds which can specifically inhibit the binding of PAF to its receptors in various cells and tissues. Such PAF antagonists include the triazolothienodiazepine WEB 2086, the 20-carbon terpene ginkgolide B (BN 52021), and ligands such as kadsurenone. Studies with these and other PAF antagonists have indicated that PAF also plays an important role in the regulation of the immune response.

Effects on lymphocytes: proliferation, cytotoxicity, interleukin 2 production and surface antigen expression

Although PAF has a highly hydrophobic structure, it binds to a cell surface-expressed receptor belonging to the seven transmembrane G protein-coupled receptor family (Figure 1). The PAF receptor is coupled to several second messenger pathways including activation of phospholipase A₂, phospholipase C, phospholipase D, MAP kinase, phosphatidylinositol-3 kinase and tyrosine kinases, and inhibition of adenylyl cyclase.

Generally, PAF appears to have an inhibitory effect on lymphocyte proliferation *in vitro*. The addition of PAF to human peripheral blood lymphocyte cultures stimulated with the mitogens phytohemagglutinin (PHA) or concanavalin A (Con A), induces a concentration-dependent inhibition of cell proliferation. The IC₅₀ ranges between 1 pM and 0.1 nM and inhibition is only observed when PAF is added early in the culture period. The effect of PAF can be reversed by the use of the PAF receptor antagonist BN 52051 or indomethacin, the effect of this latter drug suggesting that prostaglandins may be involved as secondary messengers in this response.

Figure 1 Structural model of the PAF receptor indicating the amino acids conserved among four mammalian species. It has a putative seven-transmembrane topology with the conserved amino acids shown as closed circles. Guinea pig and human PAF receptors are composed of 342 amino acids, while rat and mouse receptors are of 341 amino acids. The bracketed residue is deleted in the rat and mouse receptors. Potential glycosylation sites, a palmitoylation site, and a disulfide linkage between two cysteines are also shown. (Reproduced with permission from Ishii *et al* (1997) *Journal of Biological Chemistry* 272: 7846-7854.)

In contrast to these data, PAF and two nonhydrolyzable PAF analogs have been shown to increase the proliferation of interleukin 2 (IL-2)-stimulated human lymphoblasts, whereas some antagonists are inhibitory. Furthermore, it is possible that endogenously produced PAF may be involved in some step(s) of IL-2-induced proliferation of T lymphoblasts, as indicated by the inhibition of this process by the PAF synthesis inhibitor L-648,611. An important corroboration of some of these *in vitro* observations has been provided by the *in vivo* instillation of PAF into rats via subcutaneously implanted osmotic minipumps connected to the jugular vein. In this system, after 7 days of instillation, PAF-treated rat splenocytes showed enhanced IL-2 production in response to Con A.

Contradictory results have also been reported with regard to the effect of PAF on lymphocyte subsets, with some *in vitro* studies showing a suppressive effect of the mediator on CD4⁺ T cell proliferation or that PAF activates suppressor cells which inhibit lymphocyte proliferation and increases the CD8⁺/CD4⁺ T cell ratio. However, other studies indicate that PAF stimulates CD4⁺ T cell proliferation but has no effect on CD8⁺ cells. Little evidence is available concerning the effects of PAF on lymphocyte proliferation *in vivo*; however, in a randomized double-blind study on 18 healthy male volunteers receiving the ginkgolide mixture BN 52063 (80 or 240 mg day⁻¹) or placebo for 15 days, the results showed a dose-related reduction of up to 43% in the CD4⁺/CD8⁺ ratio in individuals receiving the PAF antagonist, but no change in the control group. The CD4⁺/CD8⁺ T cell ratio returned to normal values after the end of treatment.

Also, PAF has been implicated in the generation of cytotoxic lymphocytes, as BN 52021 potentiates alloantigen recognition in primary and secondary mixed lymphocyte cultures and enhances the generation of cytotoxic lymphocytes *in vitro*. PAF antagonists also exert a protective effect on *in vitro* rat splenic lymphocyte-mediated cytotoxicity of Langerhans islets. As cytotoxic and/or suppressor T lymphoblasts have been shown to accumulate around Langerhans islets in diabetes, PAF antagonists may be therapeutically valuable in the autoimmune form of this pathology.

Effects on monocytes/macrophages: production of cytokines and free radicals and CD23 receptor expression

Stimulated macrophages release both PAF and cytokines such as IL-1 and tumor necrosis factor (TNF),

which are essential regulators of immune cell interactions. *In vitro* experiments on human monocytes have demonstrated opposite effects of PAF on lipopolysaccharide (LPS)-induced IL-1 production depending on the concentration of the mediator. Low concentrations of PAF (1 pM to 0.1 nM) significantly enhance IL-1 production, whereas high concentrations (10 nM to 1 μ M) are markedly inhibitory. In *ex vivo* experiments using minipumps loaded with PAF placed under the back skin of rats and connected to the jugular vein, monocytes from animals receiving 1.0, 4.5 or 9.0 μ g PAF for 7 days exhibit an increased capacity to produce IL-1. In contrast, with 28 μ g PAF week⁻¹, IL-1 production by the monocytes is markedly decreased. IL-6 release by rat and human macrophages is also modulated by PAF.

Very low concentrations of PAF (1 pM to 10 nM) can activate peripheral blood-derived monocytes to produce TNF and significantly amplify the interferon γ (IFN γ)- or LPS-induced production of this cytokine. PAF also acts synergistically with IFN γ to increase monocyte cytotoxicity. Production of toxic oxygen species by monocytes is an important component of the bactericidal response of these cells. PAF can amplify superoxide generation in human monocytes preincubated with TNF, this effect being abolished by various structurally unrelated PAF antagonists. Interestingly, PAF antagonists can also partially inhibit superoxide generation elicited solely by TNF, suggesting the involvement of endogenous PAF in this response.

In addition to macrophages, natural killer (NK) cells also mediate part of their cytotoxic activity via the release of TNF. NK cell-mediated lysis of the erythroleukemic target cell line K562 is markedly enhanced by picomolar concentrations of PAF and significantly diminished by BN 52021. Furthermore, large granular lymphocytes, which comprise the effector NK cells responsible for lysis of K562 target cells, generate PAF under certain conditions and thus it appears that endogenous PAF may assist in the regulation of NK cell functions.

Finally, PAF has been implicated in the regulation of the expression of Fc ϵ R2/CD23 receptors, which are low-affinity binding sites for IgE. *In vitro* incubation of monocytes and B lymphocytes, but not T lymphocytes, with PAF induces a dose-dependent increase in Fc ϵ R2/CD23 expression. These results are supported by *in vivo* studies showing that aerosol administration of PAF to rats dramatically increases expression of Fc ϵ R2/CD23 receptors on alveolar macrophages collected from the animals by bronchoalveolar lavage.

Transplant rejection

Graft rejection is another area in which the immunomodulatory effects of PAF appear to be important. PAF is known to be released from renal allografts during hyperacute rejection and the PAF antagonist BN 52021 increases cardiac, liver, and skin allograft survival in rats, acting synergistically with azathioprine and cyclosporine. The PAF antagonist also prevents cyclosporine induced nephrotoxicity without altering the immunosuppressive effect of the drug. In addition, treatment with BN 52063 in combination with cyclosporine increases the immunosuppressive effect of the latter.

Conclusion

The experimental evidence described here indicates that PAF plays an important role in the regulation of the immune response. In addition to directly modulating immune processes and cytokine production as described above, PAF can also influence the activity of other mediators, which in turn can modulate lymphocyte function. These substances include cationic proteins and other suppressive factors released from activated eosinophils, and leukotrienes, prostaglandins and neuropeptides. Indeed, the ability of very low concentrations of PAF to both prime and amplify cell responses indicates that the mediator acts as an important amplifier of immunoinflammatory responses. Investigations with PAF antagonists will allow further elucidation of these processes and may lead to the development of these compounds as valuable immunomodulatory drugs.

PLATELETS

Joel Lawrence Moake, Medical Hematology Section, Baylor College of Medicine and the Methodist Hospital, Texas, USA

Platelet structure and function

Hemostasis is initiated when endothelial cells are damaged, and platelets adhere to the collagen and von Willebrand factor (vWF) multimers in the sub-

endothelium. These events occur in flowing blood, with platelets exposed to different shear stresses in different areas of the circulation. The subendothelial vWF forms include unusually large vWF (ULvWF) multimers that have been released in a backward

direction from endothelial cells. The ULvWF multimers (which are also synthesized within megakaryocytes and present in the α granules of platelets) are larger than the vWF multimers in normal circulation, and have a greater capacity to bind to platelets.

Platelets adhere to subendothelial vWF multimers via glycoprotein Ib (GPIb) receptors, and to collagen via GPIa-IIa receptors. These are integral membrane proteins. GPIb is a disulfide-linked heterodimer that is complexed to other smaller platelet integral membrane proteins, GPIX and GPV. vWF multimers bind to the poorly glycosylated tail regions of GPIb molecules extending from the exterior surface of the platelet membrane. Both GPIb and GPIa span the platelet membrane and are linked to its cytoskeletal undersurface via actin-binding protein.

Following platelet-subendothelial adherence, platelets are activated to generate and transmit internal chemical signals. These transducing signals include G proteins, effector enzymes (phospholipase C, phospholipase A₂, adenylyl cyclase, protein kinase C, tyrosine kinases) and second messengers (inositol triphosphate, Ca²⁺, diacylglycerol, thromboxane A₂, cyclic AMP and cyclic GMP). One important result of platelet activation is the increased exposure of fibrinogen- and vWF-binding sites on platelet surface GPIIb-IIIa complexes. Under certain conditions, platelet GPIIb-IIIa complexes can also bind vWF multimers.

One example of platelet activation signaling is the following: membrane lipases hydrolyze arachidonic acid from ester bonds in platelet membrane phospholipids. Platelet fatty acid cyclooxygenase, the enzyme that is irreversibly inhibited when it is acetylated by aspirin, rapidly converts arachidonic acid to the cyclic endoperoxides PGG₂ and PGH₂. The platelet enzyme thromboxane synthase then produces thromboxane A₂ (TXA₂) from PGH₂. TXA₂ is a short-lived compound that potentiates the release of ADP, serotonin and Ca²⁺ from platelet-dense granules, as well as several proteins from α granules. These latter include platelet-derived growth factor that is mitogenic for smooth muscle cells and fibroblasts; β -thromboglobulin; platelet factor 4 that is capable of binding heparin; and fibrinogen and vWF multimers that attach, along with their plasma forms, to activated GPIIb-IIIa complexes in the platelet membrane. The result is platelet-platelet cohesion, or aggregation, of platelets onto those already adherent to subendothelial vWF and collagen.

Thrombin generated by activated coagulation pathways, as well as epinephrine, amplify platelet release and aggregation. Any TXA₂ that leaks from activated platelets may induce further platelet aggrega-

tion and stimulate vasoconstriction locally before it is hydrolyzed nonenzymatically into the inactive end-product, thromboxane B₂.

Platelet antigenicity

GPIb is a target on the platelet surface for the attachment of quinine/quinidine drug-dependent antibodies. The result of this drug-antibody binding to (or near) platelet GPIb molecules is usually severe thrombocytopenia. Some patients with 'idiopathic' autoimmune thrombocytopenic purpura (ITP) make autoantibodies that are directed against antigenic components of either GPIb or, more commonly, the GPIIb-IIIa complex. The platelet-specific alloantigens Lek^a and Pl^{Al} are located on GPIIb and IIIa, respectively. Following transplacental isoimmunization, anti-Pl^{Al} or anti-Lek^a can cause neonatal thrombocytopenia. Pl^{Al}-specific antibodies reactive with the Pl^{Al} antigenic locus on GPIIIa have also been implicated in the still enigmatic pathogenesis of post-transfusion purpura. It is perhaps important that GPIIIa molecules have been found on endothelial cell membranes and might also be a target of Pl^{Al}-specific antibodies (with resultant endothelial cell damage) in patients with this rare syndrome.

Platelets possess HLA antigens, some of which may be derived from other cells and become adsorbed to platelets from the plasma. Platelet HLA-A and HLA-B (but perhaps not HLA-C) antigens are capable of stimulating alloantibody formation. Repetitive transfusions of platelets concentrated from random normal donors will be HLA mismatched and will, with continuing exposure, elicit anti-HLA-A or anti-HLA-B alloantibodies that will bind to the transfused platelets and prevent their circulation and participation in hemostatic events. When this occurs, HLA-compatible or partially compatible platelets (often from siblings, parents, or grown children) will have to be substituted in order for transfusions to be effective.

Incompatible platelet transfusions do not produce the catastrophic effects associated with the intravascular hemolysis of transfused, incompatible red blood cells. Platelet transfusion reactions are characterized by chills and fever, lack of increment in the platelet count after transfusion, and no (or only transient) hemostatic effect.

Thrombocytopenia

Thrombocytopenia is most often caused either by defective platelet production or excessive platelet destruction. Defective platelet production is a common manifestation of many toxic (e.g.

chemotherapy), nutritional (e.g. folate or B₁₂ deficiencies), or neoplastic disturbances of bone marrow hematopoietic stem cell proliferation and differentiation. Thrombocytopenia that is caused by an increased peripheral destruction of platelets is characterized by a shortened platelet survival (normal survival is about 10 days), increased proliferation of marrow megakaryocytes in an effort to compensate for the decreased platelet lifespan, and an increase in the percentage of large (young) platelets in the circulation (normally there are about 10%). The process is frequently immune mediated.

Drug-induced immune thrombocytopenia

Some individuals produce antibodies against a drug or drug metabolite that can result in immune platelet destruction. The drugs implicated include quinidine and quinine (stereoisomers of each other), sulfonamides and structurally similar drugs, digitoxin, rifampicin, heroin, morphine, α -methyl dopa, gold salts, histamine-2 (H₂) receptor antagonists (cimetidine, ranitidine) and valproic acid. Either the drug or its metabolite, as a hapten, may bind non-covalently to platelet surface proteins and form complete antigenic structures. The susceptible patient produces antibodies that combine specifically with the platelet protein-bound haptenic drug or metabolite. Complement component C1 is fixed and activated if immunoglobulin M (IgM), IgG1, or IgG3 is involved in the immune complex. If the classical complement pathway on platelet surfaces is activated completely via C1, C4, C2, and C3 through to the terminal membrane attack complex (C5-C9), then platelets lyse in the circulation. Alternatively, the drug or metabolite may bind to (or near) a platelet surface structure and alter the antigenicity of the external platelet surface protein. This latter mechanism probably explains the presence of IgG molecules that bind, via their Fab portions, to platelet membrane GPIb or GPIIb-IIIa components in the presence of quinine or quinidine. In drug-induced immune thrombocytopenia, platelet counts are often $<10^4$ per μ l, and bleeding complications are frequently severe.

For immune reactions to occur on platelet surfaces, the drug or drug metabolite must be present continuously. The thrombocytopenia reverses within days to weeks following discontinuation and catabolism of the drug, and its complete removal (along with any haptenic metabolites) from the body.

A considerable percentage of patients anticoagulated with heparin in therapeutic, prophylactic or 'keep open' dosages will develop thrombocytopenia. Porcine heparin may be somewhat less likely to pro-

duce thrombocytopenia than bovine heparin. Heparin attaches to positively charged platelet factor 4 molecules that are secreted from the α granules of activated platelets on to their outer membrane surfaces. In susceptible patients, antibodies are produced against the heparin/platelet factor 4 complexes. It has been demonstrated that IgG antibodies bind, via their Fab regions, to the heparin/platelet factor 4 complexes. The Fc regions of these IgG antibodies interact with adjacent Fc receptors on the platelet surfaces and stimulate release of arachidonic acid from platelet membrane phospholipids. This is followed by the production of cyclic endoperoxides and TXA₂, the release of ADP and other platelet granule contents, ADP-induced binding of fibrinogen to activated platelet GPIIb-IIIa complexes, and intravascular platelet aggregation. The consequences are thrombocytopenia that becomes progressively more severe over the course of several days, often accompanied by arterial or recurrent venous thrombosis. Discontinuation of heparin leads to a reversal of intravascular aggregation within hours (as the heparin is catabolized and excreted), and the platelet count returns to normal within days.

Idiopathic (autoimmune) thrombocytopenic purpura (ITP)

A relatively common disorder in adults, ITP often complicates diseases associated with defective immune regulation (e.g. systemic lupus erythematosus, HIV infection, lymphoproliferative disorders, Hodgkin's disease). The onset of thrombocytopenia and bleeding is usually less abrupt than in drug-induced immune thrombocytopenia caused by drugs other than heparin. In adults, ITP is usually chronic and seldom remits spontaneously. IgG and/or IgM autoantibodies react with GPIb, GPIIb-IIIa, or other antigens present on the ITP patient's platelets, on platelets from normal donors and, sometimes, on the patient's megakaryocytes. The IgG or IgM antibodies may fix and activate complement components on platelet surfaces; however, complement fixation is often incomplete, and intravascular platelet lysis is much less common than in drug-induced immune thrombocytopenia (caused by drugs other than heparin). Macrophages have specific surface receptors for the Fc portion of IgG1 and IgG3 molecules, as well as for portions of the C3 molecule, and phagocytose IgG- or C3-coated platelets.

In chronic ITP, platelet counts may sometimes drop below 10^4 per μ l. Usually, however, platelet counts are in the range of 20 000-80 000 per μ l. Anemia, when present, is often caused by blood loss. An autoimmune hemolytic anemia caused by an IgG

autoantibody directed against a component of the Rh system occasionally may occur concurrently with ITP (Evans' syndrome).

Chronic ITP is treated initially with a glucocorticoid (prednisone or its equivalent in a dosage of 1–2 mg kg⁻¹ day⁻¹). Glucocorticoids are lipophilic cholesterol derivatives that enter the membranes of spleen and liver macrophages, and decrease the capacity of macrophage surface receptors to identify and phagocytose IgG- or C3-coated platelets. Platelet survival and platelet counts increase within days to weeks as a result of the inhibitory effects of glucocorticoids on splenic and hepatic macrophage IgG Fc and C3 receptors. It has also been claimed that glucocorticoids increase platelet production by megakaryocytes.

The dosage of glucocorticoids usually required to control chronic ITP compromises host defense against infection, as well as glucose and protein metabolism. Splenectomy is usually necessary to interrupt adequately phagocytosis by splenic macrophages of platelets coated with IgG (with or without C3). Platelet survival and platelet counts return to normal or near normal after splenectomy in about 75% of patients, although platelet autoantibodies often remain in the circulation and on patient platelets. These circulating platelet autoantibodies can cause neonatal thrombocytopenia in the offspring of mothers who have previously had their ITP brought under clinical control by splenectomy.

Because of blood flow patterns through the macrophage-packed splenic red pulp, the spleen is usually the major site of platelet destruction. Phagocytosis also occurs in the macrophage-lined sinusoids of the liver. In the latter circumstance, splenectomy may not be successful.

Some patients benefit transiently from the infusion of about 1.0 mg of vincristine. Vincristine depolymerizes platelet microtubules, and this cytoskeletal alteration may produce secondary changes in the exposure of platelet membrane antigens. Intravenous polyvalent IgG concentrate (0.4–0.5 mg kg⁻¹ day⁻¹ for 4–5 days) is transiently even more likely to be effective in treating ITP, either because splenic and hepatic macrophage IgG Fc receptors become blocked or because the concentrate contains anti-idiotypic antibodies capable of neutralizing some patient platelet autoantibodies. IgG concentrate ($\pm$ vincristine) is especially useful in producing short-term elevations in platelet counts in order to amelior-

ate a severe bleeding episode or to prepare a patient for splenectomy.

Transfusions of normal donor platelets are ineffective or only transiently effective in ITP because they also are attacked by the platelet autoantibodies in patient plasma. Platelet transfusions should be restricted to episodes of life-threatening (especially CNS) bleeding.

Danazol (400–800 mg day⁻¹), an attenuated androgen that may also interfere with macrophage Fc- and C3-receptor function, and immunosuppressive agents (6-mercaptopurine, azathioprine, cyclophosphamide) are useful in some patients with ITP who do not respond to the standard glucocorticoid/splenectomy regimen ($\pm$ IgG concentrate and vincristine).

PNEUMOCYSTIS CARINII, INFECTION AND IMMUNITY

Sue A Theus and **Peter D Walzer**, Cincinnati Veterans Affairs Medical Center and
Division of Infectious Diseases, Department of Internal Medicine, University
of Cincinnati College of Medicine, Cincinnati, Ohio, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Pneumocystis carinii is an extracellular pathogen that causes pneumonia in the immunocompromised host. Pneumocystosis is one of the leading opportunistic infections and causes of death in patients with the acquired immune deficiency syndrome (AIDS). No reliable *in vitro* culture system exists for *P. carinii*, which effectively hampers research on this pathogen. Until recently, the taxonomic status of this organism, based on morphological and ultrastructural characterization, was not clearly defined. However, molecular studies have shown that *P. carinii* is more closely related to fungi than protozoa. This classification was initially based on DNA homology studies using a single RNA ribosomal gene, but was subsequently confirmed by analysis of mitochondrial genes and protein coding sequences.

Two predominant forms of the organism have been identified: the trophozoite and the cyst. The trophic form is the smaller form (1–4 µm), pleomorphic, and exists in clusters. The cyst stage is larger (5–8 µm) and contains up to eight intracystic bodies. Two prominent groups of *P. carinii* antigens have been identified. A large surface complex, termed major surface glycoprotein (MSG), gpA or gp120 has been found in organisms derived from humans and other animals with a reported molecular weight of 95–140 kDa under reducing conditions. MSG is encoded by a family of genes, suggesting the possibility of antigenic variation. N-Linked carbohydrates comprise about 5–10% of the molecular mass of this glycoprotein. A major function of MSG is to mediate the interaction of *P. carinii* with the host. The other major antigen complex is a glycoprotein that migrates as a broad band of 45–55 kDa in rat *P. carinii* and 35–45 kDa in human *P. carinii*. The gene encoding the rat *P. carinii* 45–55 kDa antigen has recently been cloned but awaits further characterization.

Immune response in the host

P. carinii infection stimulates both humoral and cellular immune responses in the host. Seroepidemiologic studies have shown that 60–95% of all individuals contain detectable levels of antibodies to the

organism, suggesting widespread natural environmental exposure. Most patients infected with human immunodeficiency virus (HIV) have pre-existing serum antibodies to *P. carinii*, but these antibodies are not capable of providing protection against the development of *P. carinii* pneumonia. The 35–45 kDa band is the antigen recognized most frequently by the serologic responses.

Evasive strategies of the organism

P. carinii maintains an extracellular existence within the lung alveoli and adheres tightly to a specific lining cell, the type I pneumocyte. With immunosuppression, the organism proliferates slowly and initiates a series of changes in the alveolar microenvironment which culminate in damage to the type I cell. The mechanisms which permit *P. carinii* to evade the host defenses are poorly understood. Impaired cellular immunity is generally considered to be the main host factor that predisposes to infection, but impaired humoral immunity also plays a role. Even with successful treatment of *P. carinii*, the host remains susceptible to recurrent episodes of pneumocystosis as long as the immunosuppressive conditions persist.

Vaccines

Recent work has begun on the development of a *P. carinii* vaccine. Immunization of rats with whole organisms has not prevented the development of pneumocystosis but passive administration of a monoclonal antibody to MSG offers partial protection. Immunization with MSG also confers partial protection against the development of *P. carinii* pneumonia induced by immunosuppression. Additionally, an even more dramatic reduction in *P. carinii* infection has been achieved by the adoptive transfer of MSG-specific lymphocytes.

POKEWEED MITOGEN (PWM)

Yasuhiro Horii and **Toshio Hhirano**, Division of Molecular Oncology, Biomedical Research Center, Osaka University, Japan

In 1964, Farnes reported that extracts of pokeweed (*Phytolacca americana*) induced transformation of human lymphocytes *in vitro*. Subsequently, Borjeson and colleagues isolated an active mitogen from the plant and demonstrated that pokeweed extracts contained materials that caused hemagglutination and leukagglutination and stimulated cell growth of both T and B cells. It was then demonstrated that pokeweed mitogen (PWM) induced immunoglobulin (Ig) production in peripheral blood lymphocytes and that this effect was dependent on both T cells and macrophages. Furthermore, interleukin 6 (IL-6) was shown to play an essential role in PWM-induced Ig production.

Preparation of PWM

The first isolation of an active mitogen from *Phytolacca americana* was published by Borjeson and colleagues, who purified PWM using the following procedure. Pokeweed roots were ground in a blender and active mitogenic molecules were extracted in PBS, then fractionated by heat coagulation, ethanol or trichloroacetic acid (TCA) preparation, and calcium phosphate column chromatography. The crude saline extract of PWM possessed the ability to agglutinate human red blood cells, white blood cells and to transform human peripheral blood lymphocytes. The TCA-precipitated fraction was further separated by the calcium phosphate column. The eluate from the column with 0.05 M phosphate buffer

at pH 7.5 was found to contain hemagglutinating, leukagglutinating and mitogenic activity.

Waxdal, using sequential hydroxyapatite chromatography and gel filtration, isolated five distinct fractions containing active mitogens, termed Pa1–Pa5. Yokoyama and colleagues also described a fractionation scheme consisting of DEAE-cellulose column chromatography, affinity chromatography on a column of desialylated human erythrocyte glycopeptide-Sepharose 4B, and gel filtration.

Characterization

The five fractions Pa1–Pa5 each contain a single molecule identified by SDS-PAGE and the mitogenic activity present in each fraction is stable to periodate and mercaptoethanol. Mitogens in fractions Pa2–Pa5 are probably in the form of a single polypeptide chain, whereas the molecule in Pa1 appears to be a polymer of 22 kDa subunits.

In comparison with phytohemagglutinin (PHA), the polypeptide part of the PWM is remarkable for its large number of internal disulfide bridges. The compositions of the molecules in fractions Pa2–Pa5 were found to have high half-cystine values, much higher than that of the molecule in the Pa1 fraction.

Yokohama and colleagues have reported that the mitogens in the Pa1 and Pa2 fractions recognize a core NN'-diacetylchitobiose moiety in asparagine-linked sugar chains of glycoproteins, and they demonstrated the presence of receptors for these

mitogens on the surface of human erythrocytes and murine lymphocytes.

Biological activity

Pokeweed mitogens have a mitogenic activity on murine T and B lymphocytes. All the fractions (Pa1–Pa5) stimulate murine T cells over a wide range of concentrations. The mitogen in the Pa2 fractions has the strongest activity and the Pa4 and Pa5 fractions have the least effective mitogens. However, only the molecule in the Pa1 fraction stimulates murine B cells in the absence of T cells.

The effects of PWM on human lymphocytes have been investigated mainly using impure mixtures of PWM. This has led to confusing and variable results, depending on the amounts of each active molecule present in the preparation. Although the Pa2 fraction showed the strongest activity for murine T cells, in studies using human T cells, both Pa1 and Pa2 had approximately the same potency. Peripheral blood B lymphocytes cultured alone with PWM did not respond with proliferation or cells was found to be dependent on T cells and macrophages. T Cell-depleted tonsillar mononuclear cells as well as peripheral blood lymphocytes had markedly diminished Ig production following PWM stimulation. The Ig production by T cell-depleted mononuclear cells could be reconstituted by cell-free supernatant obtained from PWM-stimulated peripheral blood lymphocytes or T cell-rich fraction. This probably accounts for the lack of HLA restriction for B cell stimulation. Furthermore, the PWM-induced

immunoglobulin production was found to be inhibited by anti-IL-6 antibody and thus is dependent on IL-6.

POLYCLONAL ACTIVATORS

Nicholas R StC Sinclair, Department of Microbiology and Immunology, The University of Western Ontario, London, Ontario, Canada

Colin C Anderson, Laboratory for Cellular and Molecular Immunology, National Institute of Allergy and Infectious Disease, National Institutes of Health, Bethesda, Maryland, USA

Polyclonal activators are classically defined as agents that stimulate a large fraction of lymphocytes, regardless of their antigen specificity. The responding cells proliferate and/or produce end-products such as immunoglobulins or cytokines. Another attribute is the frequent lack of requirement for cell–cell collaboration, so that cell populations other than those activated do not limit responses to polyclonal acti-

vators. This property of autonomous activation has proven useful for studying the integrity of specific lymphocyte populations. Although polyclonal activators are widely considered to be experimental models for the activation of lymphocytes by antigen, they do not utilize the same activation pathways although the pathways overlap and interact with each other.

While reasonable, these classical definitions obscure the functional links between polyclonal activators, synergism by adjuvants, and costimulation. The combination of antigen-specific signaling via antigen receptors and polyclonal activation can lead to heightened immune responses compared to that caused by antigen receptor signaling alone. Polyclonal activators may influence signals by cell surface molecules other than antigen receptors. Furthermore, since the expansion of lymphocyte populations must be followed by contraction, polyclonal activation is not without an element of inhibition or inactivation. Both polyclonal activation and inactivation may be equally important in the maintenance of an intact immune system. The effect of nominal polyclonal activators depends on the cell activity measured and the conditions under which this activity is studied. As with positively acting functional links (activators/synergism/costimulation), important links in the opposite direction, that is, inhibition/antagonism/coinhibition, also influence immune responses.

Classes of polyclonal activators

There are a variety of polyclonal activators that operate by different mechanisms on cells of the immune system (Table 1). Many have varying abilities to stimulate a sizable fraction of lymphocytes, regardless of the lymphocyte antigen specificity. Polyclonal activators can both costimulate and induce costimulatory mechanisms, thus indicating the functional connection between polyclonal activators and costimulators. The physiology of costimulatory molecules to a large degree limits the function of these molecules to lymphocytes undergoing antigen-specific stimulation. This is also the case for a number of cytokines which may induce polyclonal activation under experimental conditions, but primarily function *in vivo* to augment antigen-specific responses. One exception to this generality is septic and toxic shock in which massive and damaging production of immune products causes severe illnesses. Lastly, activation is often followed by inactivation and lymphocyte death. The precise mechanism for inactivation and death, which allows lymphocytes to be removed when they are no longer needed, depends on the nature and mechanism of the initial activating stimulus.

Polyclonal inhibitors

While polyclonal activators possess polyclonal inhibitory potentialities, the polyclonal inhibitors listed in Table 2 are, for the most part, without strong activating properties. Intact antibodies to acti-

vating receptors that signal via an immunoreceptor tyrosine-based activating motif (ITAM) also bind to inhibitory Fc receptors, induce coaggregation of the two receptors and ultimately inactivate the cell. If the intact antibodies recognize invariant determinants, then the inhibition is polyclonal. If the antibodies react to variable determinants, such as those within the antigen-binding site, then inactivation is more restricted. Intact antibodies to antigenic determinants also inhibit by Fc-dependent mechanisms; this inhibition is not determinant specific but can involve any other determinants on the antigenic molecule or particle. All these forms of inhibition involve modulation of the positive signal sent through the ITAM. In some cases, polyclonal activation of one cell type inhibits other cell type(s). For example, concanavalin A polyclonally activates T cells, including T cells that suppress B cell responses in a polyclonal fashion.

Lymphocytes undergo explosive expansion in response to antigenic challenge. This provides a basis for active immunity, but presents two problems. How are responses to self antigens controlled? How are a majority of lymphocytes that respond to an antigenic challenge dealt with after the antigenic challenge has been eliminated? Lymphocytes have a range of cell surface molecules which transmit inhibitory signals. Beside the inhibitory Fc receptor, other receptors listed in Table 2 help to keep lymphocyte activity under control. While many of these receptors can, under experimental conditions, inhibit in a polyclonal fashion, under physiologic situations most act in an antigen-specific fashion due to regulation by the antigen receptor.

Polyclonal activators may also cause profound inhibition, an example being superantigens. Such superantigens, for example those derived from *Staphylococcus aureus*, activate T cells in a polyclonal fashion, but this activation can be followed by deletion of superantigen-binding T cells. This deletion creates holes in the T cell repertoire, potentially reducing the effective number of T cell antigen receptors available in immune responses.

Interaction between polyclonal and clonal activators

Synergism

Low doses of polyclonal activators increase responses to stimulatory cytokines or induce production of these stimulatory cytokines. This partly accounts for the effect of adjuvants. Adjuvants augment immune responses by a process of synergism between signals via the antigen receptor and those lymphoid system cell surface components that interact with the many elements that make up adjuvants.

Table 1 Examples of polyclonal activators

Name	Source	Cells activated	Cells required
<i>Mitogenic lectins – bind polysaccharide of surface structures</i>			
Phytohemagglutinin (PHA)	<i>Phaseolus vulgaris</i>	T cells (human)	Monocytes
Concanavalin A (Con A)	<i>Canavalia ensiformis</i>	T cells (mouse)	
Pokeweed mitogen (PWM)	<i>Phytolacca americana</i>	T and B cells	T and B cells
Streptolysin O (SLO)	<i>Streptococcus</i>	B cells	T cells
Nocardia water-soluble mitogen (NWSM)	<i>Nocardia opaca</i>	B cells	± T cells
Some oligonucleotides	Bacterial or synthetic	B cells	
<i>Bacteria cell wall products and analogs – bind a number of receptors on lymphocytes</i>			
Lipopolysaccharides (LPS)	Gram-negative bacteria	B cells	
Peptidoglycan	Bacteria	B cells	
Lipoproteins	Bacteria	B cells	
Porin proteins	<i>Neisseria</i>	B cells	
Dextran sulfate	Synthetic	B cells	
<i>Polyene antibiotics</i>			
Amphotericin B	<i>Streptomyces</i>	B cells (T cells)	
<i>Calcium ionophores – alter calcium signals</i>			
A23187	<i>Streptomyces</i>	T cells	
Ionomycin	<i>Streptomyces</i>	T and B cells	
<i>Phosphorylation modifiers – increase stimulatory phosphorylation events</i>			
Phorbol myristate acetate	<i>Croton tiglium</i>	T and B cells	
Pervanadate	Inorganic salt + H ₂ O ₂	T and B cells	
<i>Antigen–receptor ligands – bind to non-variable portions of the receptor mechanism</i>			
(Fab') ₂ anti-immunoglobulin	Mammalian	B cells	
anti-Ig-dextran	Mammalian + synthetic	B cells	NK/macrophages
(Fab') ₂ anti-T cell receptor	Mammalian	T cells	
Staphylococcal enterotoxin	<i>Staphylococcus</i>	T cells	APC
TSST – toxic shock toxin	<i>Streptococcus</i>	T cells	APC
Superantigens (MMTV)	Retroviruses	T cells	APC
Protein A	<i>Staphylococcus aureus</i>	B cells	
<i>Ligands for costimulator molecules – bind to lymphocytes and favor stimulation</i>			
Anti-CD28/CTLA4 and B7	Mammalian	T cells	
Anti-CD40 and CD40L	Mammalian	B cells	
Anti-CD21/complement	Mammalian	B cells	
Anti-CD2	Mammalian	T cells	
<i>Transforming agents infect cells and cause continued growth and/or activation</i>			
Epstein–Barr virus	Virus	B cells	
HumanT lymphotropic virus	Virus	T and B cells	
Human immunodeficiency virus	Virus	B cells	

APC, antigen-presenting cells; NK, natural killer cells.

Lymphocytes do not respond very well to purified antigens, but must be stimulated to do so with various adjuvants, such as Freund's complete adjuvant, an oil-in-water emulsion containing heat-killed bacteria, *Mycobacterium tuberculosis*. Bacteria contain elements that are unlike vertebrate structures. These elements interact with lymphocytes via components other than the antigen-specific variable region of the antigen receptor. An example of the adjuvant activity of a B cell polyclonal activator is the increased anti-

body production by purified B cells to antigen in the presence of bacterial oligo-DNA containing hypomethylated cytosine–guanine sequences.

Lipopolysaccharide (LPS, endotoxin), a classical polyclonal activator, favors the generation of an inflammatory T cell population that may provide immunity to the forms of bacteria that display LPS. Thus, under natural conditions, polyclonal activators may act to augment protective forms of immunity. Injection of LPS induces rapid polyclonal production

Table 2 Polyclonal inhibitors

Name	Source	Cells inhibited
<i>Intact antibody to antigen receptors – cross-links antigen and Fc receptors (FcγRIIB)</i>		
Anti-B cell antigen receptor	Mammalian	B cells
Anti-T cell antigen receptor	Mammalian	T cells
Anti-IgE on FcεRI	Mammalian	Mast cells
<i>Ligands or antibodies that activate inhibitory receptors on lymphocytes</i>		
Anti-CTLA4 without CD28	Mammalian	T cells
Anti-CD22	Mammalian	B cells
Anti-Ly49, anti-p58/p70, and others	Mammalian	NK and T cells
TGFβ	Mammalian	Many cells
FasL and anti-Fas (CD95)	Mammalian	T and B cells
TNFα (receptor = CD120)	Mammalian	T cells
Polymyxin B	Bacterial	B cells

TGFβ, transforming growth factor β; TNFα, tumor necrosis factor α.

of immunoglobulin M (IgM) antibodies from short-lived naive B cells, while memory B cells are resistant to stimulation by LPS (possibly due to prior antigen receptor signaling). These observations suggest that lymphocytes may use nonclonal receptors to stimulate rapid, low-affinity, polyclonal responses to reduce microbial growth during the lag period before specific high-affinity immune responses are generated. Also, the products of innate immunity may induce suitable forms of antigen-specific immune responses which reduce the impact of invading microorganisms. However, polyclonal activators are two-edged swords in that too much activation of cells of the immune system can lead to septic or toxic shock.

Antagonism

LPS is considered to be a classical B cell activator in that it activates via a putative receptor that is not the antigen receptor, and shows very little requirement for cell types other than B cells. As such, it would seem to be totally independent of specific responses. However, activation by LPS in terms of immunoglobulin production is inhibited by prior ligation of the antigen receptor, and LPS exposure inhibits activation of B cells to antibody production via the antigen receptor. This has been termed mutual antagonism. Normally, LPS cannot polyclonally activate lymphocytes with receptors that bind self antigens to produce antiself antibodies. However, in some types of autoimmunity, antagonism between LPS- and antigen-signaling is defective. This results in increased polyclonal activation of lymphocytes and eventually leads to production of damaging antiself responses. Polyclonal activators commonly induce autoimmune disease in susceptible hosts. Normally

occurring antagonism is not likely to prevent induction of high-affinity secondary responses when triggered by bacterial antigens attached to LPS, since immune responses to antigens coupled to LPS are not inhibited by prior B cell receptor (BCR) signaling. Polyclonal activation by other agents may or may not be inhibited by ligation of the antigen receptor, suggesting that many mechanisms result in polyclonal activation.

Polyclonal activation by endogenous agents

Do functioning polyclonal activators or inactivators exist endogenously in unmanipulated animals? An indication of endogenous polyclonal activation is the considerable amount of both B and T cell activity that occurs in germ-free mice not exposed to exogenous antigens. However, the degree to which these activities are due to endogenous polyclonal activators versus multiple antigen-specific stimuli is not known. Another example is that of superantigens produced by endogenous retroviruses in certain mouse strains which result in activation followed by deletion of T cells with antigen receptors that react with the superantigens. The binding of superantigens by T cells does not involve the antigen-binding site of the T cell antigen receptors but conserved parts of the variable region. Thus, superantigens affect T cells with different antigen specificities. Superantigens link T cells to major histocompatibility antigen on antigen-presenting cells and induce the activation-in-activation cycle.

Costimulation and coinhibition are physiologically related to polyclonal activation and inhibition

The immune system did not develop in isolation, but in response to various infecting agents with which it had to deal. As discussed above, infecting agents possess polyclonally active agents that stimulate or inhibit immune responses. However, many infecting agents stimulate inappropriate responses, and others do not induce the appropriate responses. The immune system adjusts partly to this situation by making use of internal activators and inhibitors. Classical polyclonal activation may synergize with or antagonize antigen-specific immune responses. The endogenous functional counterparts of such activation and inactivation in the immune system are costimulation and coinhibition, both of which are mediated by polyclonally distributed receptors and ligands.

Costimulation

Synergistic interactions between a clonally restricted antigen receptor and a polyclonal receptor form the basis of costimulation. This is a physiologic process in which receptor–ligand interactions occur, allowing different types of cells to communicate with each other. T cells are activated by signals transmitted via the antigen receptor and other signals transmitted via a second receptor or class of receptors. The classical costimulator of T cells is the receptor CD28 whose ligand is B7 (CD80/86), but there are many others. B cells are activated by signals transmitted via the antigen receptor and other signals transmitted via a second receptor or class of receptors. The classical costimulatory receptor for B cells is CD40 whose ligand is CD40L which is found on T cells. CD40L also acts as a receptor for T cell signaling, so that a given cell surface element can serve as both receptor and ligand. Other costimulatory receptor–ligand systems have been defined, and evidence suggests others (as yet not characterized). It has been suggested that spontaneous autoimmune disease is due to an overabundance of costimulatory signals.

Coinhibition

Interactions between a clonally restricted antigen receptor and a polyclonal receptor can result in coinhibition. Because lymphocytes must be removed when they are not needed or, indeed, are dangerously autoimmune, they possess receptor–ligand pairs that result in lymphocyte death. The expression of these pairs is increased upon lymphocyte activation. In T cells, ligation of the antigen receptor and CTLA-4 leads to inactivation of the T cell. If, however, CD28

is also ligated, the result is pronounced T cell activation. Therefore, the outcome of contact with antigen via the antigen receptor is influenced greatly by what other connections the T cell makes. Mice that lack CTLA-4 develop a lethal autoimmune disease by one month of age.

B cells also have a defined coinhibitor system, the low avidity Fc receptor called FcγRIIB which binds the Fc portion of secreted antibody that is attached to antigen receptors. Antibody is able to suppress immunoglobulin production and to inactivate B cells. This inhibition requires the Fc portion of antibody and involves a coligation of the antigen receptor with the Fc receptor. This coligation results in phosphorylation of the Fc receptor, attachment of a phosphatase (SHP-1), and inactivation of the B cell. A strain of autoimmune mice lacks SHP-1, while mice lacking the Fc receptor have increased immune responses but are not noticeably autoimmune. CD22, another B cell coinhibitory receptor that signals via the recruitment of SHP-1, may take over the function of the Fc receptor when it has been deleted.

Defects in other coinhibitory mechanisms are associated with autoimmunity. Apoptosis defects result from the lack of the receptor Fas (lymphoproliferative, or *lpr* trait) or the lack of the Fas ligand (generalized lymphadenopathy, or *gld* trait). Excess of elements (e.g. Bcl-2) that prevent lymphocyte death or apoptosis also result in autoimmunity. All of these defects are associated with polyclonal activation followed by the emergence of specific antiself responses and clinical autoimmunity. Spontaneous clinical autoimmunity has been associated more with the lack of coinhibition than with augmented costimulation.

Conclusions

Polyclonal activators come from a variety of sources. These activators may stimulate one lymphocyte population and can be used to assess the functional status of that population. Some polyclonal activators require more than one cell type, and, despite their name, may induce profound inhibition and inactivation of lymphocytes. Many interactions occur between antigen-specific and polyclonal forms of lymphocyte activation and inactivation. Functional analogs and physiologic counterparts of classical polyclonal activators and inhibitors (antagonists) are costimulation and coinhibition which serve to regulate specific immune responses. Defects in interactions between these various signaling events, particularly that of antagonism and coinhibition, predispose towards autoimmune disease.

POLYENDOCRINE AUTOIMMUNITY

Anthony P Weetman, Department of Medicine, University of Sheffield, Clinical Sciences Centre, Northern General Hospital, Sheffield, UK

There are two major autoimmune polyglandular syndromes (APS), type I and type II, comprising a constellation of endocrine diseases caused by autoimmunity. The key features of each syndrome are described below. Although additional features have been described in individual patients, it is difficult to know whether these are true associations or ascertainment artifacts. Rarely, patients have features of both types of syndrome. Other polyendocrine autoimmune disorders are considered after the two main syndromes.

APS type I

This is an autosomal recessive disorder, also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy. The prevalence is around 1 in 25 000 in Finland (based on a national survey),

where the disease may be due to a single major mutation derived from a limited founder population. Linkage analysis has indicated that the autosomal locus is on chromosome 21. Iranian Jews may also have a high disease frequency (exact prevalence unknown), but type I APS is very rare elsewhere and may be sporadic.

The clinical components are shown in Table 1. The diagnosis rests on the presence of two of the three major components but the various features differ within and between families. Chronic mucocutaneous candidiasis and hypoparathyroidism usually begin in childhood and children with either of these apparently isolated disorders warrant careful screening. Addison's disease usually occurs 5–10 years later. Patients may die of untreated endocrine disease, severe infections or, in later life, hepatic failure. HLA alleles influence disease expression; HLA-A28

Table 1 Features of the autoimmune polyglandular syndromes types I and II

	<i>APS type I</i>	<i>APS type II</i>
Major components	Chronic mucocutaneous candidiasis Addison's disease Hypoparathyroidism	Addison's disease Type I diabetes mellitus Autoimmune thyroid disease Gonadal failure
Other endocrinopathies	Insulin-dependent diabetes mellitus Gonadal failure Hypothyroidism	Lymphocytic hypophysitis Isolated adrenocorticotrophic hormone or gonadotropin deficiency Lymphocytic infundibulo-neurohypophysitis
Other features	Vitiligo Alopecia Pernicious anemia Hepatitis Malabsorption Ectodermal dysplasia (enamel and nail dystrophy, keratopathy)	Vitiligo Alopecia Pernicious anemia Celiac disease Myasthenia gravis Chronic active hepatitis

is more frequent in those patients with hypoparathyroidism and diabetes mellitus.

Treatment consists of glucocorticoid and mineralocorticoid replacement for adrenal failure, 1α -hydroxycholecalciferol for hypoparathyroidism and ketoconazole for candidiasis.

There are some parallels in autoimmune models in mice and rats; neonatal thymectomy with or without irradiation can induce various endocrinopathies with a relative T cell deficiency, and it is possible that the defective gene in APS type I causes a similar impairment of T cell maturation. T cell responses have not been studied in detail, although nonspecific abnormal responses following mitogen stimulation and generalized cutaneous anergy to recall antigens have been reported. Patients with Addison's disease as part of APS type I have adrenal autoantibodies, predominantly against the cytochrome P450 side-chain cleavage enzyme. This enzyme is also found in the gonads, presumably accounting for the high frequency of premature ovarian failure in the disorder. Most patients also have antibodies against the pancreatic beta cell autoantigens glutamic acid decarboxylase and aromatic-L-amino-acid decarboxylase, irrespective of the presence of clinical diabetes. Parathyroid autoantibodies remain poorly characterized.

APS type II

This is usually defined as the occurrence of two or more of the major components listed in Table 1; some would widen this to encompass various other features such as pernicious anemia, whereas others would limit the syndrome to those patients who have Addison's disease with thyroid autoimmune disease (Graves' disease or autoimmune hypothyroidism) and/or type I diabetes mellitus. The clinical features

of the individual components do not differ from the isolated disorders in their severity or age of appearance. APS type II seems to be inherited as an autosomal dominant condition with incomplete penetrance. There is considerable variation, both within and between families, in the expression of the various components. Affected siblings usually share one or both HLA haplotypes. There is a strong association with HLA-A1, -B8, -DR3, which varies according to the disease components, but is generally greater than with the individual isolated diseases. In addition, HLA-DR4 is increased in frequency in these patients, due to its association with type I diabetes mellitus. However, not all patients have these HLA alleles (suggesting that other loci are involved in the predisposition to develop polyendocrinopathy) and some diseases known to be associated with HLA-DR3, such as systemic lupus erythematosus, do not appear to be unusually frequent in APS type II patients.

It is important to be aware that these autoimmune endocrinopathies have a long prodromal phase and may remain subclinical throughout a patient's life; the presence of appropriate antibodies in such patients may be a marker for future endocrine dysfunction and for the presence of a more extensive autoimmune process than can be appreciated clinically. In particular, occult pernicious anemia/atrophic gastritis may be more frequent than generally appreciated, as revealed by biopsy or achlorhydria after pentagastrin stimulation. Patients with pernicious anemia are especially prone to develop vitiligo.

When considering whether a patient has APS type II, those presenting with Addison's disease are the most likely to have another autoimmune endocrine disorder, 10–25% having gonadal failure, 10–25% type I diabetes mellitus, and 15–25% auto-

immune thyroid disease. In contrast, patients presenting with autoimmune thyroid disease (which is about 500 times commoner than Addison's disease) are much less likely to have the type II syndrome. This has implications for screening, since it is clearly worth testing patients with Addison's disease, but not thyroid autoimmunity, for the presence of other endocrinopathies. Since the separate components may occur 20 years apart in some individuals with the syndrome, there should be long-term follow-up. It is also essential to advise and, where appropriate, test family members for disease once a patient with type II APS has been identified. Apart from screening, the management of this syndrome is the same as that of patients presenting with the individual endocrine abnormalities.

There are no unique features of the T cell or antibody response against endocrine tissues in patients with APS type II compared to those with the isolated disorder. The major adrenal autoantigen in both APS type II and isolated Addison's disease is the 21-hydroxylase enzyme, although other P450 enzymes are also targets in a small proportion of patients. The closest animal models of APS type II are the non-obese diabetic (NOD) mouse and BB strain rat: both animals develop autoimmune diabetes mellitus and have a low but significant prevalence of autoimmune thyroiditis, but adrenalitis is absent. The obese strain (OS) chicken is a close model of Hashimoto's thyroiditis and adrenal and gastric autoantibodies have been reported although tissue destruction does not occur.

Other polyendocrine autoimmunity syndromes

Rarely, diabetes mellitus results from a decreased biological response to a normal amount of insulin. In type A insulin resistance, the problem lies in the insulin receptor, which is quantitatively or qualitatively abnormal, but in the type B syndrome autoantibodies to the insulin receptor produce diabetes mellitus. *In vitro*, using short-term culture experiments, these antibodies mimic the action of insulin, which may account for the occurrence of hypoglycemia in some patients. More typically, however, there is massive insulin resistance, so that even 15 000 units of insulin per day may not lower blood glucose, and prolonged *in vitro* experiments reveal the antagonistic properties of the antibodies. About one-third of these patients have other autoimmune diseases, including systemic lupus erythematosus, Sjögren's syndrome, scleroderma, primary biliary cirrhosis,

Hashimoto's thyroiditis and autoimmune thrombocytopenia. Serological markers include a raised erythrocyte sedimentation rate (ESR), hypergammaglobulinemia and hypocomplementemia.

The POEMS syndrome is a rare form of plasma cell dyscrasia with polyneuropathy, organomegaly (liver and/or spleen), endocrinopathy (hypogonadism, hypothyroidism or diabetes mellitus), monoclonal gammopathy and skin changes, these features giving rise to the acronym. It is likely that the POEMS syndrome represents a variant of osteosclerotic myeloma. The endocrine dysfunction may be caused by specific autoantibodies but this remains unproven.

POLYMERASE CHAIN REACTION (PCR) AMPLIFICATION

Julian F Burke, Biological Sciences, University of Sussex, Falmer, Brighton, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The polymerase chain reaction has revolutionized the study of molecular immunology. In principle it is very simple; DNA is extracted from a cell and a specific gene can then be amplified within 2 h by the addition of a synthetic oligonucleotide complementary to one strand of the DNA and a second oligonucleotide complementary to the opposite strand of the DNA. If the genomic DNA is denatured and made single stranded, cooled, and DNA polymerase added together with deoxynucleotide triphosphates, then the synthetic primers will be extended. As this synthesis is template specific, then the result is a doubling of the DNA sequences bounded by primers. If the DNA is denatured a second time, cooled (reannealed) and extended again, then the amount of DNA will again be doubled. As the procedure is repeated then this results in an exponential increase in the amount of the DNA sequence that is bounded by the primers. After 20 cycles of heating, cooling and extension, approximately a million copies of a target molecule will be produced. This is sufficient to see by agarose gel electrophoresis. Uses of the technique extends from HLA typing to the production of 'humanized' monoclonal antibodies.

Basic technique

The original PCR process was described by K. Mullis in 1983 working for the Cetus Corporation. The first publication describing the procedure appeared in 1985, and in 1993 Mullis was awarded the Nobel Prize for Chemistry. The significant factor which

Figure 1 Typical cycle profile for a PCR reaction.

made PCR possible was the use of a previously described thermal stable DNA polymerase (Taq) isolated from the bacterium *Thermus aquaticus* YT1. This grows in the hot springs of Yellowstone National Park. The enzyme works optimally at 72°C and can withstand the denaturation steps at 94°C. The significance of this is that the enzyme does not have to be replenished between steps in the PCR procedure. The cycling profile is shown in Figure 1. This is performed in a controlled heating block so that each cycle is completed within approximately 3 min. The synthetic nucleotides used in the PCR process are either purchased commercially or are synthesized by the user. Again it must be stressed that in general only genes for which the sequence is already known can be amplified by the PCR process. The standard procedure is outlined in Figure 2.

Applications

The most important determinant for the suitability for tissue transplantation has been the HLA type of the individuals. Traditionally, HLA types have been

Figure 2 The principles of PCR amplification.

identified by the use of antibodies. Now it is common to use PCR; this procedure is faster and more accurate. Specific primers are used to amplify a number of HLA genes in a single tube. After the amplification procedure the products are analyzed by gel electrophoresis. The degree of similarity (and therefore compatibility) is indicated by the banding pattern of the donor and the recipient.

Within the human genome are a number of loci known as microsatellites or short tandem repeats (STRs). As these repeated sequences vary from individual to individual they can be used for genetic mapping. Most often these microsatellites vary in the number of CA nucleotide repeats; these repeats can be detected by using synthetic primers that amplify unique sequences either side of a CA repeat. Different allele sizes are seen by the migration of amplified DNA on a polyacrylamide or agarose gel. In a standard reaction seven primer pairs are used; these not only have a discriminatory power of greater than 1×10^{-9} but can also be used to confirm the sex of an individual using primer sequences based on the human gene amelogenin, a gene that encodes a protein that makes up part of the tooth enamel.

As PCR procedures become widespread, it may be that many of the antibody-based techniques used in immunology ranging from tissue typing to microbial identification will be replaced by DNA-based methods.

POLYOMAVIRUS, INFECTION AND IMMUNITY

Keerti V Shah, Department of Molecular and Immunology, School of Hygiene and Public Health, Maryland, USA

The polyomaviruses are widely distributed in nature. Infections are species specific and largely harmless in normal hosts. The viruses remain latent after primary infection and are reactivated when T cell functions are impaired. Most of the pathogenic consequences of polyomavirus infections are associated with virus reactivation in immunocompromised hosts. Two

polyomaviruses, JC virus (JCV) and BK virus (BKV), infect humans.

Characteristics of the organism and its antigens

The virion of polyomaviruses is small (diameter

45 nm), with a noneveloped icosahedral capsid and a circular, superhelical, double-stranded DNA genome of about 5000 base pairs. The viral genome is functionally divided into an early region (2.3 kb) which codes for the regulatory T proteins, a late region (2.3 kb) which codes for capsid proteins, and a noncoding regulatory region (0.4 kb). The early and late regions are transcribed from different strands of the DNA molecule. Although polyomaviruses and papillomaviruses are classified as two genera of the family Papovaviridae, the two are not related immunologically or genetically. The capsid is composed of three proteins. The major capsid protein, VP1, which constitutes more than 70% of the virion mass, mediates viral attachment to receptors on susceptible cells and contains epitopes for neutralization and hemagglutination inhibition. The large T antigen of polyomaviruses is a multifunctional protein. It binds to specific sites in the regulatory region of the viral genome to initiate viral DNA replication, stimulates host DNA synthesis by activation of cellular genes, and modulates early and late transcription. The T antigen of primate polyomaviruses is an oncogene which is required for the establishment and maintenance of virus-induced transformation.

Polyomaviruses multiply in the nucleus and produce nuclear injury and cell death in permissive cells. Nearly all of the pathogenic effects of polyomaviruses can be ascribed to lysis of infected cells. Nuclei of infected cells are enlarged and display inclusions. Infection probably occurs by the respiratory route, after which the viruses reach their target organs by viremia. The target organs for polyomaviruses may be urinary tract epithelium (BKV, JCV and simian virus 40 of Asian macaques), oligodendrocytes in the brain (JCV), and pulmonary endothelium (K virus of mice).

Progressive multifocal leukoencephalopathy (PML) is a subacute demyelinating fatal disorder of the central nervous system caused by JCV. It was once considered rare and occurred mostly in the fifth and later decades of life. With the advent of acquired immune deficiency syndrome (AIDS) and the large numbers of organ transplantations, the population at risk for PML has increased and the disease is seen frequently and in younger individuals. PML was identified in as many as 3.8% of AIDS patients who reported neurologic abnormalities and, in the USA, AIDS-associated PML cases outnumber all other cases of PML. PML occurs as an infrequent complication in many other conditions which include lymphoproliferative disorders, chronic diseases, primary immunodeficiency diseases and autoimmune diseases. The onset of PML is insidious and may occur at any time during the course of the underlying condition. Early signs and symptoms point to multifocal, asymmetric lesions in the brain in the absence of increased intracranial pressure. Impaired speech and vision and mental deterioration occur early in the disease. Paralysis of limbs, cortical blindness, and sensory abnormalities are common. Death occurs within 3–6 months of onset. Throughout the disease, the patient has normal cerebrospinal fluid and remains afebrile. Noninvasive techniques such as computed tomography and magnetic resonance imaging are effective in the diagnosis of PML.

The key pathogenetic event in PML is the cytotoxic infection of oligodendrocytes with JCV (Figure 1). Oligodendrocytes are responsible for the formation and maintenance of myelin and their destruction leads to demyelination. The PML brain shows widespread foci of demyelination of varying size. In advanced cases, the centers of the large areas may be necrotic and form cavities. The lesions are most frequent in the subcortical white matter and the

Figure 1 (A) PML lesion showing oligodendrocytes with enlarged deeply staining nuclei (arrow) and giant astrocytes. (B) Crystalloid array of JCV particles in an infected oligodendrocyte nucleus. (Courtesy of Dr G ZuRhein.)

cerebrum is almost always affected. Microscopically, the diagnostic feature of PML is the presence of enlarged oligodendrocytes located at the edges of the foci of demyelination with nuclei 2–3 times their normal size. The affected nuclei are deeply basophilic and contain abundant numbers of viral particles. In a majority of the cases, the centers of the demyelinated areas contain greatly enlarged, bizarre, giant astrocytes which have pleomorphic hyperchromatic nuclei. These astrocytes seldom contain viral particles or viral antigen and may represent cells 'transformed' by JCV. Inflammatory response is minimal or absent. Analyses of JCV genomes recovered from PML brains indicate that specific rearrangements in the regulatory region of the virus are associated with its ability to grow in the central nervous system.

PML patients have a generally depressed cellular immunity and a marked decrease in the specific ability of lymphocytes to respond to JCV antigen. The virus probably reaches the brain by the haematogenous route, thus accounting for the widespread and multifocal distribution of discrete foci of demyelination. In PML cases, JCV has been detected in mononuclear cells in the bone marrow, the spleen, and the Virchow–Robin spaces in the brain.

BKV excretion in urine is associated temporally with hemorrhagic cystitis which is a frequent complication in bone marrow transplant recipients, especially in those receiving allogeneic marrow. Ureteral stenosis, an uncommon late complication of renal transplantation, is associated with BKV infection. BKV was incriminated as the likely cause of a fatal tubulointerstitial nephritis in a child with a primary immunodeficiency disease. Nonfatal cases of cystitis in healthy children have been occasionally linked to BKV infection. BKV and JCV are reactivated in pregnancy but do no apparent harm to the women and are not transmitted to the fetus.

BKV genomic sequences have been recovered from brain tumors and pancreatic islet cell tumors but the significance of these observations is at present unknown.

Immune responses of the host

Primary infections with BKV and JCV occur in childhood. In the USA, 50% of the children acquire antibodies to BKV by the age of 3 years and to JCV by the age of 10–12 years. Antibody response is measured by neutralization, hemagglutination inhibition

and ELISA. Virus reactivation is often accompanied by an increase in antibody titers. Virus-specific immunoglobulin M (IgM) antibodies have been described in the sera of renal transplant recipients.

BKV infections generate cell-mediated immunity (CMI) as measured by lymphoproliferative assays. In bone marrow transplant recipients, both the humoral and CMI responses to BKV infections are severely depressed.

Evasive strategies by the organism

Following primary infections in childhood, BKV and JCV are not cleared from the body but remain latent in the kidney and in B lymphocytes for an indefinite period of time. Virus reactivation may occur in as many as 50% of the previously infected seropositive adults in the face of severe immunosuppression. It is likely that CMI prevents or limits virus reactivation in healthy individuals. Impaired CMI, as may occur in physiological states such as pregnancy and aging, or in more severe conditions such as organ transplantation, immunosuppressive therapy and AIDS, results in virus reactivation and viraemia.

Vaccines

The pathogenic effects of polyomaviruses are rare, even in the populations at risk, and they result from reactivation of infections latent since childhood. Therefore, no attempts have been made to develop vaccines against polyomavirus infections.

PORCINE IMMUNE SYSTEM

Ilija Trebicharský, Section of Immunology and Gnotobiology, Institute of Microbiology,
Nový Hrádek, Czech Republic

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Pigs belong to the order Artiodactyla (with camels, deer, cattle), which appeared abruptly with primates and odd-toed ungulates in the early Eocene. The pig is of considerable interest to immunologists because of its potential use in xenotransplantation; the absence of maternal immunoglobulins in newborns; its physiological similarity to humans; its phylogenetic proximity to cattle; and the major importance of both species in human diet.

The porcine immune system differs from that of mice and humans in the following features.

1. Pigs have inverted lymph nodes (dense medulla lacks sinuses and cords).
2. Porcine lymphocytes leave lymph nodes (in the paracortex) in the blood and not in efferent lymph. The $\gamma\delta$ T lymphocytes enter the lymph nodes directly from blood vessels and not via afferent lymph.
3. Pigs have four types of Peyer's patches (PPs): dispersed jejunal PPs, a continuous ileal PP (B organ in young piglets), spiral colon PPs, and numerous single small PPs distally in the colon.
4. Pigs have small tonsillar papillae in the down of the tongue along with palatine and nasopharyngeal tonsils.
5. Porcine epitheliochorial placenta prevents transfer of immunoglobulins. This means that maternal colostrum represents a vital source of antibodies for neonates. Colostrum-deprived newborn piglets contain only traces of immunoglobulins; cells forming IgM are present in the spleen and liver. The ability to reabsorb maternal immunoglobulins decreases during the first hours of feeding and between 2 h (in the duodenum) and 2 days (in the ileum) the epithelium of the gut changes and prevents any further absorption of intact colostral immunoglobulins.

Fetal and perinatal ontogeny

Numerous natural killer (NK) cells appear in the endometrium of pregnant sow (day 9 of gestation), i.e. before attachment of the blastocyst (day 14). Pig conceptus is capable of antiviral activity (interferon α (IFN α) and IFN γ) (day 14).

Hematopoiesis starts in the yolk sac (day 16) as in other mammals and lasts only for a short period

(day 24). The majority of cells are erythroid cells, stem cells and macrophage precursors. Erythropoiesis continues (day 20) in the liver (rudiment day 17) where platelets are also observed.

Lymphoid cells appear in the liver after macrophages (day 25), natural IFN α -producing cells (day 26), and myelocytes (day 28). The CD2 molecule and Thy-1 mRNA are detected in embryonic liver (day 30). Lymphatic vessels appear (day 32). Erythropoiesis is observed also (day 31) in the spleen (rudiment day 22); lymphocytes, however, occur later.

Thymic and cord blood cells are inducible to tumor necrosis factor α (TNF α) synthesis (day 34). The thymus (rudiment day 21) contains CD3⁺ T cells (day 40).

Other sites of hematopoiesis (e.g. para-aortic area) cannot be excluded. Lymphocytes occur very early in the omentum (day 40). Few MAC320⁺ lymphocytes appear early in the liver (day 40).

The sIgM⁺ B cells occur in the liver (day 44). The first serum immunoglobulins, specific antitflagellin antibody response, and CD4⁺ and CD8⁺ thymocytes were found in the same developmental stage (day 44).

By 50 days of gestation, lymphocytes occur in bone marrow and gut, liver B cells secrete IgM, T cells are in the spleen and skin, thymus cortex and medulla are formed and lymphocyte mitogenic response is detectable.

By 55 days antiparvovirus antibodies can be detected, purified protein derivative (PPD) of *Mycobacterium tuberculosis* elicits a T cell response *in vivo* and sIgM⁺ B cells are found in the spleen.

Hassall bodies appear (day 64), thymic B cells secreting IgM, IgG and IgA (only IgM in the spleen) arise (day 67), Peyer's patches are formed (day 77) and the first plasma cells appear in immunized fetuses (day 80).

Perinatally, lung alveolar and perivascular macrophages occur. Maternal immunoglobulins are transferred from the colostrum in the first 2 days after birth.

Macrophages gain functional maturity and germinal centers appear in the spleen at day 7. By day 10, a normal white blood cell picture with predominant lymphocytes is formed. By 2 weeks an influx of T cells into the lamina propria of the gut occurs, IgA⁺ and IgG⁺ B cells (mainly in the ileum) and new

germinal centers appear (in lymph nodes and Peyer's patches).

MHC

The genome of the pigs, unlike other species, contains a relatively small class I gene family. The porcine major histocompatibility complex (MHC) class I products encoded by seven genes designated PD are composed of a 44 kDa heavy chain (chromosome 7) and a 12 kDa β_2 -microglobulin, both with sequence homology to the human analogs. Six PD genes are highly homologous, whereas the seventh (PD6 gene) is distantly related.

The MHC class II products consist of a 32 kDa heavy chain and a 25 kDa light chain. SLA-DR and SLA-DQ subsets of class II antigens have been demonstrated. Human class II gene probes cross-hybridize with pig DNA.

Complement

Hemolytic complement C and components in adults in CH_{50} units ml^{-1} of serum: total C 50, C2 2000, C3 3200, C5 800, C6 6400, C7 40 000, C8 32 000, C9 14 000. Complement in newborn piglets $3.5 \pm 1.3 \text{ CH}_{50} \text{ ml}^{-1}$, by 10 weeks $35.7 \pm 25.5 \text{ CH}_{50} \text{ ml}^{-1}$.

Peripheral blood leukocytes

Throughout life the average leukocyte count is 16 million ml^{-1} (in the range 11–22), at birth 6 million (in the range 4.2–9). The differential distribution is as follows (mean and range in %):

Mature neutrophils	37%	(28–47)
Immature neutrophils	1%	(0–4)
Lymphocytes	53%	(39–62)
Monocytes	5%	(2–10)
Eosinophils	3.5%	(0.5–11)
Basophils	0.5%	(0–2)

Unique features of porcine blood leukocytes are the high proportion of $\gamma\delta$ T cells, the fact that the ratio of $\text{CD8}^+:\text{CD4}^+$ T cells is high in adults, and the high frequency of $\text{CD4}^+\text{CD8}^+$ double-positive T cells.

Granulocytes

The differential distribution of peripheral blood leukocytes in newborn pigs is in the order of 60% neutrophils and 38% lymphocytes. This ratio is reversed by the 10th day of life. The absolute number of leukocytes is only 3 million ml^{-1} in germ-free piglets

with a persisting deficit in lymphocytes. Functional maturity of neutrophils is accelerated in the presence of endogenous gut microflora. Some heterogeneity (in MIL4 expression) has been observed in peripheral blood neutrophils. Eosinophils can also be distinguished by membrane antigens expression ($\text{SWC1}^-\text{SWC3}^+$).

Monocytes/macrophages

Four clusters of differentiation (SWC4, SWC9, CD14 and CD16) have been defined so far. New monoclonal antibodies have confirmed the antigenic heterogeneity of tissue macrophages.

Phagocytic activity and metabolic burst are very low in fetal and perinatal macrophages. Maturation of macrophages seems to be heavily influenced by the endogenous gut microflora. The metabolic burst of monocytes measured by INT (iodine nitro-tetrazolium) increased in germ-free piglets one day after per oral *Enterococcus faecalis* challenge (the INT index is the ratio of stimulated:control absorbances).

B cells

Minute amounts of immunoglobulins appear in the serum of healthy nonstimulated pig fetuses by 44 days of gestation ($\text{IgM } 24 \text{ ng ml}^{-1}$, $\text{IgG } 26 \text{ ng ml}^{-1}$ and $\text{IgA } 15 \text{ ng ml}^{-1}$). These levels increase during fetal ontogeny independently of external stimuli. Naturally occurring fetal IgM antibodies react with phylogenetically conserved molecules (trypsin, ssDNA) autoantigens (FSH, thymocytes) and bacterial components (tetanic anatoxin, *E. coli* O86). The concentrations of immunoglobulins in piglets and adults are shown in Table 1.

IgM, IgA, IgG and IgE are coded for by constant region genes. There is a high degree of sequence similarity between all pig C_{H} genes and those in humans.

Table 1 Porcine immunoglobulins in piglets and adults (mg/ml)

	IgG	IgM	IgA
<i>Serum</i>			
Adult pigs	18.3–19.5	3.15–3.19	1.44–2.68
Sow, 1 week of lactation	28.2	4.8	2.0
Sow, 1 week of gestation	36.3	6.3	1.5
Piglets, 1 day	20.4–26.3	1.02–2.9	2.62–9.1
Piglets, 1 month	5.1–6.7	0.86–1.5	0.20–1.05
<i>Secretions</i>			
Colostrum	61.8	3.19	9.66
Milk, 8–35 days	1.35	0.89	3.04

A single gene for IgA has allelic forms IgA^a and IgA^b. Pigs have the largest number of IgG subclasses of all the animals so far studied. Gene conversion seems to create antibody diversity in pigs.

T cells

αβ T cells

Porcine TcRαβ is a dimer with a molecular mass of 46–48 kDa under reducing conditions. αβ T cells express the CD2 and CD3 molecules and can be further divided into several subsets according to the expression of the CD4 and/or CD8 molecules. Classical CD4⁺CD8⁻ and CD4⁻CD8⁺ cells are present and also unusual CD4⁺CD8⁺ memory helper cells can be found.

γδ T cells

The phenotype of γδ T cells is CD2⁻ or CD2⁺, CD3⁺, CD4⁺, CD8⁻, CD5⁻, γδ TCR⁺. TcR δ chain shows a molecular mass of 40 kDa. In association with this δ chain, three γ chains differing in their molecular masses could be identified by immunoprecipitation from sorted CD4⁻CD8⁻ T lymphocyte subsets.

One γ chain with a molecular mass of 38 kDa is expressed on CD2⁺CD4⁺CD8⁻ T cells characterized by an ungulate common epitope recognized by murine anti-sheep monoclonal antibody (mAb) 86D. These γδ T cells are found in peripheral blood. Another γ chain (37 kDa) could be allocated to the 86D⁻CD2⁺CD4⁺CD8⁻ T cells present in the circulation and lymphatic tissues. A third γ chain (46 kDa) is expressed on CD2⁺ TcRγδ T lymphocytes distributed in lymphatic tissues.

Porcine γδ T cells are frequent in peripheral blood (20–30% of lymphocytes in young pigs), in gut-associated lymphatic tissues and in the spleen, but rare in lymph nodes and thymus. They migrate into inflammatory sites in mucosae and skin.

NK cells

CD2⁺, CD4⁺, CD8^{low} cells are able to lyse K562 cells, porcine kidney cells and cells infected with pseudorabies virus. Cells with this phenotype form about 30% of blood lymphocytes, 10% of spleen lymphocytes and less than 5% in tonsils and lymph nodes in young pigs.

NK cytotoxicity is low in newborn pigs, whereas ADCC (antibody-dependent cellular cytotoxicity) is comparable with that of older piglets.

Differentiation antigens

A number of monoclonal antibodies reactive with porcine leukocyte membrane molecules has been characterized. These CD molecules, wCD (Workshop) molecules or SWC (swine-specific) molecules can be detected with standard monoclonal antibodies: CD2, 3, 4, 5, 14, 16, 18, 45, wCD1, 6, 8, 21, 25, 29, 44, and SWC1, SWC2 on T cells, SWC3 and SWC9 on macrophages, SWC4, SWC5, and SWC6 on null cells, SWC7 on B cells, and SWC8 on lymphoid cells. The 74-22-15 antibody (SWC3) recognizes macrophages and some granulocytes, MIL-1 recognizes alveolar macrophages, MIL-3 and MIL-4 neutrophils and eosinophils, and MAC 320 null/γδ T cells.

Humans and Old World monkeys have natural antibodies recognizing α-galactosyl epitopes on porcine endothelium. These antibodies mediate hyperacute rejection of porcine xenografts by primates.

Adhesion molecules

E-Selectin and some integrins were studied in the course of inflammatory reactions. There is a rapidly growing panel of monoclonal antibodies directed against these molecules. The 2F4/11 monoclonal antibody recognizes CD11b or α chain of the porcine complement type 3 receptor (CR3).

Cytokines

Interferons (IFNα, IFNγ and trophoblastic IFN) and inflammatory cytokines and chemokines (TNFα, IL-1, IL-6, IL-8, TGFβ) are being intensively studied in pigs. Other cytokines have also been cloned, including IL-2, IL-4, IL-5, IL-10, IL-12, GM-CSF, G-CSF, SCF, TNFβ.

Gut

Intestinal villi

1. Pig intestinal epithelium does not express MHC class II molecules.
2. Activated T cells and the endothelium (MIL-11⁺) express MHC class II.
3. CD4⁺ and CD8⁺ T cells are lacking in newborn and young germ-free piglets. Enterocytes in newborn piglets have large cytoplasmic vacuoles disappearing after gut closure (in germ-free piglets persisting for some 6 weeks).
4. Intraepithelial lymphocytes are MHC II⁺CD8⁻ (also adjacent to the epithelium).
5. Core cells are CD4⁺ T cells coexpressing the SLA-DR molecules when activated.

Deep lamina propria

1. Eosinophils among crypts are MIL-3⁺, MHC II⁺ cells.
2. Neutrophils (e.g. *Salmonella*-infected pigs) in the base of villi express MIL-4.
3. Macrophages (74-22-15⁺, MIL-3⁻, MIL-4⁻) are distributed mostly in the interfollicular area.

Peyer's patches (PPs)

	Jejunal PP	Ileal PP
Number	25-35	1
Size	small	large
Persistence	whole life	1 year
IgM ⁻ CD2 ⁻ cells	?	35%
B/T cell ratio	1	10

PP cells produce IL-2 and IFN γ , whereas lamina propria lymphocytes secrete IL-4, IL-5 and IL-6 cytokines. Peyer's patches play an important role in the differentiation of immune cells, antigen recognition, specific immune responses, and as the site of invasion for some pathogens.

Lungs

Clearance of bacteria from the circulation occurs in adult pigs predominantly in pulmonary intravascular macrophages (PIMs), and not in Kupffer cells and splenic macrophages as in humans or newborn piglets. A 2-month-old pig clears as much as 75% of *S. aureus* bacteria by PIMs.

Airborne particles are cleared by alveolar macrophages (AMs), cells with the phenotype CD45⁺, 74-22-15⁺, SLA-DR⁺, MIL-1⁺, MIL-2⁻, MIL-3⁻, MIL-4⁻. The AMs and PIMs both originate perinatally from circulating monocytes and produce inflammatory cytokines when stimulated. The full phagocytic activity of the AMs appear in 7-day-old piglets.

The INT indexes of AMs increased one day after per oral challenge of germ-free piglets with *Enterococcus faecalis*.

Differences between alveolar and intravascular macrophages:

	AM	PIM
Function	more phagocytic	more cytolytic
Quantity	10 ⁷	10 ⁹

The bronchus-associated lymphatic tissue (BALT) is absent in germ-free piglets. Lymphocytes occur in lungs in BAL (bronchial alveolar lavages), in BALT, intraepithelially, interstitially or in vessels.

The upper respiratory tract produces predominantly IgA, whereas lungs produce mostly IgG. Oral immunization elicits an increase of plasma cells in BAL (IgG > IgA > IgM) and leads to the protection against subsequent infection. The frequency of SLA-DR⁺ cells in alveolar lavages significantly increased 24 h after *E. faecalis* per oral challenge in one-day-old germ-free piglets (from 21% to 66%). An even greater increase was observed in young germ-free piglets colonized with *E. coli* microorganisms via airways (all alveolar cells in 3-day-old piglets were SLA-DR⁺ 24 h postchallenge).

POXVIRUS, INFECTION AND IMMUNITY

R Paul Kitching, Institute for Animal Health, Pirbright Laboratory, Surrey, UK

Jef M Hammond, CSIRO, Australian Animal Health Laboratory, Victoria, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The poxviruses of vertebrates are classified into eight genera, determined by their antigenic characteristics (Table 1). Morphologically, only the parapoxviruses are distinct from the other groups, being oval rather than brick shaped, and being covered in a continuous tubular element rather than a large number of short projecting tubular elements. A precipitating 'nucleo-

protein' common to the parapoxvirus, orthopoxvirus, leporipoxvirus and avipoxvirus genera has been identified, prepared by alkaline extraction of the virion. Subsequent investigations have shown four cross-reacting polypeptides between orthopoxviruses and leporipoxviruses, and one between capripoxviruses and parapoxviruses. However, none of these are significant in cross-immunity between the genera.

Within the orthopoxviruses, there is good cross-immunity between all the members, exemplified by the use of vaccinia to protect against smallpox (variola). The antigens which stimulate protective antibodies are present in the surface tubular elements and in the envelope derived from modified cellular membrane that surrounds the naturally released virion. Virions released from disrupted cells lack this external membrane and are reported to be less infectious. The envelope also contains the glycoprotein hemagglutinin, which is common to all orthopoxviruses but absent from the other seven genera. Approximately 80 polypeptides can be identified by one-dimensional polyacrylamide electrophoresis of purified vaccinia virus. Sera prepared against the disrupted virion can be adsorbed with purified heterologous orthopoxviruses to distinguish between the different members of the group using agar gel immunoprecipitation. Monoclonal antibodies are available to characterize the major antigens.

All members of the capripoxvirus genus also cross-protect, and although differences have been identified between the viral polypeptides of different isolates, these have not yet been used to distinguish between them. As with the orthopoxviruses, polyclonal sera are equally reactive with homologous and heterologous strains of capripoxvirus. Distinction can also be made between enveloped, naturally released virion and unenveloped virion derived from a disrupted cell.

The poxviruses of birds were originally placed together in what was thought to be an antigenically closely related group. More recent investigations suggest that at least three immunologically distinct types of avian poxvirus exist, represented by type species: fowl poxvirus, quail poxvirus, and psittacine poxvirus.

The parapoxviruses form a morphologically distinct group, with shared antigens which cross-react

Table 1 The poxviruses of vertebrates

Orthopoxvirus	Vaccinia
	Buffalo pox
	Camel pox
	Ectromelia
	Monkey pox
	Rabbit pox
	Raccoon pox
	Taterapox
	Variola
	Cowpox
	Vole pox
	(Skunk pox)
	(Uasin Gishu disease)
Capripoxvirus	Sheep pox
	Goat pox
	Lumpy skin disease (Neethling)
Parapoxvirus	Contagious pustular dermatitis
	Bovine papular stomatitis
	Orf
	Pseudocowpox
	Parapox of red deer
	(Contagious ecthyma of camels)
	(Chamois contagious ecthyma)
Avipoxvirus	(Seal pox)
	Fowlpox
	Canary pox
	Junco pox
	Pigeon pox
	Quail pox
	Sparrow pox
	Starling pox
	Turkey pox
	Mynah pox
	Psittacine pox
	(Peacock pox)
	(Penguin pox)
Leporipoxvirus	Myxoma virus
	Hare fibroma
	Rabbit (shope) fibroma
	Squirrel fibroma
Suipoxvirus	Swinepox
Molluscipoxvirus	Molluscum contagiosum
Yatapoxvirus	Tanapox
	Yaba monkey tumor

in all standard serological tests. However, previous infection gives only limited protection against even homologous challenge, so that the cross-protection studies used to place new strains of poxvirus into any of the other poxvirus genera cannot be applied to novel strains of parapoxvirus.

The poxvirus genome appears to be very stable in the field situation. Isolates of capripoxvirus collected in Kenya over a 30 year period cannot be distinguished by comparing the genome fragments generated by *Hind*III restriction endonuclease digestion. The orthopoxvirus, vaccinia, has also persisted, little changed, in buffaloes as buffalo pox. Major genomic changes may occur when recombination takes place between poxviruses during a dual infection. This has been shown to occur not only in the laboratory between strains of orthopoxvirus and between strains of leporipoxvirus, but also in the field between strains of capripoxvirus. Whether recombination could occur between strains of different poxvirus genera is probably unlikely, but within genera there is potential for the evolution of new combinations with an enlarged host range or increased virulence.

Immune response

The humoral response to poxvirus infection results in the production of numerous antibodies which can be detected *in vitro* using complement fixation, immunofluorescence, virus neutralization, hemagglutination inhibition, immunoprecipitation, radioimmunoassay and ELISA tests. However, although many antibody specificities are produced, it is likely that only certain functional groups play a role in recovery and protection from poxvirus infection. These groups comprise antibodies which directly neutralize either enveloped or nonenveloped virion infectivity, those which complex with circulating antigens to aid immune clearance by phagocytes, and those which in conjunction with effector cells and/or complement mediate lysis of infected cells.

Neutralizing antibody may reduce or prevent viremia in primary and secondary infections by directly acting on extracellular virus. It is possible to protect susceptible mice from ectromelia infection by the passive transfer of serum from immune mice, and passive transfer of serum from sheep recovered from capripoxvirus infection protects sheep challenged with a virulent strain of capripoxvirus. This passive protection is short lived and limited in its effectiveness compared with active immunization with live virus, which provides far greater levels of long-lasting protection.

Highly cross-reactive neutralizing antibodies are

detectable in orthopoxvirus infections from days 6–8 postinfection and can remain elevated for over 20 years. No direct correlation appears to exist between the levels of neutralizing antibody and the immune status of the individual. Although antibody does exert some influence on poxvirus multiplication and spread, the cell-mediated response of the host has consistently proved to be the major factor contributing to protection and recovery from poxvirus disease.

In ectromelia infection of mice, there is an absolute requirement for immune T lymphocytes and cells of the monocyte/macrophage series for regression of infectious foci in the liver. Ectromelia-specific cytotoxic T lymphocytes are detectable from 2 to 4 days postinfection and reach peak levels by day 6. A delayed-type hypersensitivity reaction is detectable from day 2, whereas significant levels of neutralizing antibodies do not appear until day 8. *In vitro*, 3 hours after infection with ectromelia virus, target cells are specifically lysed by ectromelia-primed T cells, indicating that a population of cytotoxic T lymphocytes specific for determinants which appear early after infection are present.

The delayed-type hypersensitivity reaction comprising a T lymphocyte-mediated response to antigens injected under the skin was commonly used as an assessment of immunity to smallpox. In sheep, the presence of such a reaction is taken as evidence of immunity to capripox. However, the absence of a discernible delayed-type hypersensitivity response is not conclusive evidence of complete susceptibility to capripoxvirus infection.

Recovery from infection with vaccinia virus in rhesus monkeys and hamsters is mediated by a population of non-major histocompatibility complex (MHC)-restricted NK (natural killer) cells, whereas, in sheep, recovery from vaccinia virus infection is due to virus-specific MHC-restricted cytotoxic T lymphocytes.

Vaccination of individuals with vaccinia virus after they have been exposed to variola results in an accelerated immune response, with a similar reaction observed in sheep following reinfection with contagious pustular dermatitis. Vaccinia virus is sensitive to interferon (IFN), although its role in protection and recovery from poxvirus disease is unknown.

Immune interaction and evasion

During infection, the majority of newly synthesized poxvirus remains intracellular and is transmitted from cell to cell. This prevents circulating neutralizing antibody from coming into contact with rep-

licating virus. Only neutralizing antibody directed against external virus budding from infected cells has been shown to play a part in recovery. In most cases, a productive infection generally leads to host-cell death, although it has been reported under certain conditions that vaccinia virus can persist for unusually long periods, possibly in a benign form. Virus may also survive because of its ability to spread throughout the host, particularly in the skin. It is possible that the ability of the epidermal Langerhans cells to process and present poxvirus antigens to T lymphocytes may prove to be an important factor in initiating a protective immune response.

Poxviruses encode a variety of functional homologs of host cell factors which regulate the immune system. Some operate directly within infected cells, downregulating synthesis and processing of specific proteins such as interleukin 1 β (IL-1 β) and the expression of MHC class I antigens. Others, such as complement control proteins, soluble cytokine receptors and serine protease inhibitors, may be secreted into the extracellular environment and function some distance from the site of infection (Table 2).

Poxviruses replicate in the cytoplasm of infected cells and as a result encode many factors which manipulate and regulate the intracellular environ-

ment. It is now clear that by encoding a variety of virokines and other proteins which can interact with and modulate the host immune system, poxviruses can also exert a significant effect upon their extracellular environment.

Vaccines

In 1798, Edward Jenner published results of his experiments which showed that previous infection with cowpox – variolae vaccinae – protected humans against challenge with smallpox. Although the original observation can be traced back to country folklore, Jenner was the first to test the hypothesis scientifically. He had also to contend with the difficulty that cattle could be infected with either cowpox, an orthopoxvirus which did protect, or the clinically similar pseudocowpox, a parapoxvirus which did not confer protection. In 1881, Pasteur defined the term 'vaccination' to include any form of prophylactic inoculation.

At what stage cowpox virus was replaced by vaccinia is not clear. Even the origin of vaccinia is not known: suggestions include horse pox, which is now extinct, or a recombinant derived from cowpox and smallpox. Regardless of origin, cowpox vaccinia was

Table 2 Poxvirus encoded factors which interact with the host immune system

Host factor/mechanism	Virus-encoded homolog	Function
Complement control proteins	Vaccinia complement control protein (VCP) VV VV (B5R)	Secreted from infected cell binds C4b and C3b and blocks complement activation Sequence homology only, membrane bound
Cytokine receptors	IL-1 receptor VV, CPV IFN γ receptor M, SFV, VV, CPV TNF receptor SFV, M, VV IL-8 receptor SPV	Binds IL-1 β and abrogates function Binds IFN γ and abrogates function Binds TNF α and abrogates function Sequence homology only

CPV, cowpox virus; M, myxoma virus; OV, orf virus; RPV, rabbit pox virus; SFV, Shope fibroma virus; SPV, swinepox virus; VV, vaccinia virus; PKR, double-stranded RNA-dependent protein kinase; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; TNF, tumor necrosis factor. Gene designations are given in parentheses.

extremely valuable in helping to reduce the mortality rate due to smallpox and ultimately to the declaration, on 9 December 1979, that the disease had been eradicated from the world.

Complications associated with vaccination against smallpox were initially ignored as being insignificant compared with the consequences of infection. But as the industrial countries eradicated smallpox, it was seen that more patients were suffering the effects of vaccination than were being infected with smallpox. Complications included eczema vaccinatum in patients suffering from eczema, progressive vaccinia in patients with cell-mediated immune deficiency or agammaglobulinemia, generalized vaccinia, accidental infection, postvaccinal tonsillitis, postvaccinal encephalopathy in infants under 2 years old, and postvaccinal encephalitis in patients over 2 years old. In a very large survey carried out by the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia in 1968, 75 people per million given primary vaccination had associated complications, and, of these, 1 per million died, either of postvaccinal encephalitis or progressive vaccinia. Following secondary vaccination only 5 people per million had associated complications.

Vaccinia has also been used successfully in veterinary medicine to control camelpox, although it is less efficient in controlling ectromelia. However, less successful has been its apparent persistence in buffaloes as buffalo pox, and in rabbits as rabbit pox. How vaccinia was introduced to these species is not certain, but there are numerous examples of the transmission of the virus from recently vaccinated dairy farmers to the udders of their cows.

Sheep, goats and cattle can be effectively vaccinated against capripoxvirus infection, and single vaccines are available to protect all three species. Similarly, pigeon pox virus is effective in protecting chickens and turkeys against fowlpox and turkey pox. Separate vaccines are required against quail pox and against psittacine pox. Shope fibroma virus provides good protection in rabbits against myxomatosis, although it is less effective than homologous vaccine.

Vaccination against parapoxvirus infection is considerably less effective than that against ortho-, capri-, avi- or leporipoxvirus infection. Even against challenge with the homologous virus strain, contagious pustular dermatitis vaccine gives only limited protection.

Dead vaccines against smallpox and capripox have been developed, but at best these have provided only

temporary protection, compared with the prolonged protection provided by live vaccines. Part of the initial failure was due to the use of unenveloped virus derived from disrupted cells. Poxvirus in tissue culture is highly cell-associated, and yields of extracellular, enveloped virus are small. However, even when this problem had been recognized, further attempts to develop effective dead vaccines have been unsuccessful.

Poxvirus recombinants are valuable research tools; by facilitating the expression of individual gene products or particular epitopes, specific immune responses can be studied in isolation from the whole pathogen. This approach has helped to identify and decipher individual components of the immune system, including the relative functions of particular T cell subsets. More recently, there has been a revival in interest in vaccinia as a vector for the genes of pathogens such as hepatitis B, rabies, rinderpest, plasmodium, respiratory syncytial virus, vesicular stomatitis and human immunodeficiency virus (HIV). The advantages of having a replicating vector expressing the antigens of these agents are self-evident. Vaccinia virus is genetically stable, easy to produce and apply, and nononcogenic. The disadvantages of its use as a vector are its possible virulence in nontargeted hosts including humans, the possibility that it could recombine with other poxviruses in the field, and the effect it could have on immunodeficient individuals. Veterinary vaccines using capripoxvirus or avipoxvirus vectors may prove to be more acceptable than those incorporating vaccinia virus.

PRECIPITATION REACTION

Örjan TG Ouchterlony, Department of Medical Microbiology and Immunology, University of Göteborg, Göteborg, Sweden

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Immunoprecipitation is a process that takes place when a solution of antigen is mixed with corresponding precipitating antibodies and, as a result, a visible precipitate or aggregating floccules are formed. The original observation of this serological phenomenon was made by R. Kraus in 1897, when he tested filtrates of cholera, plague and typhoid bacterial cultures with corresponding immune sera. A serological specificity of the reactions was observed. Since then, a multitude of precipitation techniques for qualitative and quantitative analyses has been developed. Their application has led to observations of fundamental value for revealing and understanding the immunospecific phenomenon of antigen-antibody binding, its physiochemical background and biological implications. Among pioneers in this field of research may be mentioned K. Landsteiner (serological specificity), G. Ramon (flocculation), M. Heidelberger, E.F. Kendall, E.A. Kabat (quantitative immunochemistry), J.R. Marrack, L. Pauling (molecular structure and intermolecular forces) and J. Oudin (diffusion-in-gel).

Precipitation in fluids

As mentioned, the phenomenon of immunoprecipitation appears when a solution of antigenic material is mixed with immune serum containing corresponding antibodies. The reaction is registered by a gradually increasing turbidity, changing to the appearance of precipitating or flocculating aggregates. A common procedure for immunoprecipitation analyses is to use a series of test tubes containing a constant amount of one of the reactants, and adding the corresponding reactant in serial, stepwise dilutions. A rough estimation of the grade of precipitation can be made by the naked eye or, more precisely, by turbidimetric or nephelometric measurements. The most adequate measurement of the intensity of the precipitation reaction is made by weighing the precipitate or by chemical analyses, e.g. N-determination, or by physical measurements when, for instance, dye- or isotope-labeled materials are involved in the reaction. Moreover, such measurements make it possible to determine the antigen:antibody ratios in the precipitated material. By extensive experimental work along these lines, basic information on immunoprecipitation and its characteristics has been obtained. In this connection, monospecific anti-

Figure 1 Schematic representation of a precipitation curve when a constant amount of antibody was tested against increasing amounts of corresponding antigen (ovalbumin-rabbit antiovalbumin). The amounts of precipitated material (○—○), the antibody:antigen (Ab:Ag) ratio in the precipitates (●—●) and the presence of unprecipitated antigen or antibody in the supernatants are indicated.

bodies, usually of the immunoglobulin G (IgG) class, and corresponding multivalent antigen have commonly served as a suitable model system.

The most important characteristics of the precipitation reaction may be summarized as follows. There are two stages to the reaction, the first being the very rapid binding of antibody to antigen, which occurs within seconds. The binding is governed by the degree of structural complementarity which provides serological specificity. Physically, van der Waal forces, hydrogen bonds, hydrophobic bonds and electrostatic forces are involved. The union is firm but reversible and at dissociation each reactant can be recovered unaltered. The strength of binding is measured by the grade of avidity of the antiserum, high avidity implying greater firmness. The second stage of the precipitation reaction develops more slowly, lasting minutes to hours, the primary antigen-antibody complexes forming larger secondary complexes in a lattice formation which end up as

visible precipitating aggregates. This aggregation is electrolyte dependent. A prerequisite for the formation of registrable aggregates is that the molecules of the participating reactants have a valency of at least 2 (e.g. bivalent IgG) and a multivalent antigen. An important observation is that in the immunoprecipitation reaction, antigen and antibody molecules combine in varying proportions depending on the ratio of reactants when they are initially mixed. This phenomenon of multiple proportions is in contrast to what happens in a common, pure chemical precipitation reaction where the reactants mostly combine in a nonvariable proportion.

The variation in the amount and composition of antigen-antibody aggregates in an immunoprecipitation system assayed by serial dilution of one of the reactants is represented by the precipitation curve in **Figure 1**. The amount and the antigen:antibody ratio of the precipitates are indicated, as well as the presence or absence of free antigen or antibody in the supernatants. The general characteristics of the reaction are, in short, as follows. At a certain antigen:

antibody ratio, maximal precipitation takes place, with neither free antigen nor antibody in the supernatant (zone of equivalence, a quantitatively balanced system). Where the antigen:antibody ratio differs from that of equivalence – zones of either excess antigen or antibody – the conditions are less favorable for the creation of an extended lattice formation. Consequently, at either side of the zone of equivalence, smaller amounts of precipitate are formed, and where the reactants are greatly out of balance a zone of complete inhibition may be observed. It should be noted that this phenomenon occurs even though primary antigen-antibody binding has taken place. Whether there is total or partial solubility of antigen-antibody complexes in the regions around the zone of equivalence depends on the species origin of the immune serum and the nature of the antigen. So, for instance, horse immune sera reacting with the corresponding protein antigens usually give a more sharply defined point of maximum precipitation, and complete inhibition occurs at excess of antigen as well as of antibody,

Figure 2 Complex serological system containing a set of five antigen-antibody systems of different specificities analyzed by tube flocculation (serial dilution) and immunodiffusion precipitation (concentration gradient) techniques.

whereas for rabbit immune sera reacting with polysaccharide antigens, the point of maximum precipitation is less distinct and complete inhibition is generally seen at excess of antigen.

In the flocculation reaction, which is very similar to the precipitation reaction except that the aggregates are formed as flocculent masses, the time at which visible aggregates appear is used for the evaluation of the serological system to be assayed. Flocculation is most rapid when the reactants are in approximately equal proportions (R_{opt}) for the formation of aggregates. This information, denoted as flocculation time (L_f), can be used for quantitative determinations. Either side of R_{opt} , flocculation proceeds more slowly and inhibition occurs when antigen is in excess and, for certain systems, also when antibody is in excess, as illustrated in Figure 2. The analytical procedure used to determine reaction velocity during flocculation is also applicable to precipitation reactions.

Precipitation in gels

If a gel is chosen as the medium in which the precipitation takes place, a continuous concentration gradient of reactants can be obtained by means of gel-stabilized diffusion, thereby eliminating the need for

stepwise dilution. The reactants are applied to the gel in a way such that one of the reactants, either antigen or antibody, diffuses into the gel which already contains the corresponding reactant (simple diffusion) or both reactants diffuse into a serologically neutral gel (double diffusion). By such an arrangement the precipitating material at the highest concentration down to zero will be tested by means of the time-dependent concentration gradients established. In a monospecific serological system, precipitation will appear as a band or a line at the site in the gel where the reactants satisfy R_{opt} . When materials containing two or more serologically different entities are analyzed, each system will form its individual precipitation band and most often their sites do not coincide.

In simple diffusion techniques such as the Oudin tube test, the external reactant, usually a solution of antigen, is applied at a relative concentration greater than that of the internal reactant, i.e. corresponding immune serum in the gel. Initially a precipitate is formed in the gel close to the interphase; however, it is gradually dissolved by the excess of the diffusing reactant. Reprecipitation occurs in the direction of the diffusion, resulting in a migrating precipitation band. When the external reactant is exhausted at its original source the 'migration' ceases and the

Figure 3 Basic precipitation patterns in combined systems (Ouchterlony comparative plate technique). For explanation see text.

precipitation band rests at its final site. This phenomenon is the base for quantitation by the simple radial diffusion method of Manicini and colleagues where a monospecific immune serum is used as the internal reactant.

In double diffusion techniques the precipitation bands are formed in a gel which initially is serologically neutral. With the reactants tested at equivalent concentrations (i.e. at R_{opt}), a stationary precipitate is formed at a site in the gel governed by the diffusion coefficients of the reactants. In a simple serological system only one band is formed. A multiple system will – provided that a superimposition of bands does not occur – create a series of bands corresponding to the number of serological systems present, i.e. a precipitation spectrum. The band sites are, apart from the degree of diffusibility, greatly dependent on the concentration of the reactants at their initial sources. Worth noting is that in the double diffusion technique a precipitation band, once stabilized as to site, acts as a specific barrier for further diffusion for the integrated antigen and its antibody but not for reactants with a different serological specificity. This phenomenon is taken advantage of in the Ouchterlony comparative plate technique in which the sources of diffusion are arranged in a way that permits a registration of possible interactions between two or more serological systems, as represented by their individual precipitation patterns. For the case where antigen preparations are compared by means of an immune serum there are, in principle, four alternatives for pattern formation: complete (I) or partial (III) fusion, interference without fusion (IV) or absence of interaction (II). These four types of reaction, illustrated in Figure 3, constitute the basis for the interpretation of comparative precipitation patterns. It should be noted that, when the analytical

system is reversed, i.e. antisera are compared by means of a multideterminant antigen, the interpretation of a complete fusion of lines as identity of antibody specificities is not justified.

For the analysis of very complex serological systems by means of precipitation-in-gel a greatly increased resolution can be obtained by using gel electrophoresis in combination with the double diffusion technique. This method, originally devised by Grabar and Williams and named immunoelectrophoresis (IE), has the advantage that it combines an electrophoretic characterization with the immunological identification of the material to be analyzed. It should be mentioned that the somewhat time consuming diffusion procedure in the original IE technique can advantageously be replaced by gel electrophoresis of one or both of the corresponding serological reactants, i.e. electroimmunoprecipitation.

PRIMARY BILIARY CIRRHOSIS

M Eric Gershwin, Division of Rheumatology, Allergy and Clinical Immunology, University of California at Davis, Davis, California, USA

Ian R Mackay, Centre for Molecular Biology and Medicine, Monash University, Clayton, Victoria, Australia

Primary biliary cirrhosis (PBC) is an enigmatic chronic liver disease characterized by progressive inflammatory obliteration of the intrahepatic bile ducts. Clinical features and laboratory studies of the disease include data suggesting an underlying immunologic basis for pathology. These features

include a marked predominance of female patients, the presence of a variety of autoantibodies, circulating immune complexes, complement activation, defects in immunoglobulin class switching, T cell regulatory dysfunction, predominance of T cells in the hepatic periductular infiltrates, and an increased

association with scleroderma and the sicca complex. The autoantibodies found in PBC include antibodies to thyroid antigens, nuclear antigens, thymocyto-toxic autoantibodies, and mitochondrial-specific antibodies.

There are striking B lymphocyte abnormalities in PBC, including high levels of serum immunoglobulins, with an immunoglobulin G3 (IgG3) subclass restriction and a range of autoantibodies including, as noted above, those to mitochondrial antigens and occasionally antibodies to centromeric antigen and other undefined nuclear antigens. There is also increased serum complement consumption. The association with disease is closer for mitochondrial antibody and PBC than for any other autoimmune process; while PBC may occur in the absence of mitochondria-specific antibodies, such cases are most exceptional. Also, there are T lymphocyte immunoregulatory abnormalities that involve both CD4⁺ and CD8⁺ cells. In brief, the number of CD4⁺ and CD8⁺ cells in blood are decreased and various functional assays show deficiencies affecting both subsets of T cells. Histologically, biliary ductules in the liver are surrounded and penetrated by infiltrating T lymphocytes, mostly of the CD8 phenotype. Granulomata are prominent in the periductular infiltrates which is unusual for autoimmune pathology. The bile duct epithelium normally expresses only major histocompatibility complex (MHC) class I molecules but, in PBC, MHC class II molecules are also expressed in biliary epithelial cells, possibly under the influence of cytokines released by activated T cells. Such expression may be relevant to the autoimmune pathogenesis of PBC, since biliary epithelial cells which express MHC class II molecules could act in an inducer capacity as antigen-presenting cells for CD4⁺ helper T cells. The inducer processes and the peptide molecule(s) that stimulate T cells have yet to be identified and functional data are needed to substantiate the immunohistochemical evidence for the cytodestructive effects of CD8⁺ T cells.

The clinical signs of disease include features that are consistent with chronic intrahepatic biliary

obstruction including itching, jaundice, steatorrhea and osteomalacia. This classic presentation is now being replaced by early or asymptomatic disease recognized by the occurrences of liver functional abnormalities on autoanalyzer screening of serum. The treatment of patients is primarily directed at reducing itching as well as dietary replacement for malabsorption and osteomalacia. Treatment with corticosteroids and/or immunosuppressive agents has generally been unimpressive, perhaps because these were usually given only in advanced disease. Urso-deoxycholic acid (UDCA) is of established benefit according to the results of recent trials and there have been optimistic reports on the use of methotrexate. The results of liver transplantation for advanced disease are excellent.

The hallmark of PBC is the presence of high-titer mitochondrial autoantibodies in patients' sera. Such reactivity has been demonstrated using standard immunofluorescent assays, ELISA, complement fixation and inhibition of enzymic activity. Mitochondria-specific antibodies recognize major mitochondrial inner membrane proteins of approximately 74, 56, 52, 48 kDa and 36 kDa (Table 1). These four mitochondrial autoantigens have been identified as being protein X and the acyltransferases (E2) of three related 2-oxo acid dehydrogenase complexes: the pyruvate dehydrogenase complex (PDC), the branched-chain oxo acid dehydrogenase complex (BCOAH), and the oxoglutarate dehydrogenase complex (OGDC). The identification was established using either expressed polypeptides from DNA clones or purified enzyme preparations. Moreover, the mitochondrial autoantibodies of patients specifically inhibit the function *in vitro* of these enzymes.

These observations relating autoantigens to functional sites of proteins are of interest in that they are consistent with an emerging trend seen in a number of other autoimmune diseases. Autoantibodies to RNA synthetase in polymyositis sera are able to inhibit RNA aminoacylation and it has also been reported that synthesis of 28S and 18S RNA is inhibited by RNA polymerase I-specific antibodies in

Table 1 Molecular weights and functions of the mitochondrial autoantigens in PBC

Enzymes	Molecular weight (kDa)	Function
Pyruvate dehydrogenase (PDH)	74	Transfers acetyl group from E1 to coenzyme A (CoA)
E2 acetyltransferase		
Protein X	56	?
Branched-chain 2-oxo acid dehydrogenase (BCOAH) E1 α and β E2 acyltransferase	52	Transfers acyl group from E1 to CoA
Oxoglutarate dehydrogenase E2 succinyltransferase	48	Transfers succinyl group from E1 to CoA

scleroderma sera. In systemic lupus erythematosus (SLE) sera, autoantibodies specific for Sm and U1-RNP, which are both components of small nuclear ribonucleoproteins (snRNP), inhibit splicing of early RNA sequences, and autoantibodies to proliferating cell nuclear antigen (PCNA) inhibit DNA replication. Additionally, autoantibodies to the La (SS-B) nucleoprotein antigen, present in primary Sjögren syndrome, interfere with the transcription of small RNA molecules. The significance of these findings in terms of disease expression has yet to be determined, but two schemes are prominent. First, as for the mitochondrial antigens of PBC, many of the described autoantigens are intracellular enzymes and exist not as single proteins but as components of large complexes, and, second, the autoantibodies directed against these subcellular molecules appear to be directed against functional sites or domains, since they interfere with cellular function in assay systems *in vitro*. The capacity of PBC serum to abrogate the catalytic activity of the PDC enzyme is most impressive and is the basis of a diagnostic assay. Other assays, including the use of a hybrid recombinant protein that contains all the major epitopes of PDC-E2, BCOADH-E2 and OGDC-E2, are now also available.

Although there have been significant advances based on cloning, antigen definition and epitope mapping, there has been relatively little insight into the relevance of T cell reactivity in patients. The identification of T cell reactivity will be critical. The characterization of T cell reactivity in other autoimmune diseases has likewise been difficult because of the low frequency of antigen-specific T cell activity in peripheral blood. Moreover, even when liver tissue is studied, the frequency of antigen-specific T cells may be low because of the irrelevant inflammatory response. All of the identified mitochondrial autoantigens contain lipolate-binding sites and therefore

perhaps shared epitopes. Hence, a single common epitope could generate CD4⁺ cells to provide help for the oxo-cross-reactive B cell responses for each of the E2 subunits of the 2-OADH enzymes.

There are other theoretical considerations that should be applied to the understanding of the etiology and immunological responses in primary biliary cirrhosis. First, there is scanty data on specific etiology, i.e. environmental insult, toxin or infection. It remains plausible that the mitochondrial autoantigens are cross-reactive with a microbial antigen, but this is yet to be identified with a highly conserved component of an infectious agent. Second, PBC is often viewed as a ductal disease as lesions have been reported in other epithelial glandular tissues, i.e. salivary glands and pancreatic ducts. Third, mitochondrial autoantigens are synthesized in the cytoplasm and then transported into the mitochondria; therefore, mutations in leader sequence, or defects in breakdown, could lead to altered metabolism and expression on cell membranes. Finally, there are intriguing data that suggest that there is expression of either PDC-E2 or a cross-reacting molecule on the surface of biliary epithelial cells in patients with PBC but not controls. These data, if they reflect a primary not secondary feature of disease, would explain the specific targeting of biliary cells. The molecular basis of this molecule is still unresolved.

PRIMATE (NONHUMAN) IMMUNE SYSTEM

Todd M Allen and **David I Watkins**, Wisconsin Regional Primate Research Center and Department of Pathology and Laboratory Medicine, University of Wisconsin, Madison, Wisconsin, USA

Nonhuman primates have been widely used as animal models for human diseases. Simian immunodeficiency virus (SIV) infection of rhesus macaques provides an excellent model for human immunodeficiency virus (HIV) infections of humans. Similarly, experimental autoimmune encephalomyelitis

(EAE) induction in macaques and common marmosets has been utilized as a model for multiple sclerosis, and collagen-induced arthritis (CIA) in macaques is a good model for rheumatoid arthritis. Nonhuman primates have also been important in a variety of other studies attempting to delineate the

immune response to pathogens that infect humans. The use of nonhuman primates in such studies is largely due to the similarity between their immune systems and that of their human counterparts. In particular, the lymphocyte markers, major histocompatibility complex (MHC) molecules, and T cell receptors (TCRs) of Old World primates and great apes are very similar to those of humans. In this entry we will describe several animal models of human diseases and the similarities between the immune systems, MHC genes and TCR genes of nonhuman primates and humans.

Primates of the Anthropeidea suborder can be divided into two main infraorders. The first is the Catarrhini, which includes humans, great apes (e.g. chimpanzees, gorillas and orangutans) and Old World primates (e.g. baboons, colobus monkeys and the macaques). It is thought that chimpanzees and humans last had a common ancestor about 5 million years ago, whereas rhesus macaques and humans last had a common ancestor 35–40 million years ago. The second infraorder is the Platyrrhini, or New World primates. These include, among others, owl monkeys, squirrel monkeys and the marmosets and tamarins.

Nonhuman primates as animal models for human disease

Primates are widely used as models for studying HIV infection of humans. Although HIV does not infect all of the different species of nonhuman primates, it does infect chimpanzees. Thus far, however, there are few documented cases of chimpanzees succumbing to HIV-induced pathogenesis despite several chimpanzees having been infected for over 10 years with the virus. Therefore, combined with their endangered status, the use of chimpanzees is hardly practical for the study of HIV infection in humans. SIV infection of the rhesus macaque (*Macaca mulatta*), however, has proved to be a very effective animal model for studying HIV pathogenesis in humans. Due to the nucleotide sequence similarity between HIV and SIV and the similar course of disease progression between humans and rhesus macaques, SIV infection in rhesus macaques is widely used as an animal model of HIV infection in humans. More importantly, the immune systems of humans and rhesus monkeys have been found to bind and present peptides derived from very similar regions of HIV and SIV, respectively. Therefore, this animal model will be especially useful for conducting vaccine trials which cannot be carried out in humans.

Nonhuman primates have also been used to study the pathogenesis and immune response to other

viruses. Many of the New World primate species were extensively used to study the pathogenesis of viral infections in the early 1970s and 1980s due to their extreme susceptibility to these diseases. In particular, the cotton-top tamarin has been used to test vaccines for Epstein–Barr virus (EBV). Interestingly, the tamarin is susceptible to EBV-induced lymphoproliferative tumors upon inoculation with EBV whereas many of the other New World primate species are not susceptible to EBV. Owl monkeys, for example, develop a typical lymphocytosis similar to that seen in humans after infection with EBV. Rhesus macaques have also been used to study a variety of autoimmune diseases. These include experimental EAE and CIA. EAE can be induced in rhesus monkeys and the common marmoset by injection of whole brain homogenates or purified myelin basic protein. Also, rhesus macaques injected with collagen readily develop a disease that resembles rheumatoid arthritis. Thus, these animals can be used to understand the pathogenesis of this disease and can be used to test therapeutic modalities.

The similarities between human MHC molecules and those of nonhuman primates has facilitated a variety of transplantation-related studies. In particular, the rhesus macaque has been widely used to determine whether tolerance can be induced prior to organ transplantation. By manipulating the immune system, tolerance to kidney transplants was found to be dramatically increased in rhesus monkeys. Therefore, nonhuman primates provide preclinical large-animal models to determine whether studies conducted in mice can be extended into clinical applications in humans.

Similarities between lymphocyte markers of humans and nonhuman primates

The similarity between the various lymphocyte subsets of nonhuman primates and those of their human counterparts is one of the primary reasons that nonhuman primates are useful as animal models to study human diseases. Monoclonal antibody (mAb) reagents generated against human CD antigens can be used in many nonhuman primate species, and cross-reaction of these mAbs with the lymphocytes of nonhuman primates indicates that the structures of these cell surface molecules are likely well conserved. Table 1 gives a list of antibodies that are useful in functional studies of the immune system of the rhesus macaque. These cross-reactivities illustrate the conservation of functionally important cell surface molecules between humans and Old World primates.

A similar array of these human leukocyte-specific

Those antibodies which cross-react with the listed primate species are indicated by a +. The absence of a + does not necessarily indicate that the antibody does not cross-react, since not all antibodies have been tested for cross-reactivity in these primates. *Macaca mulatta* (Mamu) = rhesus monkey; *Callithrix jacchus* (Caja) = common marmoset, and *Saguinus oedipus* (Saoe) = cotton-top tamarin.

^aNote that the CD3-specific mAb FN18 is a rhesus-specific anti-CD3 mAb.

mAbs have been tested in two species of New World primates, the cotton-top tamarin (*Saguinus oedipus*) and the common marmoset (*Callithrix jacchus*). Not all monoclonal antibodies that cross-react with surface expressed molecules from the rhesus macaque work well in New World primates. Table 1 provides a list of those mAbs which also cross-react with lymphocytes from the common marmoset and cotton-top tamarin. However, these results were taken from a study in which only 62% of mAbs specific for human epitopes were found to cross-react with New World primate lymphocytes. Therefore, although a significant number of mAbs are able to bind to both human and New World primate cell lines, indicating the preservation of functionally important cell surface molecules between these species, the percentage of mAbs which cross-react decreases the further one travels across the phylogenetic tree.

The MHC and TCR genes of nonhuman primates

The products of the MHC and TCR genes represent some of the most important molecules involved in initiating and controlling an immune response against a pathogen. Although various mAbs specific for the human MHC molecules have been shown to cross-react with MHC molecules from humans, Old World primates, and New World primates (see Table 1), there has also been an extensive analysis of MHC molecules from these species at the nucleotide sequence level. Such analyses allow for more detailed comparisons of the conservation of the functions of these molecules than mAbs. Similarly, cloning and sequencing of the TCR genes in nonhuman primates

has revealed a striking similarity among the various TCR genes of primates.

While MHC class II genes are well conserved between humans, Old World primates, and even in some cases New World primates, the MHC class I genes appear to have undergone many more changes. The MHC class I loci can be separated into classical or nonclassical loci. Classical MHC class I molecules, such as the human leukocyte antigen (HLA)-A, -B and -C molecules, are highly polymorphic and their role in binding and presenting peptides is well established. The non-classical molecules from the *HLA-E*, *-F*, and *-G* loci, for which specific functions have not, as yet been described, are more limited in their polymorphism. The *HLA-J* and *-H* loci, however, represent inactivated MHC class I loci or pseudogenes.

Nonhuman primates belonging to the Pongidae family are the most closely related species to humans. This family includes the common and pygmy chimpanzees (*Pan troglodytes* and *Pan paniscus*), gorilla (*Gorilla gorilla*) and orangutan (*Pongo pygmaeus*). Due to their close phylogenetic relationship to humans, chimpanzees express homologs of the *HLA-A*, *-B*, *-C*, *-E*, *-F*, *-G*, *-H*, and *-J* loci (Table 2 and Figure 1). An *HLA-C* homolog has also been identified in the gorilla, while no such homolog has been found in the orangutan, which suggests that the *HLA-C* locus likely arose through gene duplication after gorillas and orangutans last shared a common ancestor.

Analysis of the MHC class I genes from the rhesus monkey reveals that homologs of both the *HLA-A* and *-B* loci are present. Since rhesus monkeys last shared a common ancestor with humans approximately 35 million years ago, this indicates that the

Table 2 MHC class I and class II loci in human, great ape, Old World primate, and New World primate species

Only positively identified loci are indicated. The absence of a + sign for a particular locus in a species does not necessarily indicate that the particular locus is absent, but simply indicates that the locus has not yet been identified in that species. Note that *HLA-B* homologs have been identified in two New World primates, the long-haired spider monkey and white-faced saki monkey (data not shown). Approximate divergence times of these various primate species is listed in Figure 1.

Figure 1 Evolutionary tree demonstrating the relationship and approximate divergence time of various primate species from the Catarrhini and Platyrrhini infraorders.

homologs of the *HLA-A* and *-B* loci are extremely stable. Interestingly, although the rhesus monkey does not appear to possess an *MHC-C* locus, both the *MHC-A* and *-B* loci can be duplicated depending on the haplotype. Because of the utility of the rhesus monkey as an animal model for several human diseases, the *MHC* class I genes and molecules of this species have been extensively characterized. As such, many nonclassical *MHC* class I genes and pseudogenes have also been identified in the rhesus monkey. Both *HLA-E* and *-F* homologs have been identified in the rhesus monkey along with an *HLA-G* homolog, which unlike *HLA-G*, has become inactivated in the rhesus monkey. Interestingly, another functional *HLA-A*-like gene in the rhesus monkey (*Mamu-AG*) possesses many of the unique features of *HLA-G* including expression in the placenta. Therefore, some of the *MHC* class I loci appear to be evolving rapidly through a pattern involving gene duplication events followed by gene deletion or inactivation events. In the case of *Mamu-AG*, this may represent a unique case in which an *HLA-A*-like gene was duplicated in the rhesus monkey with its protein products possibly serving the function of the original *Mamu-G* molecule. The presence of two genes, *Mamu-G* and *Mamu-AG*, each producing proteins capable of performing the same function may have allowed for inactivation of one of these genes in the rhesus monkey, in this case the original *Mamu-G* gene, which became a pseudogene.

The expressed classical *MHC* class I genes of New World primates are unique compared to those of the

great apes and Old World primates in that they are more closely related to the nonclassical *HLA-G* locus than they are to either the *HLA-A* or *-B* loci. Interestingly, one family of New World primates possess *HLA-G*-like loci that are distinctly different one from another. This expression of genus-specific classical *MHC* class I loci by the Callitrichidae may be due to the rapid turnover of *MHC* class I genes in New World primates. Recent examination of the *MHC* class I genes of two other species of New World primates from the Cebidae family, the long-haired spider monkey (*Alouatta seniculus*) and white-faced saki monkey (*Pithecia pithecia*), demonstrated the presence of a single *HLA-B* locus homolog in each of these species. This finding suggests that the *MHC-B* locus did indeed exist prior to the divergence of Old World and New World primates, and suggests that the lack of *HLA-A* and *-B* locus homologs in some species of New World primates is due to the deletion of these loci in these species. New World primates also possess *HLA-E* and *-F* homologs, demonstrating the stability of these loci in New World primates.

MHC class II genes

The human *MHC* class II molecules are encoded for by genes from the *HLA-DR*, *HLA-DQ* and *HLA-DP* loci. As illustrated in Table 2 and Figure 1, genes from these multiple *MHC* class II loci are present in humans, great apes, Old World primates and even some New World primates. The New World primates' *MHC* class II genes, however, do not likely rep-

resent homologs to those found in Old World primates and apes. Analysis of MHC class II genes at the nucleotide sequence level indicates that these genes are extraordinarily well conserved between most species of primates. Therefore, for the study of human MHC class II-associated diseases, various species of primates may serve as excellent animal models. For example, rhesus monkey B lymphoblastoid cell lines expressing a particular *MHC-DRB1* allele can present *Mycobacterium tuberculosis* peptides to human T cell clones. Additionally, in the rhesus monkey a clear association was demonstrated for the presence of the MHC class II allele *Mamu-DPB1 *01* with susceptibility to EAE.

TCR genes

TCR V_β (variable region of the β-chain) cDNAs have now been cloned from chimpanzees, rhesus macaques, cotton-top tamarins and common marmosets. Homologs of the various V_β families are easily recognizable in each of these primate species. Thus, even in New World primates homologs of the human TCR V_β genes are well preserved.

Summary

Due to the recent technical advances in molecular biology the number of human disease-associated genes identified will increase immensely. As such, it is now possible to investigate many of these diseases in animal models. This will facilitate the development of vaccine strategies or therapeutic modalities to control these diseases. Nonhuman primates represent the best animal models for many of these diseases due to the overall similarities of their immune systems to those of humans. This is best illustrated by the significant cross-reactivity of leukocyte-specific mAbs with both human and nonhuman primate lymphocyte subsets, and the similarities among the MHC and TCR genes of primates.

PRIVILEGED SITES

J Wayne Streilein, The Schepens Eye Research Institute, Department of Ophthalmology, Harvard Medical School, Cambridge, Massachusetts, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Certain anatomic sites and/or tissues of the body exhibit the property of immune privilege: grafts of histoincompatible tissues placed within these sites are either not rejected at all, or only very slowly. Sites which have been considered to be privileged include brain, eye (anterior chamber, vitreous cavity, cornea, subretinal space), testis and ovary, adrenal cortex, hamster cheek pouch, and the pregnant uterine decidua and the fetal-placental unit. Privilege is usually extended permanently to grafts that are weakly antigenic, i.e. that display the products of only minor histocompatibility loci, whereas privilege may be transient if the immunogenetic disparity between graft and recipient includes major histocompatibility complex (MHC)-encoded antigens. The difference in survival times of MHC and non-MHC disparate grafts in privileged sites reveals that the phenomenon has quantitative features, i.e. privilege is not 'all or none'.

Until recently, immune privilege was not thought to be extended to histoincompatible grafts placed in privileged sites of recipients previously sensitized to antigens expressed on the graft. However, it now appears that there are factors operative within immune privileged sites that can suppress at least certain components of the alloimmune rejection response, even after they have been generated. Thus, immune privilege is a process that, on the one hand, alters the induction of immunity to antigenic materials first encountered via privileged sites, and, on the other hand, inhibits the expression of certain forms of alloimmunity in these same sites.

Common features of immune privileged sites

Distinctive anatomic, cellular and molecular features are commonly found at privileged sites: 1) a blood-tissue barrier (continuous capillaries with endothelial cells united by tight junctions) across which passage of blood cells and plasma only occurs as a facilitated process; 2) absence of a lymphatic drainage pathway, necessitating that tissue fluids drain directly into the blood vascular compartment; 3) reduced or even absent expression of molecules encoded by class I and class II genes of the major histocompatibility complex; 4) constitutive local expression of Fas ligand (FasL) which can induce apoptosis among activated Fas⁺ (CD95) lymphocytes; 5) paucity of

bone marrow-derived MHC class II positive cells that function conventionally as professional antigen-presenting cells; 6) deficit in the local microenvironment of molecular mediators of inflammation, such as complement factors and clotting factors, along with specific inhibitors of these tissue-threatening enzyme cascades; 7) constitutive presence of a distinctive array of molecules within the local immunosuppressive microenvironment (growth factors, cytokines and mediators) that inhibit conventional antigen processing and presentation, suppress antigen-driven lymphocyte activation, and/or down-regulate cellular and molecular mediators of inflammation. Not all of these features are found at any single immune privileged site, indicating that privilege is multifactorial in origin.

Recently it has been discovered that antigens can escape from grafts placed in privileged sites, and, as a consequence, evoke an unusual systemic immune response. Typically, delayed hypersensitivity and complement fixing antibodies are not elicited by such privileged allografts, although other immune effector modalities, such as precursor cytotoxic T cells, non-IL-4-secreting T helper cells, and non complement fixing antibodies (especially IgG1 in mice) are regularly elicited. Animals bearing foreign tissue grafts in privileged sites often (but not always) display concomitant immunity: the graft in the privileged site remains healthy, even though genetically identical grafts are rejected when placed at conventional body sites.

Immune responses to antigenic material in immune privileged sites

The manner in which these features create immune privilege and the associated 'deviant' systemic immune response (to privileged antigens) is the subject of intense investigation at the present. Current evidence indicates that privilege may result from an actively acquired, dynamically regulated, antigen-specific immune response that is able to express itself within the privileged site while avoiding nonspecific, tissue-destructive inflammation. Since this 'deviant' immune response is systemic in nature, the selective deficiencies (delayed hypersensitivity and production of complement fixing antibodies) are evident when the same antigens are encountered at other, nonprivileged sites of the body. The unique features of

immune responses to antigens expressed on grafts placed in privileged sites are also elicited when other types of nongraft antigens are inoculated into the privileged site, including antigens associated with tumors, haptens, virally encoded antigens, soluble heterologous protein antigens, and tissue-restricted autoantigens.

In the past, immune privilege has been regarded largely as a laboratory curiosity. However, it now appears that privilege is actively acquired and maintained, leading investigators to wonder whether privileged sites serve physiologic purposes. For example, it has been proposed that privilege in the anterior chamber of the eye, including the deviant systemic immune response to antigens placed within this site, serves to limit/prevent immunogenic inflammation at that site. As a consequence, the microanatomic integrity of the eye, which is essential for vision, is spared from blinding distortion by inflammation. Privileged sites may have in common a unique vulnerability to the nonspecific, destructive potential of immunogenic inflammation, and therefore immune privilege may be an evolutionary adaptation designed to mitigate this possibility. In addition, privileged tissues, such as the eye, contain

strong tissue-restricted autoantigens that can readily cause autoimmune disease. Immune privilege is considered to be one mechanism that is used by tissues with strong 'sequestered' autoantigens to avoid destructive autoimmunity.

PROKARYOTES, IMMUNITY IN

Vincent Geli and **Yves Corda**, Laboratoire d'Ingénierie et de Dynamique des Systèmes Membranaires, Institut de Biologie Structurale et Microbiologie, CNRS Marseille, France

In this article, we review a type of immunity which confers a highly specific insensitivity upon bacteria to the lethal action of a substance. The immunity is a genetic character carried by a bacterial chromosome, a bacteriophage genome or a transmissible plasmid.

Many antimicrobial agents are produced and released extracellularly by bacteria. These compounds have a specific action on the targeted bacteria. They can be classified as 1) enzymatically synthesized antibiotics, 2) post-translationally modified peptide antibiotics, 3) protein antibiotics as bacteriocins, protein exotoxins and bacteriolytic enzymes, and 4) temperate or temperate bacterial viruses. These agents penetrate into the bacterial cell and, once inside, they have to remain unmodified to exert their action.

Many levels of insensitivity to these lethal sub-

stances are reported for bacteria. For example, resistance to the antibiotic streptomycin can result either from a mutation in the bacterial genome which alters the 30S ribosomal subunit or from a plasmid encoding enzyme that chemically modifies and inactivates streptomycin. In such a case, the resistance can be overcome by adding a high external concentration of the antibiotic in the culture medium. Similarly, insensitivity to bacteriocins or phages may result from mutations of bacterial components involved in the uptake of the toxic macromolecules. Since many bacteriophages and bacteriocins share similar uptake pathways, a single mutation may confer insensitivity to various bacteriocins or phages. Bacteria carrying such mutations are termed resistant or tolerant (but not immune) to the particular toxic agent.

The system of restriction–modification directed against foreign genetic material is another example

of a bacterial defense mechanism. When the DNA of a phage is transferred from one bacterial strain to another bacterial strain with a different restriction–modification system, the phage DNA is immediately degraded after its injection by the host restriction endonuclease. The host DNA itself is protected from the action of its own restriction endonuclease by a strain-specific modification system. Bacterial strains able to restrict DNA are protected against the invasion of foreign DNA, but the specificity of the protection is not strictly restricted to a particular DNA. These protective mechanisms are not highly specific to the action of a particular killing agent and thus will not be considered as immunity. This entry will mainly focus on immunity against bacteriocins and bacteriophages.

Immunity to bacteriocins

Some diffusible substances released by bacteria into the medium inhibit the growth of other sensitive, generally closely related, bacteria. These substances, which are proteinaceous in nature, act at low concentrations. They have been called bacteriocins. A common characteristic of bacteriocin-producing strains is their ability to resist their own bacteriocin through specific-immunity peptides or proteins. The best-documented bacteriocins are the colicins produced by various members of the *Enterobacteriaceae*.

Colicinogeny appears to be the result of selection pressure among the *Enterobacteria*. Colicins are encoded by Col plasmids and their production is induced by agents which damage DNA. In most Col plasmids three genes have been identified: the colicin structural gene, the immunity gene, which protects the producing cells against the action of their own colicin, and the lysis gene, whose expression is required for efficient colicin release. Once secreted into the medium, colicins require at least three steps to kill sensitive cells of *Escherichia coli*: 1) binding to a specific receptor located in the outer membrane; 2) translocation across the membrane; and 3) interaction with their specific target in the cell. Three different domains linearly organized along the polypeptide chain are involved in each of these steps.

Pore-forming colicins kill sensitive bacteria by forming voltage-dependent ion channels in their inner membranes. This membrane depolarization causes a series of metabolic effects such as inhibition of active transport and of protein and nucleic acid synthesis, decrease of internal ATP concentrations, and leakage of potassium. Cell death results from all these events.

Pore-forming colicins form well-defined channels in the planar lipid bilayer. These channels are characterized by their sensitivity to the difference of the

electrical potential across the membrane. The channel domain is composed of 10 α helices and has to rearrange in order to insert into the membrane. The voltage-independent insertion of a hydrophobic helical hairpin, buried in the core of the structure, and the voltage-dependent insertion of a large voltage-responsive segment leads to channel formation.

Immunity genes are constitutively expressed and are transcribed in the opposite direction to the colicin genes. Immunity proteins are produced in very low amounts and protect the cell against external colicin only. The amount of colicin reaching its target, the inner membrane, depends on the number of uptake sites (400–1000); a very low amount of immunity protein is thus sufficient to protect the cell. Immunity proteins to channel-forming colicins are membrane proteins of 11–18 kDa that span the cytoplasmic membrane three to four times. They protect the cells against the colicin they produce by specifically interacting with the C-terminal domain of the colicins. Immunity proteins act in the cytoplasmic membrane by specifically preventing pore formation. The high specificity of the immunity protein suggests that a molecular complex forms between the colicin and its cognate immunity protein. The specific determinant for immunity protein recognition has been found to be the hydrophobic hairpin of the colicin channel domain. The immunity protein diffuses freely in the membrane and then recognizes within the lipid bilayer the colicin channel domain by interacting with its hydrophobic hairpin (Figure 1).

Colicins which do not form channels have enzymatic activity: some hydrolyze the bacterial chromosome while others cleave the ribosomal RNA or inhibit murein synthesis. For instance, colicin E3 is a

Figure 1 Colicin channels are made up of four helices: the voltage responsive segment (helices 5 and 6) and the helical hydrophobic hairpin (helices 8 and 9). The colicin A immunity protein inhibits channel formation by interacting within the lipid bilayer with the colicin channel. The immunity mechanism is based on intramembrane helix–helix interactions.

highly specific RNAase which cleaves 16S ribosomal RNA at a position that is conserved in all prokaryotes and many eukaryotes. Its action requires the presence of the 50S subunit in addition to the 30S subunit and the ribosomal proteins. Other colicins of the E class are nonspecific DNA endonucleases. They cause single- and double-strand breaks in the DNA of sensitive cells. Colicin M is the only colicin known to inhibit lipopolysaccharide O antigen synthesis and murein biosynthesis, leading to cell lysis. Bacteria producing RNAase and DNAase colicins are protected from their action by the presence of immunity proteins. They inhibit the RNAase and DNAase functions of their corresponding colicins. Immunity proteins (10 kDa) form a stoichiometric complex with their cognate colicin. This complex is extremely stable and can only be dissociated under strong denaturing conditions. For instance, the dissociation constant of the colicin E9 DNAase domain immunity protein is around 10^{-17} . Immunity proteins to colicins of RNAase and DNAase types are removed from the colicin C-terminal domain during the colicin entry into sensitive cells. NMR studies on the immunity proteins of colicin E9 DNAase and colicin E3 RNAase indicate that the colicin E9 immunity protein folds into a novel structure made of a distorted antiparallel four-helix bundle whilst colicin E3 immunity protein folds into a four-stranded, antiparallel β sheet connected by loops and a single short helix. The structure of the DNAase and RNAase domains remain unknown.

Gram-positive bacteria also produce bacteriocins. These are a heterogeneous group of antibacterial substances comprising a large number of small peptides. Generally, the level of immunity of the producing strain to its own bacteriocin is stronger for colicins than it is for bacteriocins of gram-positive bacteria. Lantibiotics (lanthionine-containing peptides) are the better characterized bacteriocins produced by gram-positive bacteria. The biosynthesis of lantibiotics is achieved by successive enzyme-catalyzed modifications of ribosomally synthesized precursor peptides. Lantibiotics act on the membranes of sensitive cells and form defined channels rather than a generalized membrane disruption. A minimum membrane potential is required for lantibiotic activity.

Lantibiotic-producing strains protect themselves from their own products by producing immunity proteins. Few immunity proteins have been described and their mode of action is not yet clear. The immunity proteins against the lantibiotics Pep5 and nisin, produced by *Staphylococcus epidermidis* and *Lactococcus lactis* respectively, have been identified. Both contain a hydrophobic N-terminus which might

serve as a membrane anchor. Immunity proteins interact with their cognate lantibiotic outside the cell. They act by preventing membrane depolarization caused by the peptide toxin. The mechanism which prevents pore formation is not identified. It is interesting to note that various mechanisms are used to transport immunity proteins to the outside of the producing bacteria.

Immunity to bacteriophages

Bacteriophages are viruses comprising one type of nucleic acid, either DNA or RNA, and a capsid which protects the encapsided nucleic acid. After a random collision between the virion and the bacterial cell, the phage becomes specifically and irreversibly attached to a receptor located on the outer surface of the host cell. The phage DNA is then injected into the cytoplasm of the host. Two consequences of phage infection are possible: 1) The bacteriophage replicates its DNA, produces the structural components of new phage particles, and packages the newly replicated DNA into the preheads. The progeny phages are released concomitant with lysis of the cell. This genetically well-regulated process is defined as the lytic cycle. 2) The phage structural proteins are not synthesized and the phage genetic material integrates into the bacterial chromosome and becomes dependent on the bacterial multiplication process. A cell that has integrated a phage DNA into its chromosome is referred to as a lysogen and the integrated phage DNA is termed a prophage. These two outcomes are possible for temperate phages, in contrast to the virulent phages which only go through the lytic cycle. Immunity to phage is the refractory state of an infected bacteria to be reinfected by a phage of the same type. Immunity to superinfection proceeds differently with temperate phages and with virulent phages.

Virulent phages

After infection of cells with the virulent T4 bacteriophage, genetic markers from a superinfecting phage of the same or closely related type are not recovered. The superinfecting phage adsorbs to the cell surface but superinfection immunity prevents entry of the bacteriophage DNA into the cytoplasm of the bacteria. The DNA is ejected from the phage capsid into the intermembrane space of the bacteria where it is degraded by an endonuclease. Ghosts of phage T4 which lack DNA are also capable of killing noninfected bacteria. They provoke a depolarization of the cytoplasmic membrane but, in contrast to the action of intact T4 phages, the membrane is irreversibly depolarized. It is thought that transmembrane

channels allow the penetration of phage DNA into the cytoplasm of the bacteria. On superinfection, binding of T4 to cells, tail-sheath contraction and penetration of the tail tube into the periplasm occur normally, but phage DNA is not liberated into the cytosol. An immunity mechanism causes the degradation of the ejected DNA.

The T4 bacteriophage immunity gene has been identified in the T4 genome. It encodes an immunity protein that acts 1–2 min after infection and which is responsible for most of the immunity to superinfection. The deduced amino acid sequence from the DNA sequence suggests that this protein has the structural features of an integral plasma membrane protein. The protein contains two hydrophobic segments which serve as membrane anchors. The action of the immunity protein specifically prevents superinfection by T-even phages. It is located at specific sites on the plasma membrane, bound to another protein. It may act indirectly by changing the conformation of the bound protein to prevent DNA transfer (Figure 2). The immunity protein acts stoichiometrically, therefore it must be located near the injection site or be able to diffuse very rapidly to this site since immunity develops in less than 2 min.

Temperate phages

Lysogenic bacteria are immune to infection by a phage of the carried type. Superinfecting phages of the same type as the integrated phage are unable to express their vegetative functions. This process is due to the expression of a prophage gene product called repressor which represses the expression of vegetat-

ive viral genes. The immunity thus depends on the synthesis of a repressor and on the sensitivity to this repressor, which is conferred by the repressor DNA binding sites. For the phage λ , these flank the gene encoding the repressor. The region delimited by the repressor binding sites is referred to as the immunity region because it determines the type of superinfection immunity conferred by the prophage. Immunity of temperate bacteriophages is thus based on a protein–DNA interaction which prevents the replication of the integrated phage and of superinfecting phages of the same type.

Immunity to bacteriophages λ , Mu and P1 is caused by a repressor which prevents transcription initiation at key promoters for lytic gene expression. Expression of the genes involved in the lytic cycle may also be prevented by the premature termination of transcription, as seen for phage P4. In this case, the trans-acting immunity factor is not a protein but a short RNA which causes transcription termination by pairing with complementary target sequences. For temperate bacteriophage P1, lysogenic bacteria do not carry the prophage integrated into the host chromosome, but the bacteriophage DNA remains as an autonomous plasmid in the cytoplasm of the host cell. Superinfection immunity is conferred by two repressors which prevent DNA replication associated to the lytic cycle: a protein repressor called C1 negatively regulates the expression of the lytic genes and an antisense RNA (C4) inhibits the translation of an antirepressor whose product interferes with the activity of the C1 repressor. Synthesis of only one repressor does not render a P1 lysogen immune to superinfection by P1 unless the other repressor is also expressed. In addition to this double control of immunity, C1 repression is strengthened by an auxiliary repressor protein which enhances the binding of C1 repressor to its operator sequence. These three components form a tripartite immunity system.

Figure 2 The immunity protein, probably bound to a plasma membrane protein, inhibits superinfecting phage DNA transfer. Its action may be indirect and remains poorly understood.

Conclusion

Colicins and bacteriophages are some of many agents that contribute to the relative competitiveness of bacterial strains. The immunity mechanisms are highly specific and based on protein–protein, protein–DNA or RNA–DNA interactions. Many different mechanisms have evolved to confer immunity to prokaryotic organisms against specific bactericidal agents. The mechanisms for some of them have been elucidated. However, other systems probably remain to be discovered. It is worth noting that the term immunity is also employed for the replicons carrying a transposon: a second copy of a transposon cannot

insert into a replicon that already carries one copy of the same element.

PROLIFERATION, LYMPHOCYTE

Bruce L Levine, Immune Cell Biology Program, Naval Medical Research Institute, Bethesda, Maryland, USA

James J Mond and **Carl H June**, Departments of Medicine, Molecular and Cell Biology, Uniformed Services University of the Health Sciences, Bethesda, Maryland, USA

Bone marrow-derived cells contain three classes of cells: first, those that continuously proliferate throughout the life of the animal (e.g. stem cells); second, those that divide during differentiation and then cease further division after terminal differentiation (e.g. red cells and neutrophils); finally, lymphocytes, which have a more complex regulation and have an extensive proliferative capacity involving a poorly characterized means for reversible cell cycle entrance and exit. Lymphocyte homeostasis requires the control of both lymphocyte proliferation and lymphocyte death rates. This process is controlled at the clonal level as well as at the organism level. The former results in shaping of the repertoire and is the cellular basis of immune memory while the latter process determines total lymphocyte mass.

Lymphocyte proliferation and homeostasis

Cytokine feedback systems control the compartmental size of some bone marrow-derived cell lineages. For example, erythropoietin produced in the kidney regulates red cell mass while thrombopoietin produced in the liver controls platelet mass. In contrast, total lymphocyte mass is precisely controlled by mechanisms that remain obscure. Thus, delineation of the processes that regulate the size of the lymphoid compartment remains a central problem in immunology. It takes years after transplantation or chemotherapy for an adult to repopulate lymphoid

mass, suggesting that the feedback system is either slow or else the regenerative capacity of the human adult system is limited. In contrast, rodents rapidly repopulate lymphoid compartments within several weeks after ablation of the immune system, implying a more robust regenerative power. In the mature, steady-state animal, lymphopoiesis is controlled by the rates of cell division and cell death (Figure 1). The processes of cell growth and cell cycle are independently controlled but are interrelated. For example, lymphocytes may respond to environmental signals by enlarging and by secreting cytokines, and then return to arresting state without entering the cell cycle. However, once a cell is recruited to

Figure 1 Mechanisms of lymphocyte proliferation and homeostasis. In response to environmental signals, lymphocytes grow in size and enter the cell cycle. Most cells leave the cycle and die by apoptosis within a short time, however some cells survive for extended time as memory cells.

enter the cell cycle, the lymphocyte must grow to double the size of the resting cell before completing cell division. Thus, the cell activation and growth process is reversible while the cell cycle process is irreversible once a cell has reached the S phase of the cell cycle. Here the lymphocyte is committed to cell division and cannot return. In fact, the lymphocyte will die by apoptosis if cell cycle arrest is induced.

The period between sequential mitotic events is known as interphase. In adult humans, the average interphase survival of memory T cells has been estimated as 22 weeks while the survival of naive T cells has been estimated as 3.5 years. This is counterintuitive as the expectation had been that memory cells would be longer lived, thus supporting the notion that maintenance of immune memory requires frequent lymphocyte proliferation. The survival of any given lymphocyte clone, however, can be considerably longer, based on the product of the intermitotic lifespan and the number of population doublings. Estimates based on measurements of the *in vitro* population doubling capacity are that the lifespan of a given lymphocyte clone is in a range similar to the lifespan of a rodent or human. Lymphocyte interphase survival in mice is considerably shorter than that in humans.

Antigen-induced lymphocyte proliferation of mature cells *in vivo* does not normally occur in the blood and lymphatic ducts but, rather, in lymphoid tissues such as tonsil, lymph nodes, and spleen. It begins about 1–2 days following inoculation of antigen, and by 7 days lymph nodes may increase as much as 15 times normal size, reflecting a striking increase in lymphocyte size and number, as well as in lymphocyte ingress (homing). Several key aspects of lymphocyte proliferation and homeostasis are summarized in Table 1.

Lymphocyte proliferation: the cell cycle

Conceptually, the cell cycle process occurs in a series of phases (Figure 2). Fundamentally, these exist to ensure that DNA replication and chromosome segregation are completed with high fidelity. Cells must ensure that chromosome duplication and segregation occur in the correct order, and that segregation only occurs after all sister chromatids are aligned on the mitotic spindle. Another concept is that cells have evolved surveillance mechanisms or ‘checkpoints’ to ensure that critical processes are completed correctly. Examples include the DNA damage checkpoint, the DNA replication checkpoint and the spindle assembly checkpoint (Table 2).

The eukaryotic cell cycle is controlled by a complex series of regulatory cascades involving proteins

Table 1 Key concepts in lymphocyte proliferation

1. The cell cycle time for lymphocytes in exponential division varies from 6 h to 24 h, and is somewhat shorter for mouse lymphocytes than human lymphocytes, and shorter for memory than naive lymphocytes.
2. The time from activation of quiescent human lymphocytes to the onset of DNA synthesis (G_0 to S phase) is about 30 h, considerably longer than that for fibroblasts. This implies that lymphocytes enter a ‘deeper’ resting (G_0) state or that the control process in lymphocytes is more complex than in fibroblasts.
3. Proliferation of mature lymphocytes occurs in many anatomic compartments. Lymphocytes in circulation do not usually proliferate. Lymphocyte proliferation with concomitant antigen receptor rearrangements occurs in a more tissue-restricted fashion, usually in the thymus in the case of T cells.
4. The total lymphoid mass of B and T lymphocytes in an adult human is about 10^{12} cells. About 2% circulate while the majority reside in secondary lymphoid organs.
5. Lymphoid mass is maintained by differentiation of precursor cells as well as proliferation of mature lymphocytes. In steady state this is controlled by balanced rates of production and apoptosis.
6. After cell division, most lymphocytes die by apoptosis, and only a small proportion (1–10%) survive to return to a resting state as memory cells.
7. Lymphocytes have a finite replicative capacity *in vitro*, estimated at 30–50 population doublings in the case of adult mature lymphocytes. Naive lymphocytes have longer telomeres than memory lymphocytes, suggesting a more extensive replicative history for memory cells *in vivo*.
8. The intermitotic lifespan of lymphocytes varies from days to years. The lifespan of an individual lymphocyte clone is the product of the number of cell divisions times the intermitotic survival time.
9. Lymphocyte proliferation can be antigen specific, superantigen mediated and polyclonal. An example of polyclonal proliferation is ‘bystander’ division induced by inflammatory cytokines.

termed cyclins and their associated cyclin-dependent kinases (CDKs). Cyclins are divided into a number of classes based on sequence similarity and physiological function: mitotic cyclins (cyclin B), S-phase cyclins (cyclin A) and G_1 cyclins (cyclins C, D, E and F in vertebrates, and called Cln in yeast). The stability of cyclin proteins varies, whereas the CDKs are stable throughout the cell cycle. The CDKs were first identified as the product of two cell division cycle genes: *cdc2* of the fission yeast, *Schizosaccharomyces pombe*, and *CDC28* of the budding yeast, *Saccharomyces cerevisiae*. CDKs are serine/threonine kinases and their activity is regulated by a series of complex post-translational reactions involving kinases, phosphatases and ubiquitin-dependent proteolysis. Most of these events appear to be highly conserved throughout evolution, however some forms of cell

Figure 2 Lymphocyte cell cycle. Quiescent G_0 lymphocytes respond to stimulation by enlarging and then entering interphase. Interphase is divided into G_1 , S and G_2 . Mitosis (M phase) occurs and the daughter cells return to G_1 and either re-enter the cell cycle or exit to G_0 . The G_0/G_1 transition is regulated by antigen and costimulatory signals while the G_1/S -phase transition requires cytokine signal transduction. The CDKs CDC2, CDK2, 4 and 6, and the CDK1 regulators p27 and p21 are indicated.

cycle regulation appear to be tissue specific. For example, the D-type cyclins are expressed differentially in various tissues and thus are likely to confer cell-type specificity to proliferation.

Lymphocytes normally exist in the quiescent (G_0) stage of the cell cycle, but remain responsive to mitogenic signals and, therefore, can enter and exit the cell cycle in a reversible manner. The critical events that drive lymphocytes from G_0 to G_1 and reversal to G_0 are not known. Regulation of the cell cycle in lymphocytes occurs primarily in the G_1 phase, where cells can revert to a quiescent state (G_0) or proceed to the S phase. The transition of lymphocytes from G_0 to G_1 is a complex event. For example, human T lymphocytes express at least 70 new genes within 4 h (early G_1) after stimulation with the mitogenic lectin phytohemagglutinin.

Two major control points lie on the pathway that leads lymphocytes from the resting state into cell division. Stimulation of cells through the antigen receptor accompanied by appropriate costimulation permits passage through the first control point which takes the cells from the resting G_0 state into G_1 . However, in order to undergo mitosis, lymphocytes must also traverse a control point which restricts passage from G_1 phase into S phase, termed the 'restriction point' in animal cells and the 'start point' in yeast. In mammalian cells the restriction point is the principal point in the cell cycle where proliferation is regulated by growth factors. This signal is provided by the binding of cytokines including interleukin 2 (IL-2) and IL-4 to functional lymphocyte surface receptors. The first signal induces the expression of cytokine and cytokine receptor genes and other genes which render cells competent to respond to the second signal. The second signal, in

contrast, activates the cell cycle machinery required for cells to initiate DNA synthesis and to undergo mitosis.

Recent advances have identified the proteins that drive progression through the phases of the cell cycle. Cyclins of the D family and CDK6 are likely to play a major role in the entry of lymphocytes into G_1 , the beginning of the cell cycle. In G_1 , CDK1 (p34cdc2) lacks any associated cyclins and has no protein kinase activity. The activity of CDK1 is dependent on its association with certain regulatory molecules, the mitotic cyclins A and B, whose levels vary with the cell cycle. In mammalian cells the restriction point involves CDK2 and cyclin E. In cells in S phase, CDK2 is found complexed to cyclin A. Mitosis (M phase) is initiated by the activation of CDK1 bound to cyclin B. The precise removal of a tyrosine phosphate from CDK1 during late G_2 is one of the events that leads to the induction of mitosis. The discovery that mitotic cyclins must be degraded for cells to exit mitosis has shown that proteolysis is critical for control of CDK activity and regulating progression through the cell cycle.

B cell proliferation

Two major functions of B cells are to secrete immunoglobulins and to bind antigens, process them, and present them to T cells. Each B cell produces immunoglobulins with a single specific antigen-binding site. By virtue of immunoglobulin on its surface (slg), B cells bind specific antigens which then deliver a signal to these cells to proliferate and clonally expand into memory cells or to differentiate into Ig-secreting cells. Since only one in 10^7 – 10^8 normal B cells has specificity for a particular antigen, the

Table 2 Key concepts and terms in cell cycle

<i>Concepts</i>	
Timing	The eukaryotic cell cycle is a set of ordered events characterized by DNA replication and cell division. Prokaryotic organisms have overlapping periods of replication and DNA segregation, i.e. simultaneous S and M phases of replication
Checkpoints	Cell cycle arrest is induced if a particular condition at a checkpoint is not met. Mammals and other metazoan cells may also activate apoptotic pathways if a checkpoint is not met, while apoptosis is lacking in yeast and other lower eukaryotic cells
Conservation	Basic aspects of the cell cycle are highly conserved in eukaryotic cells. The major differences are increasing complexity in higher eukaryotic cells. For example, there is one CDK gene in yeast while there are seven in mammalian cells
<i>Terms</i>	
Restriction point	The point in G ₁ phase when commitment to DNA replication occurs. After a lag time, S phase begins. In yeast, the restriction point is called 'Start'
Cyclin	Regulatory subunits for CDKs. They encode cyclin destruction boxes that target cyclins for periodic or cyclic ubiquitin-mediated proteolysis, hence their name. Cyclins are classified into mitotic cyclins (cyclin B), S-phase cyclins (cyclin A) and G ₁ cyclins (cyclins C, D, E and F in vertebrates)
CDK	Cyclin-Dependent Kinases are heterodimeric serine/threonine protein kinases that require cyclin subunits for activity as well as positive and negative regulatory phosphorylations
CDKI	Cyclin-Dependent Kinase Inhibitors. A family of proteins that bind CDKs and block kinase activity of cyclin:CDK complexes. There are two families of CDKI: Cip/Kip (p21, p27, p57) and Ink4 (p16, p15, p18, p19)

number of potential antigen-binding B cells are too few in number to provide an appropriate model to study the mechanisms of cell activation.

In order to stimulate larger numbers of cells via sIg cross-linking without resorting to purification of specific antigen-binding cells, investigators have used antibodies which react with sIg on the B cell (anti-Ig). By themselves, anti-Ig antibodies stimulate a number of measurable events reflecting B cell activation. Within 3 h, B cells enlarge in size, show enhanced expression of a number of surface determinants including major histocompatibility complex

(MHC) class II molecules, and show a substantial increase in RNA synthesis. The enhanced expression of MHC class II by antigen is an immunologically relevant event since these molecules interact with receptors on T cells, and their enhanced expression leads to enhanced cognate interaction between B and T helper cells. This interaction enhances the ability of T cells to activate B cells. To drive B cells beyond G₁ into S phase more efficiently, anti-Ig must either be used at high concentrations or must be added in the presence of T cells. As noted below, physiologic B cell activation *in vivo* probably involves antigen binding to sIg with coligation of CD19 and CD21 by the action of complement breakdown products. Activation of B cells to proliferate does not lead to Ig secretion *per se*. For this differentiative event to occur, additional lymphokines including IL-4, IL-2 and IL-5 need to be added together with anti-Ig. These lymphokines support the stimulation of a polyclonal antibody response but not, in the case of T-independent antigens, an antigen-specific response, for which antigen-specific T cells are required.

Recently, the importance of CD40-mediated signaling in B cell proliferation and differentiation has been described. CD40 is constitutively expressed on B cells and engagement by CD40 ligand (gp39), which is primarily expressed on activated CD4⁺ T cells, induces proliferation in B cells. The level of proliferation can be enhanced by the addition of IL-4, IL-10, and in some systems, IL-2. CD40 stimulation can also rescue B cells from anti-Ig-induced apoptosis.

Discovery of the mechanisms of signal transduction by these cell surface molecules has led to the use of 'postmembrane' chemical stimuli to study B cell proliferation and activation. When surface Ig is cross-linked by anti-Ig, or by antigen, phospholipase C is activated to hydrolyze phosphatidylinositol biphosphate (PIP₂) into inositol triphosphate (IP₃) and diacylglycerol (DAG). In support of the hypothesis that protein kinase C (PKC) activation and [Ca²⁺]_i elevation may lead to B cell proliferation, is the finding that the combination of ionophores and phorbol esters leads to B cell proliferation (Table 3).

However, LPS (lipopolysaccharide) does not induce the hydrolysis of PIP₂ or increase [Ca²⁺]_i, but is nevertheless one of the most potent inducers of murine B cell proliferation. Moreover, unlike anti-Ig plus IL-4, LPS can further drive B cells to differentiate and secrete Ig in the absence of added lymphokines. It has been shown that when the intensity of cross-linking surface immunoglobulin is increased by coupling anti-Ig to a large molecular weight carrier molecule such as dextran, B cells can be activated at picomolar concentrations compared to micromolar

Table 3 Reagents and experimental systems used for lymphocyte proliferation *in vitro*

Antigen-specific T cell proliferation	
e.g. mixed lymphocyte culture, soluble recall antigens (tetanus toxoid, mumps, purified protein derivative, etc.), superantigens (staphylococcal enterotoxins, etc.)	
Antigen-nonspecific T cell proliferation	
Plant lectins, e.g. phytohemagglutinin, concanavalin A, pokeweed mitogen	
Antibody-induced proliferation, e.g. anti-T cell receptor antibodies, antibodies to CD2, CD28, Thy-1, and Ly-6, etc.	
Viral transformation, e.g. herpesvirus saimiri, HTLV-I	
Oxidative mitogenesis, e.g. sodium metaperiodate, neuraminidase and galactose oxidase	
B cell proliferation

Cytokines and chemokines	

concentrations that are required for unconjugated anti-Ig. Recently, an explanation for enhanced B cell activation at low antigen receptor occupancy levels was provided by studies of mice immunized with a recombinant model antigen, hen egg lysozyme (HEL), fused to the murine complement component, C3d. HEL bearing two and three copies of C3d was 1000- and 10 000-fold more immunogenic, respectively, than HEL alone. Thus, C3d is a molecular adjuvant of innate immunity that profoundly influences B cell proliferation. Understanding the mechanisms which lead to the various stages of B cell activation may ultimately provide the means to manipulate the immune response.

T cell proliferation

A fundamental property of the immune system is that cellular proliferation is required for most effector functions of T cells. Several requirements dictate that continued T cell proliferation must occur throughout life in order to maintain an intact immune response. First, at least half the peripheral T cells in the mouse have a short lifespan of only a few days. Steady-state levels of T cells are maintained by export of cells from the thymus ($\sim 1 \times 10^6$ per day) and, more importantly, by cell division of peripheral T cells. Second, since only a small proportion

of the potential T cell repertoire is expressed at any time, the organism must maintain continuous T cell proliferation and senescence in order to select for the optimal repertoire in the face of changing environmental conditions (Table 1).

T cell proliferation occurs as a consequence of interactions between a large number of molecules on the surfaces of both the antigen specific T cell and the antigen-presenting cell. These interactions result in the generation of intracellular signals in the form of biochemical changes which initiate a programmed set of cellular responses. After stimulation of T cells with antigen, or the binding of antibody to the T cell receptor or CD3 complex, protein tyrosine kinases activate at least three distinct signal transduction pathways: the phosphatidylinositol second messenger bifurcating pathway leading to calcium/calineurin and protein kinase C activation, the Ras pathway, and the phosphatidylinositol 3-kinase pathway. These biochemical pathways are also activated after B cell stimulation. These biochemical signals result in blast transformation (cell enlargement and G_0 to G_1 transition) and the expression of high-affinity receptors for IL-2. In the presence of IL-2, nearly all T cells will progress through at least one round of the cell cycle after appropriate stimulation by antigen.

Lymphocyte proliferation as a consequence of molecular mimicry by infectious agents

An increasing number of viruses are known to infect lymphocytes, and directly or indirectly induce lymphocyte proliferation. Both retroviruses and DNA viruses infect lymphocytes. Human $CD4^+$ T cells are infected by the nontransforming retroviruses human immunodeficiency virus type 1 (HIV-1) and HIV-2 and by the transforming retrovirus human T lymphotropic virus type I (HTLV-I) while CD8 cells are transformed by HTLV-I. Human B cells are infected with two herpesviruses: Epstein-Barr virus (EBV) and human herpesvirus 8 (HHV8). Likewise, human T cells are infected with at least three herpesviruses: HHV6 and HHV7 and herpesvirus saimiri. Mouse B cells are infected with murine mammary tumor virus (MMTV), resulting in augmented T and B cell proliferation. Other organisms have subverted lymphocyte signal transduction pathways for enhanced replicative fitness, to impair the host immune response or both. A list of some of these agents and their targets are found in Table 4.

Table 4 Examples of pathogens that can alter lymphocyte proliferation

Organism	Comment
Viruses	
HIV	Infects CD4 cells via CD4 and chemokine coreceptors <i>env</i> gp120 primes uninfected CD4 T cells for antigen-induced apoptosis <i>nef</i> p27 perturbs TCR signal transduction, and may predispose thymocytes to negative selection HIV gag proteins bind to cyclophilins A and B via a cyclosporine-inhibitable interaction, and gag:CyP binding may inhibit T cell activation Vpr gene product arrests infected T cells in the G ₂ +M phase of the cell cycle
HTLV-I, II	Transforms T cells. An immunosuppressive peptide homologous to the p15E product of FeLV, MuLV, and HTLV-I inhibits protein kinase C-dependent responses
Feline leukemia virus (FeLV)	FeLV-infected lymphocytes have impaired calcium mobilization to a variety of stimuli
Bovine leukemia virus (BLV)	BLV can transform bovine lymphocytes. The <i>env</i> gene for BLV encodes a TAM motif, and this may induce aberrant or constitutive signal transduction through the Src family of protein tyrosine kinases
Poxviruses	Poxviruses produce soluble IL-1 and tumor necrosis factor α (TNF α) binding proteins that inhibit cytokine signals by ligand:receptor competition
EBV	LMP2A, a transmembrane protein of Epstein-Barr virus, encodes a TAM motif, and signal transduction via the motif may contribute to immortalization of B cells The binding of EBV to the B cell receptor CR2 elevates calcium, and may be involved in the initial infection of B cells. EBV-transformed B cells have impaired antigen receptor-induced calcium mobilization
HHV-6	Infects T cells and increases CD4 expression. Transactivates HIV expression.
HHV-7	Infects human CD4 cells. Uses CD4 as a receptor
H. saimiri	Some strains transform human T cells
MMTV	Infects mouse B cells, and causes superantigen specific T cell proliferation
Bacteria	
<i>Staphylococcus</i>	T cell activation induced by microbial superantigens, and this may induce proliferation or apoptosis of T cells
Protozoa	
<i>Theileria parvum</i>	<i>T. parvum</i> is an intracellular parasite that can transform bovine lymphocytes and causes constitutive IL-2 mRNA expression

Experimental approaches to lymphocyte proliferation

Several experimental *in vitro* models exist to study antigen-specific and nonspecific (polyclonal) T cell proliferation (Table 3). The use of antigen-specific proliferation is limited by the fact that cell proliferation is limited to the frequency of cells having a clonally rearranged antigen receptor that is specific for the test antigen. For example, the frequency of circulating human T cells responding to alloantigen is on the order of 10^{-2} , the frequency of cells responding to soluble 'memory' antigens such as tetanus toxin is 10^{-5} , and the frequency of cells responding to a primary antigen is $<10^{-6}$. For this reason, T cell clones of antigen-specific cells are used to study antigen-specific responses, and have proved quite useful for analysis of the molecular basis of cellular interactions. A limitation of this approach, however, is that the triggering properties of T cell clones are much less stringent than primary T cells. Antibodies to the T cell receptor (TCR) are a con-

venient and effective way to cause polyclonal T cell proliferation. Antibodies to either the heterodimeric T cell receptor or the associated CD3 complex are effective mitogens. Antibodies may be added in solution or immobilized onto the surface of culture vessels or beads. The manner of addition of the antibody to the culture system is a critical experimental variable. For example, soluble antibodies are much more dependent upon the presence of accessory cells for their mitogenic effect than are immobilized antibodies. Furthermore, when using soluble antibody as a stimulus for human T cells, the isotype of the anti-TCR antibody is important due to the varying affinity of Fc receptors on accessory cells for murine monoclonal antibodies. Antibodies to the CD2 and CD28 coreceptors also cause polyclonal T cell proliferation.

Chemical reagents can also be used to mimic the biochemical signals provided by TCR-induced T cell activation, as was previously discussed with respect to B cell activation. This concept has been termed 'membrane bypass activation'. As in B cells, calcium

ionophores together with phorbol esters cause T cell proliferation, however the proliferation is accompanied by high rates of apoptosis unless appropriate costimulatory signals are provided. A general principle of lymphocyte proliferation is that multiple stimuli are required in order to elicit a full proliferative response and to avoid induction of apoptosis. For example, lectin-stimulated proliferation requires the presence of accessory cells such as monocytes. Pure populations of T cells will not divide unless the primary stimulus as well as the biochemical signals provided by the accessory cells are supplied. In practice, small and variable quantities of monocytes are required for *in vitro* proliferation (0.1% monocytes for phytohemagglutinin (PHA)-induced proliferation; 1% monocytes for anti-CD3 and calcium ionophore-induced proliferation).

Both B and T cell proliferation can be assayed in a variety of ways. [³H]Thymidine added to stimulated cells becomes incorporated into newly synthesized DNA, and thus is a measure of stimulation of the initial cell population. Bromodeoxyuridine measures proliferation using the same principle, but is detected by flow cytometry with a fluorescent antibody. Proliferation measured using these agents must take into account ongoing cell death in the population as a whole. Hoechst 33342, a DNA-binding dye and Pyronin Y, a RNA-binding dye can also be detected by flow cytometry and measure cell cycle phase. PKH-26 and other vital membrane dyes can discern divided and nondivided cells, but become less accurate the more a population of cells has divided. Tetrazolium salts are converted by metabolically active cells to formazan, which can be quantified by measuring absorbance at 490 nm.

Communication between cells involved in the immune response requires cell-to-cell interactions and the production of soluble messengers which may act in a paracrine or autocrine manner. The presentation of antigen by macrophages to T lymphocytes requires a direct cell-to-cell interaction, but cytokines are also produced during this process which control the induction of immunity. Lipid mediators derived from cell membranes, such as the prostaglandins, are also produced during T cell-macrophage interactions and may modulate the behavior of immunocompetent cells.

Pathways of prostaglandin formation

Prostaglandins are acidic lipids which can be enzymatically produced by most mammalian cell types in response to mechanical, chemical or immunological stimuli. The unsaturated fatty acid arachidonic acid is the precursor for the synthesis of the major classes of prostaglandins and leukotrienes, collectively known as eicosanoids. The level of free arachidonic acid in cells is very low, but it is stored in high concentrations in an esterified form in membrane phospholipids. The arachidonoyl moiety is located almost exclusively at the 2-acyl position and consequently, the action of phospholipase A_2 causes the liberation of arachidonic acid. In some cell types, arachidonic acid may also be liberated by the sequential action of phospholipase C and diacylglycerol lipase. As shown in Figure 1, the liberated arachidonic acid can then be converted to the cyclic endoperoxides prostaglandin G_2 (PGG_2) and PGH_2 by the cyclo-oxygenase enzymes present in the 'microsomal' fraction of most mammalian cells. There is a constitutive form of cyclo-oxygenase (COX 1) which is present in many cell types and prostaglandins produced by this enzyme play a role in physiological processes such as hemostasis and the regulation of blood flow in the gastrointestinal tract and the kidney. In recent years it has been discovered that a second form of cyclo-oxygenase (COX 2) can be induced in certain cells by infectious and immunological stimuli and this enzyme is believed to be largely responsible for the production of prostaglandins at sites of chronic inflammation. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce prostaglandin production by inhibiting the cyclo-oxygenase enzymes and this action underlies both their therapeutic efficacy and side-effects, as discussed later. The unstable endo-

Figure 1 Pathway of eicosanoid production from membrane phospholipids. The solid lines represent enzymatic conversion and the dashed lines nonenzymatic breakdown. PG, prostaglandin; Tx, thromboxane; LT, leukotriene.

peroxides can degrade nonenzymatically to the primary prostaglandins PGD_2 , PGE_2 and $PGF_{1\alpha}$. However, there are distinct isomerases which catalyze the conversion of endoperoxides to PGD_2 and PGE_2 and the formation of $PGF_{2\alpha}$ may be catalyzed by aldoketoreductases. Some cell types, such as the mast cell, produce PGD_2 , but not PGE_2 , which suggests that the relative distribution of these isomerases is important in determining which prostaglandin is formed.

In endothelial cells, the major cyclo-oxygenase product is prostacyclin (PGI_2), which is enzymatically produced from endoperoxides by prostacyclin synthase. Prostacyclin is unstable under physiological conditions and is rapidly hydrolyzed to the considerably less potent 6-keto- $PGF_{1\alpha}$. Thromboxane A_2 (TxA_2) is produced from endoperoxides in platelets, macrophages, and some other cell types, by an enzyme termed thromboxane synthase. Thromboxane A_2 is highly unstable and decomposes rapidly to the biologically inactive TxB_2 . Macrophages are rich sources of prostaglandins, particularly PGE_2 , which they produce in response to a range of

immunological stimuli or during phagocytosis. In contrast, lymphocytes produce little if any prostaglandins, the low levels present in lymphocyte cultures being probably due to macrophage contamination.

Lymphocytes can take up arachidonic acid and incorporate it in their phospholipids but cannot convert that arachidonate into prostaglandins, presumably due to lack of cyclo-oxygenase enzyme activity. However, *in vitro* experiments have demonstrated that arachidonic acid can be donated by lymphocytes to other cell types and metabolized to biologically active prostanoids. It is not certain if this process can occur *in vivo* where protein binding is likely to dramatically reduce the concentration of free arachidonic acid.

Role of prostaglandins in inflammation

The primary prostaglandins such as PGE₂, as well as the breakdown products of prostacyclin and TxA₂, have all been detected in elevated levels at sites of acute and chronic inflammation. The most abundant cyclo-oxygenase product is usually PGE₂, but this depends on the nature and location of the inflammatory response. For example, in conditions where mast cell degranulation is central to the pathology, such as in systemic mastocytosis, PGD₂ and its metabolites can be detected in high amounts in plasma and urine. The enzymatic source of prostaglandins depends on the chronicity of the lesion. The early production (within minutes) of prostaglandins which occurs in acute pain models (zymosan-induced writhing in mice, for example) is likely to be solely due to the activity of the constitutive COX 1 while the delayed, cytokine-dependent production of prostaglandins is dependent upon the induction of COX 2.

Prostaglandins produced at a site of injury contribute to the signs and symptoms of inflammation. Prostaglandin E₂ and prostacyclin can sensitize nerve endings to painful chemical and mechanical stimuli, a process termed hyperalgesia. Consequently, inhibition of prostaglandin biosynthesis in inflamed tissues by NSAIDs accounts for the analgesic activity of this class of compound. Prostaglandin E₂ and prostacyclin are also potent vasodilators and are responsible in many circumstances for the increased flow of blood to sites of inflammation.

Prostaglandins are not chemotactic for neutrophils nor do they directly induce vascular permeability, but the increased blood flow may potentiate leukocyte accumulation and edema formation. The ability of NSAIDs to suppress edema formation has been attributed to inhibition of prostaglandin synthesis,

but the doses required to inhibit edema formation are much higher than required to inhibit the production of prostaglandins in many circumstances. Furthermore, it is well recognized that the antiedema or 'anti-inflammatory' doses of NSAIDs are much higher than the analgesic doses. It is puzzling why the doses of NSAIDs required to inhibit these end-points should differ if inhibition of prostaglandin synthesis is responsible for both effects. Differences in site of action, degree of inhibition required to inhibit each end-point or COX1/2 selectivity may explain the divergent potencies of NSAIDs as analgesic compared to anti-inflammatory agents.

Reduction in the tissue concentrations of vasodilator and cytoprotective prostaglandins also explain why NSAIDs cause gastrointestinal ulceration and kidney damage. These side-effects can be serious, particularly in the elderly population, and limit the dose of NSAID which can be used. Since inhibition of the constitutive COX 1 is likely to be responsible for the side-effects there has been a large effort in recent years to identify novel agents which selectively inhibit COX 2 in the hope that gastrointestinal and renal toxicity will be reduced while anti-inflammatory efficacy will be retained. Several companies have been successful in identifying such compounds and COX 2 inhibitors, a potentially new class of NSAID, are in the late stages of development. Preclinically, COX 2 inhibitors have shown efficacy in reducing edema and suppressing adjuvant arthritis but, unlike traditional NSAIDs, COX 2 inhibitors do not cause gastrointestinal ulceration. The results of clinical trials with COX 2 inhibitors are awaited with interest. It is possible that reduced side-effects may enable the doses to be increased to achieve more profound anti-inflammatory activity. On the other hand, COX 1 may contribute to prostaglandin production in inflamed tissues and/or spinal cord in some circumstances.

Role of prostaglandins in fever and infection

The febrile response which often accompanies infection is the result of the production of endogenous pyrogens from phagocytic leukocytes in response to microbial products. Endogenous pyrogens, which include interleukin 1 (IL-1) IL-6 and tumor necrosis factor α (TNF α), are released into the circulation during severe infections and stimulate specialized endothelial cells in the brain capillaries to produce PGE₂. This leads to increased levels of PGE₂ in hypothalamic tissue and in the third ventricle, which can elevate core temperature. The role of prostaglandins in mediating fever is well established; prostaglandins

of the E series are potent pyretic agents when given centrally, while the reduction of fever by antipyretic drugs, such as aspirin and paracetamol, correlates with their ability to inhibit prostaglandin synthesis in brain tissue.

Fever is a phylogenetically ancient response which may have a protective role in infection, since elevation of core temperature leads to activation of host-defense systems. At febrile temperatures, T lymphocyte proliferation is enhanced, as is the induction of primary humoral immunity. Consequently, one would predict that infective organisms can be eliminated more effectively at febrile temperatures and that treatment with antipyretic drugs may consequently prolong infection. Indeed, in mice, treatment with drugs that inhibit prostanoid synthesis and reduce fever, has been shown to exacerbate *Listeria* and *Coxsackie* virus infections. However, mechanisms other than reduction of fever may explain such effects and there is little clinical evidence that antipyretic drugs prevent or delay recovery from infection.

The local release of vasodilator prostaglandins may also contribute to increased blood flow to sites of infection. This may serve a physiological role in increasing the recruitment of phagocytic leukocytes. Thus, postcapillary venules become more permeable at inflamed sites and concurrent hyperemia will therefore lead to enhanced plasma extravasation. These processes lead to increased opsonization and engulfment of invading microorganisms. While inhibition of prostaglandin synthesis may account for the mild anti-inflammatory activity of NSAIDs, reduction in prostaglandin-mediated blood flow to sites of infection may be deleterious in some situations.

Prostaglandins and chronic autoimmune diseases

In addition to participating in some aspects of acute inflammation, prostaglandins of the E series and prostacyclin can suppress a number of chronic immunological responses. Systemic administration of PGE₂ or its analogs can suppress disease activity in animal models of chronic inflammation such as adjuvant arthritis, immune colitis or glomerulonephritis. These actions have been attributed to effects on lymphocyte function, since prostaglandin E₂ is a potent inhibitor of lymphocyte proliferation and can suppress the production of lymphokines from T cells.

Macrophage activation is also decreased *in vitro* in the presence of concentrations of PGE₂ that can be detected at sites of inflammation. In particular, there are many reports that PGE₂ can inhibit the pro-

duction of IL-1 and TNF α . These cytokines are found at sites of chronic inflammation and play a central role in the recruitment of neutrophils, macrophages and lymphocytes. Interleukin 1 and TNF α can also induce procoagulant activity on endothelial cells which leads to deposition of fibrin, a characteristic feature of chronic autoimmune reactions. Furthermore, these cytokines cause tissue damage by the induction and release of proteolytic enzymes from mesenchymal cells, which also respond by synthesizing prostaglandins. The prostaglandins so produced may act through a feedback mechanism to inhibit cytokine generation from macrophages. Prostaglandin E₂ has been convincingly demonstrated to inhibit the production of mature TNF α protein activity and downregulate the level of mRNA for TNF α in macrophages. Whether PGE₂ inhibits IL-1 secretion is less certain, but since PGE₂ inhibits T cell function, this could indirectly suppress IL-1 generation. These interactions between eicosanoids and cytokines are shown in Figure 2.

Since NSAIDs inhibit prostaglandin synthesis in inflamed tissues, treatment with these drugs may

Figure 2 A proposed scheme to demonstrate the interaction between T lymphocytes and macrophages that can lead to cytokine production which, in turn, initiate the processes of leukocyte infiltration, fibrin deposition and tissue damage. Prostaglandin E₂ is also produced during this interaction which can downregulate T cell and macrophage activation.

enhance cytokine production and exacerbate some chronic aspects of autoimmune disease. Indeed, both indomethacin and ibuprofen have been shown to enhance TNF α production *in vivo* which is likely to explain why these agents increase mortality in murine endotoxic shock and enhance cartilage degradation in rabbits with antigen-induced arthritis. These findings have obvious clinical implications for patients receiving NSAID therapy for the treatment of chronic inflammatory diseases. It is tempting to speculate that in diseases such as rheumatoid arthritis NSAIDs, while ameliorating the disease symptoms may exacerbate the underlying disease process leading to enhanced bone and cartilage destruction. There have been several suggestions in the literature that NSAIDs may accelerate the radiological changes that occur in osteoarthritis but definitive proof is lacking because long-term trials with large numbers of patients comparing an NSAID with placebo have never been conducted since all patients require NSAID therapy to provide analgesia. However, there is clear clinical evidence that NSAIDs can exacerbate inflammatory bowel diseases (IBD) such as Crohn's disease and ulcerative colitis. Such actions may reflect a reduction in the local biosynthesis of cytoprotective prostanoids in the intestinal mucosa. However, since increased cytokine production leading to fibrin deposition and multifocal infarction has been implicated in the pathogenesis of IBD, removal of immunosuppressive prostanoids may underly the exacerbation of colitis by NSAIDs.

Prostaglandin E₂ can also inhibit the expression of major histocompatibility complex (MHC) class II molecules, and consequently can interfere with the presentation of antigen to T cells by macrophages. Although PGE₂ and prostacyclin have potent effects on immunocompetent cells, there is little evidence that other cyclo-oxygenase products, such as thromboxane, can effect lymphocyte or macrophage function.

In addition to suppressing T cell and macrophage function, prostaglandins in some circumstances can stimulate immune responsiveness. The production of immunoglobulin M (IgM) rheumatoid factors by human rheumatoid mononuclear cells is inhibited by

indomethacin *in vitro*, an effect reversed by exogenous PGE₂. These observations can be explained by inhibition of T suppressor cell activity by PGE₂. In contrast to these findings, indomethacin has been shown to enhance humoral immunity in some animal models. Clearly, the site of production and the concentration of mediator produced is critical in determining whether prostaglandins have immunosuppressive or immunostimulatory effects.

Conclusions

Increased prostaglandin synthesis occurs in response to a range of immunological stimuli. The prostaglandins so produced mediate fever and increase blood flow to sites of infection and inflammation. Prostaglandins, particularly PGE₂, also modulate the function of immunocompetent cells. At concentrations detected at sites of inflammation, PGE₂ can downregulate the function of macrophages and T lymphocytes. Consequently, inhibition of PG synthesis by NSAIDs may exacerbate some aspects of autoimmune disease such as those occurring in chronic arthritis and inflammatory bowel disease.

PROTEIN KINASES

Thomas A Hamilton, Department of Immunology, Cleveland Clinic Foundation, Cleveland, Ohio, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Protein kinase is a general term to describe an enzyme activity that can catalyze the transfer of phosphate from a donor source (usually nucleotide triphosphate, either ATP or GTP) to an acceptor amino acid residue in a polypeptide substrate. The resulting covalent modification of peptide structure leads to a new activity status for the target protein. That protein kinase-mediated protein phosphorylation is of central importance in biology is clearly evidenced by the broad distribution of such enzymes in both the plant and animal kingdoms.

The following discussion will address the central role for protein phosphorylation in stimulus-response coupling, the broad spectrum and characteristics of the protein kinases which participate in such activity, and the involvement of various protein kinases in the function of myeloid cell types. The reader is referred to related entries on cell activation for a discussion of the role of protein kinases in non-myeloid immune cell types.

Role for protein kinases in cellular physiology: stimulus-response coupling

While at rest, most cells no doubt express a multitude of protein kinases whose activities are not subject to modulation and which phosphorylate proteins whose routine function requires such post-translational modification. Tremendous interest, however, has been focused on the role of protein kinases as major contributors in stimulus-response coupling or intracellular signal transduction. This process, whereby extracellular stimuli are transduced into intracellular behavioral change is a multistep sequence of events which begins with the interaction between the stimulus and the cell surface and ends with the acquisition of new functional competence. The intermediate events are now known to be multifactorial and frequently involve a sequential cascade of change in protein function which results from reversible or irreversible covalent modification of the target protein. Protein kinases are one of the most common enzymatic activities participating in intracellular signal transduction.

Sensitivity to extracellular stimuli

One major requirement for protein kinases as central mediators of signal transduction is sensitivity to

extracellular stimulation. Essentially all extracellular information is transduced through interaction of the stimulus with some form of receptor. In general, receptors are protein in nature, are localized in the plasma membrane and display a stimulus recognition structure on the exterior surface of the cell. Some receptor systems (e.g. steroids, retinoids, etc.) detect the presence of the stimulus after it has entered the cell. Receptors may couple with protein kinases either directly, or indirectly through the action of nonprotein second messengers. At least three categories of second messengers have been identified. These include the cyclic nucleotides (cyclic AMP and cyclic GMP), various phospholipid hydrolysis products, and alterations in localized concentrations of Ca^{2+} ions. Some protein kinases (particularly the protein tyrosine kinases, see below) are integral parts of the receptor structure and enzyme activity is subject to modulation by receptor-ligand interaction. Other tyrosine-directed protein kinases are structurally distinct but associate with and/or become activated by interaction with ligand-binding receptors in stimulus-dependent fashion.

An additional complexity is the well-documented existence of protein kinase cascades. In these, the response to direct or indirect stimulation of a kinase activity may be dramatically amplified through multiple cycles of protein kinase activation in which the activity of each sequential enzyme in the chain is modulated by phosphorylation. Thus there are many protein kinase activities in cells that participate in signaling pathways but which are not directly sensitive to the primary action of the extracellular stimulus.

Categories of protein kinase activity

Protein kinases can be divided into two broad classes on the basis of whether the amino acids serine/threonine or tyrosine are the primary phosphate acceptor sites. The following sections will consider first the serine/threonine-directed enzymes, subdivided on the basis of stimulus sensitivity, and second, the tyrosine-directed enzymes, either as receptor-linked or nonreceptor-linked.

Serine/threonine-directed protein kinases

Cyclic nucleotide-dependent protein kinases The first stimulus-sensitive protein kinases to be studied

were those regulated by cAMP. This second messenger is generated by adenylyl cyclase which couples to multiple cell surface receptors through heterotrimeric GTP-binding proteins. Cyclic nucleotide levels are also subject to control through the action of phosphodiesterases. cAMP-dependent protein kinases (PKAs) consist of two subunits: a catalytic subunit and a regulatory subunit. The catalytic subunit is normally inactive when complexed with the regulatory subunit. Interaction of the complex with cAMP results in subunit dissociation and subsequent activation of the enzyme. Multiple forms of each subunit class have been characterized. Substrate specificity of PKAs is quite broad and the response to elevated cAMP exhibits a diverse array of downstream consequences.

Ca²⁺/calmodulin-dependent protein kinases There are multiple protein kinase activities that are controlled by changes in intracellular Ca²⁺ levels through interaction with calmodulin, a Ca²⁺-binding regulatory protein. When Ca²⁺ levels are elevated, Ca²⁺-calmodulin complexes associate with several different protein kinases and such association results in enhanced catalytic activity of the enzymes. At least six different forms of calmodulin-dependent protein kinases have been defined. Three of these isoforms (phosphorylase kinase, myosin light chain kinase, and Ca²⁺/calmodulin kinase III) exhibit a high degree of substrate specificity. Isoforms I, II and IV exhibit much broader specificity and are referred to as multifunctional forms. The different forms exhibit substantial structural complexity, frequently being composed of multiple distinct subunits.

Phospholipid-dependent protein kinases Phospholipid hydrolysis is now a well-documented early event in intracellular signaling. The activation of different phospholipase activities with highly distinct substrate specificities is linked to multiple receptor systems in using a variety of distinct molecular coupling mechanisms.

There are two broad categories of protein kinase activities that are sensitive to specific phospholipid hydrolysis products which act as second messengers. The first of these families is a group of enzymes known collectively as protein kinase C (PKC). These enzyme activities were discovered as a Ca²⁺- and phospholipid-dependent activity and were subsequently found to be the target of the tumor promoter phorbol diesters. At least 11 structurally distinct forms of PKC-like enzymes are known and these can be divided into three subgroups on the basis of cofactor requirements. These include α , β and γ isoforms which require Ca²⁺, phospholipid,

and a diacylglycerol (DAG) activator, the δ , ϵ , η and σ isoforms which are Ca²⁺-independent but still require DAG, and the ζ and λ isoforms which require only phospholipid for activity. In addition, two structurally related enzymes known as protein kinase D and PKC μ are also DAG-sensitive and Ca²⁺-independent.

Activity of the Ca²⁺-dependent isoforms of PKC may require the concomitant elevation of intracellular Ca²⁺. These cofactor and activator requirements provide some opportunity for stimulus-dependent specificity in the function of the different isoforms of PKC. However, there appears to be little substrate specificity inherent in PKC structure and, at least *in vitro*, many proteins can serve as targets for the different forms of enzyme. One potentially important determinant of specificity may be subcellular localization. Some forms of PKC show preference for association with different membrane sites and may so associate in an activation-dependent fashion. Furthermore, PKC isoforms exhibit interaction with other nonprotein kinase proteins which may also be important determinants of selective function or activation. Following activation, some forms of PKC undergo Ca²⁺-dependent proteolysis. Cleavage may selectively remove the regulatory domain of the protein, rendering it constitutively active at least transiently.

A second form of phospholipid-dependent protein kinase has been identified whose activity is modulated by ceramide, a hydrolysis product of sphingomyelin. Several different extracellular stimuli (tumor necrosis factor α (TNF α), interleukin 1 (IL-1) and vitamin D₃) have been convincingly linked with the sequential activation of a neutral sphingomyelinase which generates ceramide, and at least some downstream signaling events are mediated by activation of the ceramide-dependent protein kinase. The enzyme is a member of a large family of serine/threonine-directed protein kinases which recognize substrate peptides in which the phosphoacceptor site is N-terminal to a proline residue. While specific substrates are not definitively known, activation of the ceramide-dependent signaling pathway(s) has been linked with the activation of the MAPK cascades, with activation of the NF κ B transcription factor, and with the stimulation of apoptosis.

The MAPK signaling pathway A major functional class of protein kinase activities which has been studied intensively in recent years is now known collectively as the mitogen-activated protein kinase (MAPK) cascade. While there are multiple structural forms of protein kinase activity which participate in the MAPK cascade, they are linked together in a

functional unit which can mediate information transfer from the exterior of the cell to the nucleus, resulting in stimulus-dependent alterations in gene expression. Indeed these signaling pathways can be initiated by a highly diverse array of important extracellular stimuli which induce both cell proliferation and functional differentiation.

Two general features of this signaling process deserve special comment. First, there are multiple forms of the MAPK cascade that may coexist in the same cell and which exhibit differential sensitivity to different forms of extracellular stimulation. Second, the different MAPK cascades exhibit at least five sequential layers of protein kinases. At each layer, multiple isoforms of kinase activity have been described. The nomenclature for these enzymes is quite complex and the simplest system relates all kinase activities to the originally identified mitogen-activated protein kinase termed MAPK. Thus the MAPK kinase is termed MAPKK while the next upstream enzyme is termed MAPKKK or MAP3K and so on. Enzymes which are downstream of MAPK are termed MAPK-activated protein kinases or MAPK-APK.

The MAPKs are members of the proline-directed protein kinase family (like ceramide-activated protein kinase, see above). MAPKKs are relatively unique enzymes which phosphorylate MAPK on both tyrosine and serine or threonine residues, both events being required for full activation of MAPK activity. The MAPK cascades can be initiated through multiple entry points and include action of receptor-linked protein tyrosine kinase activity (see below), phospholipid-dependent kinases, and intracellular receptor-initiated events (steroids). Furthermore, there is substantial cross-talk between the distinct cascades. Through such combinatorial mechanisms this system is capable of generating remarkable diversity in information transfer.

Other serine/threonine protein kinases There are no doubt many additional serine/threonine-directed protein kinases which participate in stimulus-response coupling. Prominent examples include the double-stranded RNA-dependent protein kinase known as PKR which is associated with response to interferon (IFN) and with acquisition of antiviral function. Recent studies using mice in which this enzyme has been deleted by gene targeting through homologous recombination indicate that this enzyme may play an important role in cellular response to extracellular stimulus.

Another class of enzymes known to exhibit change in activity in response to stimulation are collectively known as casein kinases based upon their preference

for casein as a substrate. Two classes of casein kinases have been studied. Both show relatively broad substrate specificity. Although casein kinase activities vary in response to extracellular stimulation, there is little mechanistic understanding of how enzyme activity changes during cell treatments nor how important these enzyme forms may be in processing such extracellular information.

Tyrosine-directed protein kinases (PTKs)

Protein kinases that utilize tyrosine residues as the principal phosphate acceptor site have been classified into two categories on the basis of whether the enzyme activity is an integral part of a cellular receptor or has no demonstrable receptor function.

Receptor-linked PTKs Although the first tyrosine-directed protein kinase discovered was not receptor associated, the linkage of tyrosine-directed phosphorylation with response to extracellular stimulation focused early attention on those enzyme activities which were integral parts of the receptor protein structure. This paradigm is now well-established and is associated most closely with receptors for growth factors such as insulin and insulin-like growth factors, epidermal growth factor, fibroblast growth factors and the macrophage colony-stimulating factor CSF-1. The linkage to cell proliferation is not exclusive as these stimuli are also capable of producing developmental changes in cells related to the acquisition of selective functions. Receptor-linked PTKs are activated upon ligand binding by receptor subunit aggregation. Activated enzymes phosphorylate the receptor itself as well as other substrates, at least some of which associate with the receptor via protein domains which recognize and bind to phosphotyrosine residues. Thus the phosphorylation induced by ligand-receptor interaction initiates a signaling cascade which may involve additional protein kinases as well as other enzymes. The receptor-linked PTKs are highly pleiotropic and can couple to many downstream signaling pathways, including those involving the serine/threonine protein kinases discussed above.

Nonreceptor-linked PTKs There are at least eight categories of PTK that are not part of any stimulus-binding protein and exhibit no extracellular domain. These eight subclasses are distinguished by specific structural features. All possess at least one kinase domain which contains the active site. Many possess regions that allow interaction with phosphotyrosine residues or with other specific amino acid sequence motifs which are expressed on the cytoplasmic domains of specific receptors. In addition, enzyme activity is frequently subject to positive or negative

regulation by phosphorylation on critical tyrosine residues. These latter two characteristics are critical to the function of at least three classes of nonreceptor PTKs. Cell surface receptors aggregate upon ligand binding, which results in the activation of PTKs associated with the cytoplasmic domains of the receptors. These enzymes phosphorylate themselves as well as the receptor subunits, leading to interaction with a multitude of downstream signaling intermediates in a fashion remarkably similar to that described above for the receptor-linked PTKs.

Nonreceptor PTK classes that function in this manner include the Janus family (JAK1, JAK2, JAK3, Tyk2), the Syk family (Syk, Zap), and the Src family (Src, Yes, Fyn, Yyn, Lck, Blk, Hck, Fgr, and Yrk). Many of these mediate signaling pathways restricted to hematopoietic cell types. Although the other classes of nonreceptor-linked PTKs have not been so closely associated with receptor-mediated events, they are also likely to be involved with intracellular communication and regulation.

Protein kinases in myeloid cells

While much of our current knowledge of protein kinase function in cellular control and stimulus-response coupling has been developed in cell types not considered to be components of the immune system, both lymphoid and myeloid cell types have frequently served as exceptionally useful models. Indeed, much of the current detailed understanding of the nonreceptor-linked PTKs as primary mediators of ligand-induced cellular response has emerged from studies utilizing antigen- and/or cytokine-mediated activation of T lymphocytes. The reader is referred to the entry covering T lymphocyte activation for more detailed coverage. Thus the focus of the remaining discussion here will be on the roles for different forms of protein kinase activity in mediating responses of myeloid lineage cell types to extracellular stimulation.

Because there are numerous myeloid cell derivatives and these may exhibit a highly diverse set of characteristics in different tissue settings, the discussion will be limited to mononuclear phagocytes (monocytes and tissue macrophages) and neutrophilic polymorphonuclear leukocytes (PMNs). These two categories of cells share many functional capabilities (though these may involve either markedly or subtly different mechanisms).

A major difference between the two cell types is the degree to which their functional competence is subject to modulation by extracellular stimuli. For example, PMNs are constitutively competent to exhibit certain acute secretory responses although such

function may be increased or decreased in quantitative terms following exposure to exogenous stimuli. In contrast, monocytes and macrophages are relatively quiescent cells in their resting or unstimulated state and they often require exposure to appropriate activating agents in order to acquire enhanced functional competence. Such adaptive behavior may require hours or days to develop following stimulation. Nevertheless, both acute and adaptive responses frequently require the participation of protein kinase activities.

Categories of extracellular stimulation

Three classes of extracellular stimuli will be considered. The first two of these are generally associated with the triggering of acute responses and have been frequently studied in detail using PMNs. These are the structurally diverse collection of agents which induce chemotaxis, and the opsonins for which specific receptors have been defined (e.g. Fc and complement receptors). The third class of stimuli are largely associated with induction of proliferation or adaptive functional activation of more plastic cell types such as mononuclear phagocytes. Stimuli responsible for such change include cytokines, growth factors and bacterial cell wall products such as lipopolysaccharide (LPS). The adaptive change following such stimulation is usually mediated in large part by alterations in gene expression. Studies of acute responses have been done more frequently in PMNs while analyses of adaptive behavior responses involving new gene expression have utilized macrophages (or other cell types) as models. Nevertheless both cell classes exhibit both forms of response.

Chemotactic factors Much of the current knowledge regarding the actions of chemotactic factors has been developed in PMNs using formyl-Met-Leu-Phe, the complement fragment C5a, leukotriene B₄, and members of the chemokine gene family, in particular interleukin 8. The principal common denominator for all of these agents is their interaction with structurally related receptors which are characterized by seven transmembrane-spanning domains. These receptors all couple to downstream signaling pathways using the heterotrimeric GTP-binding proteins. The responses to most chemoattractants in PMNs are quite similar and involve the activation of substrate-specific phospholipase C activity which selectively hydrolyzes phosphatidylinositol biphosphate (PIP₂), resulting in the generation of DAG and inositol triphosphate (IP₃), which activate PKC and release Ca²⁺ from intracellular storage sites, respectively. The consequences of this series of events include the initiation of one or more MAPK cascades

as well as the triggering of several acute response pathways which culminate in cell polarization and mobilization, in degranulation, and in the assembly of the NADPH oxidase complex.

Opsonins Responses very similar to those in PMNs stimulated with chemotactic agents are seen following exposure to opsonized materials. Opsonins are bivalent proteins which recognize foreign material and interact with specific receptor structures on leukocyte cell surfaces (e.g. complement fragments C3b and C3bi or immunoglobulin). The cell surface receptors which interact with these materials are quite diverse as well and in addition, initiate a broad spectrum of responses. These include the phagocytic uptake of opsonized particles, which is frequently accompanied by degranulation and activation of the NADPH oxidase system. Despite the strong similarity between response to chemotactic agents and opsonins, these processes appear to involve quite distinct initiating mechanisms. The best understood example of signaling in response to opsonins is that mediated by members of the receptor families that recognize the Fc portion of immunoglobulin chains. In contrast to the chemoattractant receptors, which utilize the seven transmembrane-spanning receptors, the Fc receptors generally contain one or more cytoplasmic domains that exhibit immunoreceptor tyrosine-based activation motifs (ITAMs). These sequence motifs are able to interact with several of the nonreceptor-linked PTKs, in particular members of the Src and the Syk families and ligand binding results in PTK activation. These kinase activities are then able to couple with various intracellular signaling pathways as outlined above.

Cytokines, growth factors and LPS Knowledge of the mechanisms responsible for stimulus-response coupling in immune system cell types following exposure to cytokines and growth factors has undergone an explosive expansion over the last 5 years. Cells of myeloid lineage have served as useful models for much of this work. Major progress has come from the structural characterization of the receptor systems with which many cytokines and growth factors interact and the immediate as well as the ultimate mediators of intracellular signaling following receptor occupancy. The following discussion will consider three distinct response categories: those mediated by cytokines and growth factors which bind to the collection of diverse but structurally related 'cytokine family' receptors, those mediated by the broad acting proinflammatory agents TNF and IL-1, and those mediated by bacterial cell wall products, prototypically lipopolysaccharide (LPS).

Members of the cytokine receptor family bind ligands through single or multichain structures. Interestingly, some individual subunits are shared by several different ligands. The ligand-induced aggregation leads to activation of tyrosine kinases of the Janus family, which are frequently associated with the cytoplasmic portion of the receptor. Some receptors utilize only one kinase isoform while others may involve the function of as many as three. Activated Janus kinases phosphorylate specific tyrosine residues on selected receptor subunits and these are able to serve as docking sites for other downstream signaling molecules which recognize and bind phosphotyrosine. Most prominent amongst these are members of a family of proteins termed the signal transducers and activators of transcription (STATs). These proteins dissociate from the receptor following phosphorylation and form homo- and hetero-oligomeric complexes which translocate to the nucleus where they are able to interact directly with specific sequence motifs responsible for regulated inducible transcription of nearby genes. Phosphorylation of STATs on tyrosine may also be mediated (though perhaps less efficiently) by other nonreceptor-linked PTKs, in particular those of the Src family. STAT protein function is also dependent upon serine-directed phosphorylation. The enzymes responsible have not been unambiguously identified but may be part of or depend upon activation of one or more MAPK cascades. The cytokine receptor family kinases have also been shown to initiate MAPK cascade activity.

TNFs and IL-1s are structurally dissimilar and interact with structurally unrelated receptor proteins. Nevertheless, both cytokines induce a diverse but overlapping set of responses in virtually all cell types. The signaling pathways utilized by these two agents are still only poorly understood but appear to share at least one important common feature. Both stimuli result in the rapid hydrolysis of sphingomyelin to release ceramide, thereby activating the ceramide-dependent protein kinase pathway. As discussed above, this may lead into a number of distinct downstream signaling events including activation of other phospholipid hydrolysis events (phospholipase A₂), the MAPK cascades and the activation of several nuclear signaling molecules, in particular members of the Rel homology group which participate in the formation of NFκBs.

LPS is the prototypic microbial cell wall-derived stimulus and may be among the most potent of stimulatory agents for myeloid cells. Indeed, while a variety of cells exhibit sensitivity to LPS, the mononuclear phagocyte family is clearly the professional cell type for this response. LPS stimulation of macro-

phage activation has been studied intensively for many years and yet understanding of signaling pathways remains limited. In the last 5 years, evidence from many laboratories have implicated serine/threonine- and tyrosine-directed protein phosphorylation events in the response to LPS. Several members of the Src family of nonreceptor-linked PTKs (Lyn, Hck, Fgr) and one or more of the MAPK cascades have been shown to be activated in LPS-stimulated monocyte/macrophages. The contribution of each of these events to particular functional endpoints remains to be fully explored. Although the responses to cytokines such as IFN γ and LPS overlap in many circumstances, there has been no evidence implicating participation of the Janus family of PTKs in response to LPS.

Perspectives – control of protein kinase function

Protein kinases play a major role in cellular activation processes. An important aspect of activation is the need to provide stringent controls which will allow for appropriate enhancement and diminution of function. Protein kinase activities are regulated by interaction with other proteins. Some of these may be protein kinases themselves as occurs during multi-layer protein kinase cascades. Other protein–protein interactions contribute to controlling kinase activity in a second messenger or receptor–ligand interaction dependent manner (e.g. Ca²⁺/calmodulin kinases). A third category involves enzyme activities that directly control the level of target protein phosphorylation. These enzymes are collectively termed protein phosphatases and are the functional antagonists of protein kinases. Frequently, protein phosphatase activities are regulated by the same stimuli which participate in controlling protein kinases activities. Thus protein phosphatases are sensitive to second messenger systems and receptor–ligand interactions.

Finally, subcellular localization is known to be an important determinant of both protein kinase (and phosphatase) activity and specific physiologic function. The impact of kinase or phosphatase activities may be dependent upon their being directed to subcellular regions where appropriate substrates are

localized. Such subcellular distribution may be determined by amino acid sequence motifs present in the kinase protein itself or by other proteins with which kinase activities associate. As the number of individual protein kinase activities expands, understanding the mechanisms through which they are regulated will become an increasingly important area of research interest.

PROTEIN SEPARATION TECHNIQUES

Sue Cresswell, Pharmacia Biosystems Limited, Milton Keynes, UK

Our understanding of the biochemical processes involved in living systems has progressed at an increasingly rapid pace over recent decades. Underlying these developments has been the ability to understand and describe the structural basis of the biological function of biomolecules. The isolation, purification and characterization of these biomolecules, typically proteins, has been crucial to this process.

Separation of a protein is nowadays rarely a major project, but has become a routine requirement for many research programs. The separation must, therefore, be performed smoothly and efficiently to enable the mainstream work to continue. Similarly, we see the need for large-scale protein production from a wide variety of biological sources for subsequent clinical application (e.g. vaccines, antibodies, recombinant proteins). Here, too, the purification must be efficient, cost-effective and safe.

This constant demand on technologies to produce more efficient, easy-to-use and inexpensive techniques for protein separation has produced a fascinating array of media and instrumentation. However, to many workers coming into the area of protein separation for the first time, this selection must seem somewhat daunting rather than fascinating. It is hoped that this brief review will put into perspective the major techniques available and how they interrelate during a protein separation process. It is not intended to include precise technical details, but to outline the basic principles involved and their interrelationships.

Protein structure

Before progressing further, we must remind ourselves of the basic characteristics of all proteins, for it is the variation in these which provides the 'handles' by which we can eventually extract a single protein from a mixture of thousands. All proteins are comprised of amino acids, and it is the precise number, composition and distribution of these amino acids, together with any postsynthetic modifications the protein may undergo (such as glycosylation), which gives each protein its individual features. We can summarize these briefly:

1. *Size*: the molecular weight, which may range from $<10^3$ to $>10^8$ kDa.
2. *Charge*: the net charge at a particular pH is a

function of the individual pK_a values of the amino acids (note that a protein has zero net charge at its isoelectric point, pI).

3. *Hydrophobicity*: most hydrophobic amino acids will be positioned within the structure of the protein, well away from hydrophilic environments. However, some may appear on the protein surface, resulting in hydrophobic 'patches'.
4. *Biospecificity*: specific sites on a protein may interact reversibly with a complementary binding substance or ligand, e.g. the Fc fragment of an antibody reacts reversibly with protein A.

Preliminary considerations

To achieve successful results, the *total* separation problem must be considered from the beginning and, as more information accrues, the procedures in use must be frequently reassessed. The first step is to obtain as much information as possible from the current literature on the protein of interest and, secondly, to define the purpose of the purification. For example: Are large amounts required? What degree of purity is needed? It is then possible to set minimum objectives for the end-product in terms of purity, yield and economy. Decisions can now be made regarding more practical details:

1. *Selection of source*: primary considerations when selecting source material include ease of extraction together with quantity and stability of the protein within the material itself.
2. *Assay development*: throughout the separation, it is essential to determine total protein in the sample using routine assays such as Lowry or Bradford together with assaying for activity of the specific protein. These assays provide constant monitoring of recovery and reveal immediately any sudden loss of activity. This information can be used to modify and improve procedures.
3. *Protein stability*: both investigation of source material and development of an activity assay will yield information on the stability of the target protein. It is vital to be aware at an early stage of any protein sensitivity to temperature, pH, organic solvents, ionic strength, metal ions, inhibitors or contact surfaces; any one of these may result in significant loss of activity and should therefore be taken into account during

development work. Avoidance of protein disruption during initial extraction procedures will be discussed below.

Protein characterization

Size and charge

To determine both the size and charge characteristics of the protein and, indeed, of the contaminating proteins, we must use *electrophoretic separation methods*. Although preparative electrophoresis techniques have been developed, these can be costly, time-consuming and difficult to use on any large-scale purification. The value of electrophoresis lies in its ability to provide highly resolved, analytical separations of complex protein mixtures.

Many electrophoretic media are available; however, polyacrylamide gels are by far the most commonly used for high-resolution protein separations. These gels are easily adjusted, controlled and reproduced, easily stored, and can be scanned if required.

Native polyacrylamide gel electrophoresis (PAGE) is most suitable for studying the composition and structure of native proteins, as both their conformation and biological activity will remain intact during the analysis. However, it is often difficult to find standard proteins which resemble the shape, partial specific volume and degree of hydration of the native protein under investigation. Consequently, SDS-PAGE (sodium dodecyl sulfate) is easier and in most cases more reliable than native PAGE for molecular weight determinations.

In SDS-PAGE, proteins are first treated with SDS under reducing conditions at an elevated temperature. This treatment denatures the proteins, causing them to unfold and assume a rod-like structure coated with SDS molecules. SDS binds to protein in a constant weight ratio and provides a net negative charge. Thus when applied to the polyacrylamide gel in an electric field, all the SDS complexes will migrate at the same rate until the sieving properties of the gel take over. The outcome is a separation based on size. The molecular weight of the proteins can be calculated by comparing their electrophoretic mobility with that of protein standards of known molecular weight.

Isoelectric focusing (IEF) is a high-resolution electrophoretic technique for separating proteins on the basis of their isoelectric points (pI) and, as a consequence, can be used to determine the range of isoelectric points of proteins in a mixture. Homogeneous gels are prepared containing carrier ampholytes, such as Pharmalyte®. Under an electric field, the ampholytes create a stable, linear pH gradient across the gel (the pH range being dependent

upon the ampholytes selected) and proteins will then migrate, essentially unhindered by the gel, to a point in the pH gradient that corresponds to their pI. Markers indicate the pH positions across the gels.

Electrophoretic titration curve analysis is a two-dimensional technique for analyzing protein charge characteristics. In the first dimension, the pH gradient is generated, as in IEF. The gel is then rotated through 90° and the sample applied perpendicular to the pH gradient across the middle of the gel. The proteins become positively or negatively charged, depending on their pI, and will migrate toward the anode or cathode. The rate of their migration will depend on the magnitude of their charge.

From the titration curves, we can predict optimal conditions for further separation by chromatography, in particular ion exchange chromatography as shown in Figure 1. All of these electrophoretic techniques can be run on any horizontal electrophoresis system and it is advisable to use these powerful analytical tools not only for initial sample characterization but also for continual evaluation of all stages of purification. Considerable time and effort can be saved by using precast gels on dedicated equipment, such as PhastSystem™, which enables analyses to be performed in under 30 minutes.

Biospecificity and hydrophobicity

The biospecificity of the protein is likely to be known only if precise details of its activity and structure are known beforehand. The hydrophobicity of the protein is less easily defined. All proteins are, to some extent, hydrophobic, and it is only the difference in their *relative* hydrophobicities which makes selection

Figure 1 Electrophoretic titration curve: typical titration curve analysis showing pH-dependent charge characteristics of a protein. From this analysis, appropriate ion exchange media and buffer pH can be selected for subsequent chromatography.

possible. Addition of increasing salt concentration to a protein mixture to observe at what stage the protein of interest precipitates is the simplest investigative measure, i.e. high salt enhances hydrophobic interaction, in this case precipitation, hence the less salt required to cause precipitation the more hydrophobic is the protein.

Preliminary separation steps

At this stage, the *method of extraction* must be selected. Unless dealing with a secreted protein in cell culture, any extraction from a biological source will require mechanical disruption of cells. This leads to dispersion and dilution of cell contents resulting in release of proteolytic enzymes and general acidification. Appropriate buffer solutions can be used to guard against rapid acidification and addition of sucrose or maltose may help to stabilize lysosomal membranes and hence reduce the release of proteases.

It is advisable to maintain the ionic strength of the medium to aid protein stability. Many other additives can be included at this stage, e.g. protease inhibitors, or EDTA to chelate metal ions which can catalyse oxidation. However, with prior knowledge of the protein stability these can be kept to a minimum as they will inevitably have to be removed at a later stage and may cause unnecessary complications and delay. As a general rule, the preliminary extraction should be performed quickly, at sub-ambient temperatures.

Protein separations

Having acquired the crude extract, we can begin to separate out the protein of interest. To isolate a single component from this complex mixture usually requires a combination of fractionation techniques that can be divided into two categories: differential solubility and chromatography. Most schemes will start with techniques offering high capacity and low resolution, i.e. differential solubility methods. Later on, more highly resolving chromatography methods will dominate.

Differential solubility techniques are used to remove gross impurities, particularly if the protein of interest is less than 1% of the total sample protein. Several of these methods include:

1. *Salt fractionation*: typically using ammonium sulfate precipitation.
2. *Polyethylene glycol*: precipitation complementary to ammonium sulfate.
3. *Protamine sulfate*: very useful for removal of nucleic acids.

4. *Heat treatment*: occasionally beneficial for the isolation of heat-stable proteins.
5. *Isoelectric precipitation*: used as an alternative in some applications.

Chromatographic techniques are the vital part of virtually all preparative purification schemes. When combining different techniques using the 'handles' we have established (size, charge, hydrophobicity and biospecificity), four main parameters need to be considered: resolution, speed, recovery and capacity. They are closely interrelated – an improvement in one may lead to impairment in another. The aim is to achieve a desired balance – determined by the objectives set for the purification.

Resolution becomes increasingly important throughout the separation. Methods need to be more selective as the quantity of sample material is reduced. *Speed* and resolution are inversely related. An increase in speed above recommended specifications will decrease resolution. *Recovery* can only be maximized by using a minimal number of steps, and recovery of biological activity can only be achieved by maintaining a biocompatible environment throughout the separation. *Capacity* of a technique refers to the sample size (both in terms of mass and volume) that can be handled. This can have considerable significance in considering both the speed and cost of a separation procedure.

To achieve good resolution, recovery and speed (regardless of which chromatographic principle is being applied), it is essential that all matrices should be hydrophilic, inert, physically and chemically stable and provide reproducible results. Particularly for adsorptive techniques, the matrix must be porous and highly substituted with the chosen group, to give high capacity over a large molecular weight range. As a general rule, smaller bead size and narrower bead size distributions produce faster and more highly resolved results. However, these advantages may be compromised by decreasing capacity of the matrix, increasing cost due to more complex production, and, if bead sizes are sufficiently small, more sophisticated equipment is required to work against the back pressures created when the beads are packed in a column. In protein chromatography, all low-pressure *standard* chromatography media can be run using peristaltic pumps. The very fast, high-resolution matrices such as Superose or MonoBeads must be run on an FPLC[®] system specifically designed to pump against the medium pressure they create. All standard media can also be run on an FPLC system, frequently with advantage, as this system produces highly accurate and controllable gradient elution conditions.

With these considerations in mind, we can now review the chromatographic techniques available, their basic principle of action, and media selection.

Gel filtration separates proteins according to molecular weight (size). The basic principle is simple: as solute molecules pass through the column of gel filtration media, the smaller molecules are retarded to a greater degree than the larger ones. Sample components are thus eluted in order of decreasing molecular weight. Fractionation range is important when considering gel filtration gels. A suitable range must cover the molecular sizes of interest in the sample to be fractionated.

The gel medium most widely used is Sephadex[®], a cross-linked dextran polymer developed some 30 years ago. Sephadex G-25 is still the medium of choice when desalting is required, i.e. group separation by gel filtration. Here samples up to 30% of the total column volume can be rapidly desalted and/or buffer exchanged. However, since the first release of Sephadex, experimentation and production has continued resulting in improved media such as Sephacryl[®] High Resolution (HR), Superdex[®] and Superose[®]. These provide high resolution and high flow rates coupled with chemical stability, making them far easier to use than the original Sephadex matrix.

The main advantages of gel filtration are that it is a mild technique, predictable and simple. However, it is relatively slow and poorly resolving compared to alternative methods; more importantly, it has a very low capacity (maximum sample volume = 5% of column volume for optimum resolution) and the sample is always diluted after separation. Consequently, it is best used as a 'polishing' step at the end of a strategy when handling small sample volumes.

Ion exchange chromatography (IEX) separates proteins according to differences in their charge. It is based on the reversible interaction between a charged protein and an oppositely charged matrix. Consequently, a mixture of proteins can be bound to a gel and subsequently eluted differentially by a change of conditions, typically by altering salt concentrations or pH.

These changes may be made in a stepwise fashion, for example, if using older Sephadex (DEAE, CM, SP, QAE) or Sephacel DEAE media. However, far better resolution can be obtained from the modern media, particularly if gradient elutions are performed. Again, there has been continual improvement of IEX media culminating in the use of modified polymers (such as Sepharose Fast Flow, Sepharose High Performance and Monobeads[®]), providing more porous matrices than dextran and consequently giving higher capacity for binding techniques, higher flow rates and good chemical stability. The selection

of the charge group on these matrices is important. QAE and SP will maintain their full charge over a wide pH range, whereas DEAE and CM must be used within specified ranges. The latter can, however, offer high throughput and slightly changed selectivity which may be advantageous.

IEX is a powerful technique. It effectively concentrates the sample (as do all adsorptive techniques) and provides excellent resolution, capacity and yield. With knowledge of the protein characteristics, it is also highly predictable. It is ideal for use at an early stage in a strategy.

Chromatofocusing is a technique which separates proteins according to differences in their pI. This is achieved by passing the protein sample through a linear pH gradient formed automatically by simultaneous passage of a specific elution buffer (Polybuffer[®]) through a weak ion exchange matrix (Polybuffer exchanger or high-resolution Mono P[®]).

Chromatofocusing can be extremely highly resolving, and is therefore ideal, for example, in separating isoenzymes with differences of less than 0.05 pH units in pI. It is also very simple to perform as the gradient is self-generating, and hence no special equipment is required. As in ion exchange, prior knowledge of protein characteristics ensures predictable results and samples will be concentrated during the separation. It should be noted, however, that this is not a high-capacity technique and, as with gel filtration, is far better used at the final purification stages once all major contaminants have been removed.

Hydrophobic interaction chromatography (HIC) separates proteins on the basis of their differing strengths of interaction with a matrix bearing hydrophobic groups. To enhance these hydrophobic interactions, protein samples are loaded in high concentrations of salt, such as ammonium sulfate or sodium chloride. The unbound proteins are washed away and the adsorbed proteins differentially desorbed by elution with a decreasing salt gradient, thus separating individual protein species. As with ion exchange, stepwise elutions can be performed if comparatively low resolution is sufficient. Sepharose CL-4B, Sepharose High Performance or Superose are used as matrices to which a hydrophobic group is attached. A phenyl substituted matrix is usually the medium of choice for samples where the hydrophobic characteristics have not been established, as, in this uncertain situation, selection of a strongly hydrophobic gel could result in irreversible binding of the protein of interest. If, however, the protein fails to bind or elutes too early, Octyl Sepharose CL-4B may be used. This gel is particularly useful for membrane

proteins as it can be used in the presence of the solubilizing detergents often required.

The use of HIC is particularly suitable after a salt precipitation or after an IEX step as, in both instances, samples are already in higher salt concentrations. It is also complementary to gel filtration as it will have concentrated the sample and the filtration step will remove excess salt.

Reverse phase chromatography (RPC) also separates proteins on the basis of their differing strengths of interaction with a hydrophobic matrix. However, the nature of these matrices, usually silica or polymer-based substituted with carbon chains (most often C-8 or C-18), produces an interaction with proteins which is so strong that subsequent elution requires the use of organic solvents, such as methanol or acetonitrile. In most instances, this will destroy the biological activity of the protein. It should also be noted that all reverse phase media must be run on medium- or high-pressure equipment (FPLC or HPLC, respectively).

If retention of biological activity is not a requirement of the purification, then RPC, although a very low-capacity technique, is ideal for high-resolution analysis, or as a final polishing step in a strategy. It is ideal for separation and analysis of peptides and amino acids, as these are unlikely to be damaged by exposure to the harsh elution conditions used.

Affinity chromatography is a highly resolving technique in which the molecule to be purified is specifically and reversibly adsorbed by a complementary binding substance (ligand) immobilized on an insoluble matrix. Protein mixtures are loaded under conditions favoring the binding reaction, unbound proteins are washed away, and conditions altered to elute the protein of interest. Again this is a simple technique requiring no gradient formation and with a high capacity. Its high selectivity results in excellent separations and concentration of the sample. Porous agarose media such as Sepharose 4B, Sepharose CL-6B, Sepharose Fast Flow or Superose are used as matrices and are provided linked to a specific ligand (e.g. protein A or protein G for antibody separation) or as coupling gels where the required ligand can be easily attached, e.g. CNBr Activated Sepharose or NHS Activated Superose. When used with detailed prior knowledge of the interaction, the technique is predictable and fast. However, in some cases, harsh conditions may be required to elute the protein and cause damage to the protein itself (e.g. low pH); this must be carefully monitored. Difficulties in using affinity chromatography may arise when isolating a specific ligand as this in itself may be costly and time consuming. This effort may be worthwhile to establish such a powerful step in the overall strategy.

To summarize, if when we consider that the main contaminant in any protein solution is in fact water, then we need to bear in mind whether our chosen technique has a concentrating or diluting effect on the sample, as dilution in particular could cause later handling problems. Therefore, the order of chromatographic steps will, in most instances, be: 1) the use of adsorptive techniques (i.e. IEX, HIC, affinity) in the initial stage where the aim is concentration and group separation; 2) further adsorptive techniques such as IEX or HIC at an intermediate stage with the aim of high-resolution separation; and 3) the use of gel filtration, if required, as a final polishing step. For general examples, see Figure 2.

Conclusions

The purification of most proteins should be a relatively straightforward procedure, using both electrophoresis and chromatography to enable protein characteristics to be defined and a logical strategy

Figure 2 Examples of purification strategies. * Major concentration steps; GF, gel filtration; IEX, ion exchange; HIC, hydrophobic interaction; RPC, reverse phase chromatography.

developed. It must be stressed that both media and instrumentation are continually being improved. Consequently, considerable time and effort can be saved by an understanding of the basic principles involved, and by analyzing any established protocol and looking for possible improvements. For example, a lengthy dialysis may be avoided by using the faster desalting method of gel filtration, and using an improved matrix may reduce a separation fivefold or more.

When problems do arise, it should always be remembered that no matter what the media or the protein extract, the basic principles governing the behavior and interaction of proteins between themselves and with other media remain the same.

PROTEUS, INFECTION AND IMMUNITY

Susan R Heimer and Harry LT Mobley, Division of Infectious Diseases, University of Maryland School of Medicine, Baltimore, Maryland, USA

Proteus mirabilis and *P. vulgaris* are motile, urease-positive, lactose-negative, indole-negative, gram-negative rod-shaped bacterial species of the family Enterobacteriaceae. They deaminate phenylalanine and produce abundant hydrogen sulfide. These species, which can differentiate from short vegetative cells to elongated, highly flagellated forms, are found in soil, water and the human intestinal tract. *P. mirabilis* is probably most familiar to clinical microbiologists who frequently observe agar plates on which this organism overtakes the entire surface as a result of swarming differentiation (Figure 1). *Proteus* was aptly named by Hauser in 1885 for the character in Homer's *Odyssey* who 'has the power of assuming different shapes to escape being questioned'.

Infections

Among the urease-positive genera of the Enterobacteriaceae, *P. mirabilis* is the most frequent agent of human infection. It is primarily associated with urinary tract infections (UTIs) and nosocomial infections (Figure 2). *P. mirabilis* causes approximately 5% of uncomplicated UTIs; *Escherichia coli* is the most prevalent pathogen identified in these cases. UTIs in patients with functional or anatomical defects in the

Figure 1 *P. mirabilis* morphology and swarming on Agar. Short swimmer cells, when plated on an agar surface differentiate into elongated, multinuclear heavily flagellated swarmer cells (up to 80 µm long). Swarmer cells associate with one another and spread away from the point of inoculation. After several hours, swarmer cells consolidate into numerous swimmer cells thus completing the cycle. Alternating cycles of differentiation and consolidation result in a bull's-eye pattern of swarming on an agar plate.

Figure 2 Percent of UTI caused by *P. mirabilis*. In specific studies with selected patient populations, the number of specimens for which *P. mirabilis* was cultured per total number of specimens is shown. Actual data are: acute cystitis, 4/136, 3%; hospital UTI-men and women, X/25371 (numerator not provided), 5%; recurrent UTI-women, 29/518, 6%; recurrent UTI-men, 16/262, 6%; complicated UTI, 12/137, 9%; intermittent catheterization 7/48, 15%; condom catheter, 5/20, 3%; ileal loop 11/34, 33%; and long term urethral catheter 512/1158, 44%.

urinary tract as well as immunosuppressed individuals are considered to be complicated. *P. mirabilis* infections account for nearly 10% of these UTIs. In one study, this pathogen was found at $>10^5$ colony-forming units (CFU) ml⁻¹ in approximately 44% of patients with urinary tracts complicated by long-term instrumentation such as catheterization. Clinical syndromes correlated with *P. mirabilis* infections of the urinary tract include urolithiasis, cystitis, acute pyelonephritis and asymptomatic bacteriuria. Characteristics of cystitis are frequent and urgent urination, dysuria and suprapubic pain. Acute pyelonephritis is often accompanied by fever, flank pain, sweats, nausea, vomiting and malaise. Asymptomatic bacteriuria is usually identified by two consecutive urine cultures with $\geq 10^5$ organisms ml⁻¹.

Immunity

Most of our understanding of host immunity to *P. mirabilis* has been extrapolated from rodent models of ascending UTIs and from rheumatoid arthritis (RA) patients. Sera collected from mice transurethra-ly challenged with *P. mirabilis* have been shown to react *in vitro* with purified lipopolysaccharide, flagella, outer membrane protein (OMP) and man-nose-resistant *Proteus*-like (MR/P) fimbriae. Partial immunity has also been observed following vac-cination in mice. In one study, animals were preim-munized with *P. mirabilis* and cleared using ampicil-lin. After one week of a secondary challenge *P. mirabilis* colonization in the bladder and kidney was significantly decreased compared with an unvac-cinated group. Intramuscular injections of purified OMP has also been demonstrated to protect mice from *P. mirabilis* renal infection.

Serum from patients with active RA also react with *P. mirabilis*. The immunogenic response may be due to a hexamer peptide within hemolysin which has a high degree of similarity to the susceptibility

sequences of HLA-DR1 and DR4. Future research is aimed at determining whether the production of antibodies against *P. mirabilis* hemolysin stimulates the autoimmune response observed in RA patients.

Virulence factors

A number of specific proteins encoded by chromo-somal genes have been implicated as virulence factors that allow *P. mirabilis* to colonize its host, evade host defenses, and cause damage to the host (Figure 3). The production of one of these proteins, urease, is a hallmark of *Proteus* infection. This enzyme, which catalyzes the hydrolysis of urea to carbon dioxide and ammonia, elevates urine pH to a level where normally soluble ions precipitate to form struvite or apatite stones. These stones, which form around the bacterium itself, can grow to a size that obstructs normal urine flow or prevents normal kidney func-tion. The gene cluster encoding urease is comprised of eight genes, ureRDABCEFG. UreR encodes a tran-scriptional activator that induces transcription of urease genes in the presence of urea; ureABC encode the structural subunits of the enzyme itself; ureDEFG encode accessory proteins that are responsible for inserting nickel ions into the active site of the urease metalloenzyme. Mutations in the urease genes of *P. mirabilis* attenuate the organism; the ability of the urease-deficient *P. mirabilis* to colonize the urinary tract in an experimental mouse model of ascending UTI is much diminished. In addition to reduced his-tological damage, the formation of kidney and blad-der stones is never observed for this mutant.

P. mirabilis also produces an Hpm hemolysin. This high molecular weight protein is secreted by the bac-terium, resulting in lysis of erythrocytes or mem-brane damage to other cultured epithelial cells. The *in vitro* effect of the hemolysin secretion is quite dra-matic. Cytotoxicity is observed within an hour of exposure of the cultured epithelial cells to hemolysin.

Figure 3 Virulence factors of *P. mirabilis*. Proteins produced by this species that have either been demonstrated or proposed to contribute to virulence are depicted. Mutants in urease, flagella, hemolysin, MR/P fimbriae, and PMF fimbriae have been constructed and tested in a mouse model of UTI. Of these factors, urease, flagella, and MR/P fimbriae appear to contribute most significantly to virulence. Abbreviations: MR/P, mannose resistant/*Proteus*-like; PMF, *Proteus mirabilis* fimbriae; ATF, ambient temperature fimbriae; NAF, non-agglutinating fimbriae (also called uroepithelial cell adhesin).

The *in vivo* effects of hemolysin are less well understood. Mutations in the hemolysin structural gene (*hpmA*) do not appear to significantly attenuate the organism in the experimental mouse model of UTI. Its cytotoxic effect may be more subtle *in vivo* and cannot yet be defined as an important virulence determinant.

P. mirabilis also produces at least four kinds of fimbriae, proteinaceous surface appendages that may play a role in adherence. Fimbrial types thus far identified for *P. mirabilis* include the MR/P fimbria, *P. mirabilis* fimbria (PMF), ambient temperature fimbria (ATF), and uroepithelial cell adhesin (also called nonagglutinating fimbria, NAF). MR/P fimbria, which has received the most attention, causes agglutination of mammalian and avian erythrocytes. Mutation of the MR/P genes result in loss of fimbrial production and inability to agglutinate erythrocytes. In addition, there is a slight, but significant diminishment of virulence of the organism. Numbers of bacteria recovered from infected mice drop about ten-fold in MR/P mutants. As a result, less histological damage is observed in the infected animals.

The organism also secretes an immunoglobulin A (IgA)-degrading protease and an amino acid deaminase which converts amino acids to keto acids. These keto acids are able to complex iron, and thus, may act as an iron-acquisition system for the bacterium. The contribution to virulence of the deaminase has not been determined due to the lethality of introducing this mutation into *P. mirabilis*.

Finally, *P. mirabilis* produces flagella for motility. In broth cultures, the organism produces polar flagella; on solid agar cultures, the organism converts into an elongated 'swarming cell' which produces thousands of flagella (Figure 1). Mutation of flagella genes that inactivate flagella synthesis significantly diminishes the virulence of the organism in a fashion similar to the mutation in urease. Thus, flagellum-mediated motility appears to be a critical virulence determinant for this organism.

Model for pathogenesis

From data accumulated from virulence studies, we are able to establish a model of pathogenesis for *P. mirabilis*, a virulent uropathogenic organism. *P. mirabilis*, which establishes itself around the periurethral area, can colonize the bladder epithelium via PMF fimbriae, which may bind to receptors on the bladder epithelium. We postulate that once established, highly flagellated differentiated swarmer cells ascend the ureters to the kidney. MR/P fimbria can then bind to the renal epithelium. Bacteria that are established in the kidney can hydrolyze urea, raising the local pH and cause precipitation of saturated polyvalent cations and anions to form kidney and bladder stones (struvite and apatite stones). Epithelial cell necrosis has been observed during this stage of infection. Hemolysin, a potent cytotoxin *in vitro*, may be involved once the organism has reached the kidney parenchyma. Bacteria may also invade or be internalized by renal tubule epithelial cells causing further damage, which may, in turn, allow the organism to breach this thin barrier and occasionally enter the bloodstream.

PSEUDOMONAS AERUGINOSA: INFECTION AND IMMUNITY

Robert EW Hancock, Department of Microbiology and Immunology, University of British Columbia, Vancouver, Canada

Joseph S Lam, Department of Microbiology, University of Guelph, Guelph, Ontario, Canada

Pseudomonas aeruginosa is a major cause of infections in Western society, being the causative agent of about 200 000 nosocomial infections per year in North America. Such infections tend to be rapidly progressing and pose serious risks to patients. However, *P. aeruginosa* can also cause long-term (up to 10 years or more) chronic infections in the lungs of patients with cystic fibrosis, and the onset of *P. aeruginosa* infection signals the eventual deterioration of lung function in such patients, leading to death from respiratory failure. *P. aeruginosa* shows high intrinsic antibiotic resistance. While there are antibiotics that show initial success against *Pseudomonas* infections, even modest mutations lead to clinically significant resistance, making development of antibiotic resistance common and successful treatment difficult. For this reason considerable effort has been expended in seeking vaccine or immunotherapeutic solutions to such infections. At the same time, diagnosis and epidemiology, each of which use specific antigens, has become important in monitoring the

onset and course of infection and can influence the eventual success of therapy.

Process of infection

P. aeruginosa causes rapidly progressing infections in animals and humans. Generally speaking, these infections only occur in those animals and people which have a reduced capacity to defend against infection (or at body sites that have intrinsically weaker defenses). Thus, in animal models, mild alcohol burns or neutropenia induced by cyclophosphamide lead to a reduction in the LD₅₀ (the concentration of bacteria that kill 50% of animals) by up to 100 000-fold. Similarly, the types of human conditions which tend to predispose towards *P. aeruginosa* infections include neutropenia induced by anticancer drugs, burns, major surgery, steroid therapy, etc. In such patients the likelihood of *P. aeruginosa* infection increases with length of hospital stay.

P. aeruginosa produces a multitude of virulence

Table 1 Immunogenicity and antibody response to major antigens of *Pseudomonas aeruginosa*

Antigen	Characteristics/function	Specific antibodies/use	Immunogenicity
<i>Cell associated:</i>			
Outer membrane protein OprF	Major pore-forming protein; structural role	Opsonic and protective; mAbs used in structural studies, diagnostics; antigenically conserved	Strong Ab response
OprL (= H2)	Peptidoglycan-associated lipoprotein (PAL); structural role	mAb reveals conserved antigen in type I Pseudomonadaceae	Strong Ab response
OprI	Braun lipoprotein	Protective; mAbs reveal antigenic conservation	Strong Ab response
Iron-regulated outer membrane proteins	Transport of iron-siderophore complexes		Ab response accompanies chronic infection
Variant lipopolysaccharide (LPS) A-band (D-rhamnan)	Common antigen, induces influx of PMN	Not neutralizing or opsonic	Ab response appears late in patients with chronic infections
LPS B-band (O antigen of LPS)	O-polysaccharide of conventional LPS; forms the basis for serotype-specificity	Serotype-specifically opsonic and protective; mAb/polyclonals against each serotype produced; useful in serotyping and epidemiology	Strong Ab response
LPS core polysaccharide	Conserved region which links O antigen polymers to lipid A	Cross-reactive; inner core epitope exposed on cell surface	Strong Ab response
LPS lipid A	Anchors LPS in the outer membrane; endotoxic moiety – causes fever and septic shock	Ab broadly cross-reactive even with other species; reacts poorly with intact cells	Weak immunogen, includes <i>P. aeruginosa</i> -specific response
Mucoid exopolysaccharide/alginate	Exopolysaccharide in the form of loose slime; associated with biofilm/microcolony formation	Both conserved and selective Abs available	Weak unless conjugated to protein
Flagella	Motility; chemotaxis and invasion	Two major serogroups (type a with 4 subgroups and type b); opsonic; inhibit motility; protective; mAbs available	Strong Ab response
Pili	Adherence and initial colonization	About 14 types; antigenically variable; Neutralizing and passively protective; many mAbs available	Weak to intermediate Ab response
Ribosomes	Protein synthesis	Protective property not confirmed; may be due to contamination	
<i>Extracellular proteins:</i>			
Elastase	Degrades connective tissues. Tissue invasion		Observed in chronic infections
Exotoxin A	Inhibition of host cell protein synthesis	Cross-reactive neutralizing activity	Strong Ab response
Exoenzyme S	Inhibition of host cell protein synthesis	Neutralizing activity	

factors including the extracellular toxins exotoxin A and exoenzyme S, a periplasmic cytotoxin, two secreted proteases elastase and alkaline protease, secreted lipase, phospholipase and heat-stable hemo-

lysin (also called rhamnolipid), a neurominidase, slime glycolipoprotein, mucoid exopolysaccharide, and endotoxin. Each of these has been shown in animal models to have a role in pathogenesis, making

Pseudomonas pathogenesis truly multideterminant, and in many cases in those same animal models, immune intervention directed against the virulence factor in question will reduce the impact of, or even prevent infection. In rapidly progressing infections, which can be common in nosocomial situations, perhaps the most important characteristic of *P. aeruginosa* is its ability to grow rapidly *in vivo*, with a doubling time equivalent to that observed on a nutrient medium *in vitro*. Thus in a relatively short time (24–36 h) such infections can become overwhelming.

In the more complex situation posed by the chronic infections observed with cystic fibrosis patients, it is still not entirely clear why this disease predisposes a patient towards a long-term, localized lung infection by a bacterium which normally causes rapidly developing invasive infections. The suggestion is that localized defects lead to establishment of infection. One newer concept is that the high salt concentration induced by the mutation of the cystic fibrosis transmembrane regulator (CFTR) protein, renders ineffective the natural antimicrobial defense peptides in the lung.

Antigenicity

As indicated in Table 1, there are a wide range of antigens that have been studied in detail in *P. aeruginosa*. Specific antisera and in many cases monoclonal

antibodies (mAbs) have been raised against these (and other) antigens and have been useful in demonstrating the varied levels of serological conservation in these antigens. Thus, there are 20 lipopolysaccharide (LPS) O-serotypes, about 14 pilin antigenic variants and about five flagellin variants (representative of two major serotypes) in *P. aeruginosa*. This makes these antigens ideal as targets for epidemiological studies. On the other hand, the outer membrane proteins OprF, OprL and OprI, LPS rough core and lipid A, exoantigens and mucosal exopolysaccharide have only one or two variant antigenic types. Such antigens therefore have substantial potential as targets for diagnosing *P. aeruginosa* infections and most of these are or have been considered as vaccines. The mAbs raised against *P. aeruginosa* antigens have also proven to be excellent tools for studying these antigens and have assisted in the study of the structure, function, molecular genetics and immunology of these proteins.

Immunogenicity and immunotherapy

All of the antigens listed in Table 1 have been shown to elicit antibodies in animal models, cystic fibrosis patients with *P. aeruginosa*-infected lungs, and/or humans with burn wound infections. This has provided the rationale for pursuit of vaccine and passive immunotherapy studies (Table 2). In many cases,

Table 2 Recent immunotherapeutic or immunoprophylactic preparations against *Pseudomonas aeruginosa*

Vaccine	Efficacy assessment and other remarks
Octavalent LPS	Engendered IgG response that was protective. However human intravenous immunoglobulins versus this vaccine did not show statistically significant protection in human trials
O-polysaccharide–toxin	
A conjugate vaccine	Serum antibodies from rabbits were opsonic and promoted killing of <i>Pseudomonas aeruginosa</i> , and had neutralizing activities towards toxin A
Alginate–toxin A conjugate vaccine	Induced LPS-specific response in mice
Anti-idiotypic antibodies	Significant antibody titers in human volunteers after immunization; protective in immunosuppressed mouse model study
OprF–OprI hybrid vaccine	
Alginate vaccine	Different sizes of alginate in preparation had variable effect in eliciting opsonic antibody response; large molecular size antigen preparation was tolerated well in volunteers; human trials apparently abandoned
Synthetic peptides of OprF epitopes	Linear B cell epitopes of OprF-conjugated with carrier protein as vaccine. Elicited protective response
ScFv of OprF-specific antibody	Modern technology; single-chain antibody specific against an OprF domain. Applicable for epitope mapping and further antibody engineering
Killed whole bacteria delivered mucosally	Demonstrated heterologous protection in mice
Pilin peptides	Limited cross-reactivity observed but attempts are being made to improve this by peptide engineering; protective in mice
Human mAbs	Five serotype-specific anti-LPS O-antigen human mAbs were opsonophagocytic and protective in mice; three flagella specific human mAbs were protective in mice
Human–Murine heterohybridomas	Human antibody specific against <i>Pseudomonas aeruginosa</i> , scale-up production successful, but efficacy is not defined at present

injection of the antigen into animals leads to a sufficient production of antibodies that promote opsonophagocytosis and protection against subsequent infections. Since *P. aeruginosa* is generally considered to be an extracellular infection, there is a general consensus that an antibody response is required for protection. However, this is not necessarily sufficient for protection since the lungs of patients with cystic fibrosis continue to remain chronically colonized despite exuberant serum antibody responses to several antigens. Furthermore, there are few circumstances in which *P. aeruginosa* infections are truly predictable, making active vaccination a less attractive prospect. For this reason passive protections with hyperimmune intravenous immunoglobulins from volunteers immunized with a *Pseudomonas* antigen has been pursued. Unfortunately, the most recent of these studies using an intravenous immunoglobulin with strong titers to the most predominant LPS serotypes and to exotoxin A, was abandoned due to its inability to show statistically significant protection in humans at the dosage used combined with a less favorable adverse reaction profile. While it is too early to discard the possibility for success with one of the other vaccine strategies being pursued, it may require a novel approach to yield success.

The laboratory rabbit (*Oryctolagus cuniculus*) belongs to the order Lagomorpha and the family Leporidae. A recent analysis has shown that the order Lagomorpha is phylogenetically more closely related to Primates and Scandentia than to Rodentia. The family Leporidae includes the genera *Sylvilagus* and *Lepus* which contain cottontails and jackrabbits, some of which may be confused with the true rabbit. *O. cuniculus* existed in antiquity only at the borders of the Mediterranean and was probably first domesticated by the Phoenicians. Today feral rabbits exist in widespread locations including Australia and South America.

The rabbit was prominent in early studies of immunology and basic questions about immunoglobulin genetics, including the phenomenon of allelic exclusion and the inheritance of idiotypes, were first answered with this species. Although it is obvious that the rabbit cannot replace the mouse in investigations requiring numerous genetically identical animals there is a niche for an animal of this size in biomedical research, and there are good reasons to consider the rabbit for certain studies.

The rabbit was used for a number of studies in transplantation and histocompatibility. Disease models for rheumatoid arthritis, myasthenia gravis, atherosclerosis, syphilis, herpesvirus infection, adult T cell leukemia-lymphoma (ATLL), and human immunodeficiency virus (HIV) infection have been reported in this species.

In rabbits, arthritis can be induced by injecting a soluble antigen into the synovium of immune animals. This antigen-induced arthritis is similar to rheumatoid arthritis histologically and in its immune pathogenesis. Another autoimmune disease, myasthenia gravis, can be induced in the rabbit by immunization with nicotinic acetylcholine receptor. The immunized rabbits develop clinical signs of muscle weakness as do humans with the disease.

Experimental models for atherosclerosis involve the use of rabbits fed a high cholesterol diet or the Watanabe heritable hyperlipidemic (WHHL) rabbit.

The WHHL rabbit has a heritable defect in the LDL receptor gene resulting in the production of a non-functional protein.

Syphilis can be experimentally induced by infection with *Treponema pallidum*. In many small animal models of syphilis the disease follows the course of the natural disease in humans. In rabbits the infection persists and viable *T. pallidum* can be readily isolated for the life of the animal.

The rabbit is widely used as a model for human T lymphotropic virus type I (HTLV-I) infection. In the rabbit, infection has been transmitted via blood transfusion and orally through mother's milk with transmission rates similar to those found for humans. While most infected rabbits remain free of overt signs of disease, inoculation with an HTLV-I-transformed cell line (RH/K34) resulted in ATLL-like disease manifested in lymphomas, lymphocyte infiltration of the viscera and thymic atrophy. In one rabbit similarly infected, a skin disease with symptoms associated with human cutaneous lymphoma was reported. The current availability of infectious molecular clones of HTLV-I derived from rabbit cell lines will further the development of the rabbit as a model for HTLV-I infection.

The use of the rabbit as a model for HIV-1 infection has been hampered by lack of consistent signs of disease in infected animals. HIV-1 can be detected in certain tissues from infected rabbits and CD4 lymphocytopenia has been reported in rabbits transfused with HIV-1-infected blood. In addition, the function of tat, rev and the long terminal repeats of the virus has been demonstrated in rabbit cells. Rabbits transgenic for the human CD4 gene have been described and their efficacy as a model for HIV infection is being evaluated.

Rabbits have been used in studies of gene therapy for diseases such as atherosclerosis and hemophilia. Genes can be delivered to the rabbit via adenovirus or retroviral vectors.

Basic biology of the rabbit immune system

The rabbit immune system is comparatively similar to the human system with only minor differences in tissue and cellular organization. The rabbit gut-associated lymphoid tissue (GALT) is organized into a prominent appendix, obvious Peyer's patches and some diffuse lymphatic nodules. The human appendix is vestigial and has more diffuse lymphatic nodules. The GALT, as well as other peripheral tissues of the rabbit and human, are innervated with a well-developed lymphatic system of nodes and ducts. Also, similar to human, the rabbit has a prominent spleen and a thymus which atrophies in adulthood. Lymphopoiesis begins in the rabbit's bone marrow, and as the cells mature they populate the appropriate tissues and organs. Rabbit leukocytes are categorically similar to those in other mammalian reticulo-endothelial systems. The composition of lymphoid cell populations and circulation pathways in the normal dynamic nature of the immune system are also similar, an observation which accents the relevance of studying immunology in the rabbit.

Cytokines described in rabbits include migration inhibition factor (MIF) (which was first identified in the rabbit), chemotactic factor, migration stimulation factor (MSF), interleukin 1 (IL-1), IL-2 and tumor necrosis factor α (TNF α). It is interesting that both native and recombinant human IL-2 are effective at stimulating rabbit T cell proliferation, whereas rodent IL-2 is not.

Rabbit immunoglobulins

The complement of immunoglobulin (Ig) genes in the rabbit includes IgM, and IgE and is unusual in having only one IgG gene and 13 IgA genes; no IgD gene has been reported. A major distinguishing feature of the rabbit Ig family is the magnitude of structural differences between allelically determined immunoglobulin molecules. Several groups of allotypes have been described for the rabbit: the most important are the group *a* on the V_H region (*a*1, *a*2 and *a*3), groups *d* and *e* in the hinge region (*d*11, *d*12) and the C_{H2} portion (*e*14, *e*15) of the γ chain, and the group *b* on the constant part of the κ light (L) chains (*b*4, *b*5, *b*6 and *b*9). It should be pointed out that by extending the study of allotypes to include feral rabbits the number of alleles increases dramatically. This demonstrates that the domesticated pool represents only a fraction of the genetic diversity of the rabbit population.

The group *a* and *b* allotypes are distinguished by large differences in primary structure that charac-

terize the allelic forms. There is as much as 20% difference in amino acid sequence between two alleles of the *b* types and these differences reflect the strong serologic reactivity of the alloantisera used to detect them.

The κ/λ ratio is about 95/5, but this may vary (based on the allotype of the κ chain) with observations of λ chain as high as 15% in rabbits with certain *b* allotypes.

Molecular studies of the κ locus have indicated that there are two C_κ genes in the rabbit and that six of the seven J region genes of the *b*4 and the *b*5 types are not functional. Most of the κ light chains in the rabbit result from rearrangement of the C_κ 1 gene. Light chains derived from the C_κ 1 gene are of the K1 isotype, the five allelic forms of the K1 isotype determine the group *b* allotypes described above. The K2 isotype is encoded by the C_κ 2 gene and is expressed infrequently. There are six to seven λ chain constant region genes but expression seems to be restricted to only the C_λ 5 and C_λ 6 genes.

Antibody diversity in the rabbit is generated by somatic gene conversion. Rabbits have many germ-line V_H genes but only one is productively rearranged in most B lymphocytes. These V_H genes are members of one large V_H gene family and can function as donors in gene conversion. It has also been shown that all B lymphocytes in the rabbit are CD5⁺ and thus may be self-renewing with little or no B lymphopoiesis occurring in mature rabbits.

The major histocompatibility complex (MHC) genes

Studies at the molecular level have identified a number of genes of the class I and II type for the rabbit. The class I gene family consists of 8–14 members depending on the haplotype. Early analysis of protein products from spleen and transformed cell lines indicated that expression of the class I genes is limited to one or two molecular species. However, when class I RNA was studied, at least four transcripts were found indicating that more genes are expressed at the nucleic acid level. A comparative study of the primary structure of the class I genes reveals strong homology to human, porcine and murine genes. The similarity found with human genes is striking, with the exon 4 sequence of rabbit being over 90% identical to that of human class I; in contrast, it is only 75% similar to that of mouse.

The class II genes are likewise very similar to those of humans with homologs of the class II HLA-DR, -DQ, -DP α and β genes as well as DO β and -DZ (or DN) α described for the rabbit. Expression patterns of class II antigens follow the expected pattern

with high levels in lymphoid tissue and liver and low levels in brain and skeletal muscle.

Molecular genetic typing has defined 13 distinct haplotypes which resulted from combinations of 11 RLA-A (class I) and 10 RLA-D (class II) subregions. Among class II genes, DQ α showed the highest level of polymorphism; 9 of 10 D regions could be distinguished by DQ hybridization. Several haplotypes were found to be identical with respect to either class I or class II genes, suggesting that class I genes are clustered in the A subregion and class II genes in the D subregion, and that these haplotypes have resulted from recombinations between the A and D subregions. Unlike the murine MHC where class I gene clusters are localized on both sides of the H-21 subregion, the rabbit, like humans, appears to have discrete class I and class II regions. Results of random typing of colonies at the National Institutes of Health (NIH) and the Institut Pasteur suggest that there are only a limited number of molecularly defined haplotypes in addition to the 13 found in the recent survey.

T cell receptor (TCR)

Although there are no reported studies at the level of protein structure, molecular cloning of rabbit TCR α genes has been carried out using libraries prepared from thymus and from a transformed T cell line. Eleven rabbit V β genes have been cloned and have been assigned to nine V β families (family members have $\geq 75\%$ nucleotide sequence identity).

Approximately 25% of circulating peripheral blood mononuclear cells (PBMCs) in the adult rabbit express TCRs of the $\gamma\delta$ type. This is relatively high compared with TCR $\gamma\delta$ expression in humans and mice and is similar to levels seen in ruminants.

Genes for rabbit C γ , C δ , V γ and V δ have been cloned and sequenced. The deduced amino acid sequence of the rabbit TCR C γ gene shows 60% identity to the human C γ 1 gene. It was also shown that all rabbit TCR γ transcripts utilize this constant region gene and no rabbit homolog of the human C γ 2 gene has been detected. The deduced amino acid sequence of the rabbit TCR δ gene also showed 60% similarity to the human TCR δ gene.

Cell lines

Until recent years very few rabbit cell lines existed. Two of the most well known are RK-13, a rabbit kidney line, and SIRC, a rabbit corneal line; both are used in viral infectivity studies. Herpesvirus, SV40 and HTLV-I have been used to derive lines of lymphoid origin (Table 1). The derivation of rabbit T cell lines using HTLV-I as a transforming agent has become routine. There are numerous cell lines in

Table 1 Rabbit lymphoid cell lines

Line	Transforming agent	Cell type
RL-5	Herpesvirus ateles	T cell
MF/120	Sheep-associated malignant catarrhal fever virus	NK cell
Ra1-Ra5	HTLV-I	T cells

RH/K30	HTLV-I	T cell
RH/K34	HTLV-I	T cell
KSH-5a	HTLV-I	T cell
BJ-610	Alcelaphine herpesvirus-1	T cell
240E1-1-2	c-myc / v-abl	Plasmacytoma

existence that have been derived by transformation with HTLV-I. In addition, there are rabbit B cell lines derived from transgenic rabbits that carry the proto-oncogenes c-myc or v-abl conjugated to either the rabbit immunoglobulin heavy chain or κ chain enhancers. A rabbit fusion partner for the production of rabbit $\times$ rabbit monoclonal antibodies has been developed using plasmacytomas derived from the transgenic rabbits described above.

Lymphoid cell markers

Rabbit lymphoid cells can be divided into the general categories of T and B cells. Other cell types, such as macrophages and polymorphonuclear leukocytes (PMNs), can also be identified by differential staining and functional assays. A survey of recent literature revealed that there are over 60 different monoclonal antibodies reported to react with rabbit lymphoid cells. Unfortunately, most of these are not adequately characterized and claims of cellular specificity are supported precariously by available data. Table 2 lists monoclonal antibodies and nucleotide sequences for rabbit lymphoid markers. The use of these reagents will allow general characterization of leukocytes. There are, in addition, certain antibodies directed against markers of other species that cross-react with rabbit cells. The identification of T cell subsets is now possible with the development of both monoclonal antibodies (mAbs) and probes for CD4 and CD8.

Conclusions

The 'state of the art' in rabbit immunology reflects the combined effort of many investigators over many years. Use of the rabbit as a disease model is increasing as scientists realize the advantages of size, docility and biologic similarity to humans. The paucity of inbred rabbit strains may be overcome by the estab-

lishment of rabbit MHC typing and MHC matched breeding colonies. Molecular genetics of Ig genes are reasonably well-defined, as are the MHC genes. Studies of T cell receptor genes and proteins are progressing in step with the development of probes and reagents for their characterization. The establishment of long-term cell lines should lead to more rapid progress of rabbit immunology including a better understanding of cellular interactions and functional definition of lymphoid cells and their surface markers.

RADIATION, EFFECTS ON IMMUNE SYSTEM

Ionizing radiation (e.g. X- and gamma rays, neutrons and charged particles) damages DNA and other cellular components. Organized lymphoid tissues and recirculating lymphocytes are the most radiosensitive cells in the body. Following exposure to radiation, most cells of other lineages maintain their viability for one or two mitotic cycles. Small lymphocytes are unique in that even small doses of radiation (as low as 0.25 Gy (25 rad)) result in programmed cell death (apoptosis). Myeloid progenitor cells, also vital to host defenses, are similarly radiosensitive, but the mode of their death remains to be established.

At the cellular and tissue level, sensitivity to radiation has been evaluated by determining cell viability and functional capacity. The sensitivity of the immune system to radiation is reflected by 1) the magnitude of the suppression of the primary or secondary immune response, 2) the reduction in size of the lymphoid organs, and 3) the decrease in the number of surviving lymphoid cells. Despite the exquisite radiosensitivity of most lymphoid cells, a number of radioresistant immune functions (and cells) are maintained, even after doses of radiation that may lead to the death of the animal. Thus, although radiation-induced death of mice, within a dose range below 16 Gy (1600 rad) is often caused by opportunistic infections, the reduced resistance of the host is caused primarily by the ablation of the hematopoietic tissues, rather than total ablation of the immune system. This condition is referred to as the hematopoietic syndrome.

Consequently, to understand the effects of radiation on the immune system and host resistance, we must consider the deleterious effects of radiation not only on lymphocytes but additionally on the leukocytes which mediate nonspecific host responses.

Radiosensitivity of cellular components of the immune system

The type and magnitude of specific immune responses is determined by the interaction of antigen-presenting cells such as dendritic cells and macrophages with T and B lymphocytes. However, the effector arms of the immune system depend on interactions of numerous leukocyte subsets. In addition to lymphocytes and macrophages, natural killer

(NK) cells, eosinophils and granulocytes contribute significantly to host resistance to infections.

Macrophages are relatively radioresistant, as are other nondividing cells in the body. Although phagocytic function and migratory activity of the macrophage are resistant to doses of up to 100 Gy (10 000 rad) given to cells *in vitro*, it is uncertain whether at these doses macrophages maintain their ability to catabolize, degrade, produce antigenic peptides or kill microbial organisms. In general, macrophages are activated following irradiation, as evidenced by enhanced RNA synthesis, enhanced production of cytokines such as IL-1, and increased production and release of lysosomal enzymes.

As in the case of macrophages, the phagocytic ability of polymorphonuclear cells (PMNs) is not decreased by radiation. Moreover, radiation given during or following phagocytosis increases the intracellular killing capacity of these cells. However, radiation results in profound depression of PMN production, due to the destruction of extremely radiosensitive progenitors (D_0 , the dose of radiation that reduces survival of cells to 37% on the exponential portion of the survival curve, is only 0.9 Gy (90 rad) in mice). Given the short lifespan of mature PMNs, a dose of a few gray (a few hundred rads) leads to greatly reduced numbers of PMNs in the circulation within days after irradiation and results in enhanced susceptibility to infections.

Lymphocytes are unique in that the majority of mature resting lymphocytes die rapidly, within hours, after low doses (0.8–5 Gy (80–500 rad)) of radiation. Lymphocytes stimulated by antigen or mitogen, however, become much more radioresistant and maintain their function and viability even after relatively high doses (e.g. 10 Gy (1000 rad)) of radiation (Table 1). The exact mechanism for such enhanced radioresistance remains unknown, but may be based on altered pathways leading to apoptosis, i.e. reduced expression of p53 and/or increased expression of apoptosis-preventing molecules, such as Bcl-2. Alternatively, because mitogen-stimulated lymphocytes contain elevated levels of DNA polymerase and ligase it has been suggested that these cells have an enhanced ability to repair single-strand scissions in DNA.

Table 1 Radiosensitivity of cellular components of the immune system

Type of cell	Radiosensitivity (D_0)	Radioresistance (D_0)
Macrophages	—	Resistant to <i>in vitro</i> doses of 100 Gy (10 000 rad)
B cells	0.8–1 Gy (80–100 rad)	—
Plasma cells	—	60–90 Gy (6000–9000 rad)
T helper cells	Unprimed 1–2 Gy (100–200 rad)	Primed >10 Gy (>1000 rad)
T suppressor cells	Unprimed 1–5 Gy (100–500 rad)	Primed >10 Gy (>1000 rad)
T cytotoxic cells	Minority 2–5 Gy (200–500 rad)	Majority >10 Gy (>1000 rad)
Granulocytes	—	Resistant to ~50 Gy (several thousand rad)
Natural killer cells	—	Resistant to 20 Gy (2000 rad)
Hematopoietic precursors	<1 Gy (<100 rad)	—

Radiosensitivity of lymphoid tissues

The thymus is the most radiosensitive lymphoid tissue, as changes can be detected even after exposure to a dose as low as 0.05 Gy (5 rad). The sensitivity of immature CD4⁺CD8⁺ thymocytes is based on upregulation of p53 expression leading to apoptosis, with thymocytes from p53^{-/-} mice being radioresistant. Although the exact pathways of p53-induced apoptosis remain to be determined, it is clear that p53 is a guardian of genetic integrity, and prevents potential malignant transformation.

Localized irradiation of human thymus, as shown by studies of individuals irradiated prophylactically in infancy for an enlarged thymus to prevent 'status thymolympathicus', resulted not only in an increased frequency of tumors, but also increased frequency of asthma and other autoimmune disorders (including sarcoidosis, enteritis, thyroiditis and others). However, no impairment of delayed hypersensitivity reactions was noted, suggesting that T cells with regulatory functions are more radiosensitive than those with effector roles.

The loss of spleen mass is less pronounced than that of the thymus, as only about 70% of splenic volume in the mouse is composed of lymphocytes. The apoptotic death after radiation of mitogen- or antigen-activated mature T and B cells and NK cells, depends on an antioncogenic transcription factor, interferon regulatory factor (IRF1) and is independent of p53. Necrosis and cell loss are more pronounced in B-cell-enriched areas than in T-cell-enriched areas. Germinal centers are the most sensitive, with necrosis occurring in the follicular outer cortex. Despite apparent rapid recovery of germinal centers following sublethal radiation, T cells in the spleen appear to recover more quickly than B cells. As with the thymus, the stromal elements of the spleen are considerably more radioresistant, thus providing a microenvironmental stimulus for the recovery of either surviving or exogenously supplied stem cells.

Irradiated lymphocytes lose their normal homing

ability. Although they retain their capacity to migrate to spleen and lymph nodes immediately after transfer to a syngeneic host, the subsequent cell traffic into the tissues is impaired, apparently due to membrane damage manifested within hours after irradiation. Thus, radiosensitivity of a given lymphoid cell subset can best be evaluated by *in vitro* assays of their function, because changes in the migration ability preclude accurate *in vivo* measurements in an adoptive host.

Radiosensitivity of the immune response

Humoral immunity

In general, radiation is more deleterious to the antibody response than to delayed hypersensitivity responses. In the primary antibody response, radiation suppresses the inductive more than the productive phase, because plasma cells, unlike immature B cells, are extremely radioresistant (D_0 values of 60–90 Gy (6000–9000 rad)), and radiation does not affect the biological activity of antibodies. However, most plasma cells are short-lived and survive only for several days, resulting in the eventual reduction of antibody titers. Despite reduced antibody titers, the antibody affinity is considerably higher in irradiated animals than in nonirradiated animals, possibly due to the relatively greater radioresistance of more differentiated antibody-producing cells.

Radiation has been used as a tool to elucidate regulation of antibody production. Depending on the time of irradiation in relation to antigenic challenge, depression or augmentation in primary antibody response may result. For example, irradiation of mice with 4.4 Gy (440 rad), a few hours or days *before* antigen exposure, results in immune suppression, whereas the same dose of irradiation 4 days *after* antigenic challenge leads to enhanced titers of antibody. This may be based on selective radiosensitivity of certain suppressor cell populations. In addition to timing, the type of antigen, its mode of presentation, the animal species or strain, and the class of antibody

are important in determining whether exposure to radiation will result in increased or decreased antibody titers.

Although the *in vivo* secondary response has repeatedly been found to be more radioresistant than the primary, the D_0 values for immunoglobulin M (IgM) and IgG plaque-forming cells (PFCs) were found to be similar in the primary and secondary responses, and ranged from 0.8 to 1 Gy (80–100 rad). These findings indicate that factors other than B cell survival, operating *in vivo*, account for the relatively greater radioresistance of the secondary response. The mechanism of this enhanced radioresistance may have a quantitative rather than qualitative basis.

Studies of mammalian T and B cells established that as far as death of dividing cells is concerned, the D_0 for T and B cells is similar. Apoptotic death, however, is more rapid for B cells than T cells. The T helper cell is critical in determining the magnitude of the T-dependent antibody response to most common antigens. Although different experimental procedures have shown heterogeneity in the radiosensitivity of T helper cells, several conclusions can be drawn. Unprimed helper T cells are quite radiosensitive. Priming renders helper T cells resistant to several thousand rad. This resistance, however, can be demonstrated primarily in *in vitro* assays. In contrast, D_0 values in *in vivo* adoptive transfer were found to be as low as 2.3 Gy (230 rad). These low D_0 values were explained by the loss of homing capacity of irradiated lymphoid cells. Radioresistant primed T helper cells can survive and function until stimulated to divide, at which time mitotic death occurs.

Regulatory suppressor cells may also be divided into radiation-sensitive and radiation-resistant populations, with antigen or mitogen-activated suppressor cells being more radioresistant than resting cells.

Cellular immunity

Delayed-type hypersensitivity (DTH) is relatively radioresistant when compared to antibody production. However, as measurements of skin test reactions cannot be evaluated with the same degree of sensitivity as antibody titers, the D_0 values for the DTH reactions are difficult to determine. The homing properties of the DTH subclass of T cells are impaired by radiation, similar to the T helper cells. Furthermore, irradiation of a recipient prior to cell transfer also results in reduced DTH.

The majority of cytotoxic T lymphocytes (CTLs) are radioresistant to doses of several thousands rad. However, a fraction of CTLs are sensitive to doses ranging from 2 to 5 Gy (200–500 rad). The radio-

resistant fraction of CTLs is particularly beneficial in resistance to those infections that depend on cell-mediated immunity, e.g. most viral infections.

Susceptibility to infection

Whole-body exposure to doses of radiation that are injurious to the hematopoietic system results in greatly increased susceptibility to infections, often leading to death. Susceptibility is increased not only to pathogenic microorganisms, but also to nonpathogenic normal flora of the gut and mucous membranes. Leukopenia, due to the stem cell killing, and the loss of physical integrity of mucous membranes, are the primary reasons for such opportunistic infections. Susceptibility to acute infections is most pronounced 3–4 days after radiation exposure, which correlates with the nadir in numbers of bone marrow and lymphoid cells. Increased permeability of biological barriers, such as skin, gastrointestinal tract and blood–tissue barrier, contribute greatly to disseminated infection. Radiation, however, may also alleviate symptoms of some viral infections (encephalitis in humans or choriomeningitis in mice) by destroying lymphocytes that contribute to the pathogenesis of the disease.

Immunotherapeutic applications of radiation

Whole-body irradiation has been used with increasing success for nearly two decades to ablate neoplastic cells in the bone marrow. It is followed by allogeneic bone marrow transplant or a purged autologous graft to restore normal hematopoiesis. Total lymphoid irradiation (TLI), with sparing of the bone marrow, a procedure developed a decade ago, has been used as a treatment of Hodgkin's disease and autoimmune rheumatoid arthritis, and is now being tested in multiple sclerosis patients. With this treatment, patients receive 20 Gy (2000 rad) delivered in doses of 1.5–2 Gy (150–200 rad) per fraction for 2–3 weeks, to their cervical, axillary, mediastinal and hilar lymph nodes and the thymus. The patients are immunosuppressed and show long-lasting remissions in disease activity. Several months after TLI patients show a marked decrease in the percentage of total T cells and $CD4^+$ cells, decreased mixed lymphocyte reaction (MLR) and decreased lymphocyte proliferation to T cell mitogens which is correlated with an increased ratio of $CD8^+$ to $CD4^+$ lymphocytes. Despite such marked immunosuppression, these patients do not experience any increase in the incidence of bacterial infections. In addition, allogeneic transplant survival was recently shown to be

enhanced following TLI due to the T cell-mediated, acquired tolerance. Thus, radiation may be considered as a means of promoting tolerance to grafts prior to transplantation.

Immunodeficiency and radiation sensitivity

Many immunodeficient states have been associated with increased radiation sensitivity. Ataxia telangiectasia (AT) is associated with an increased sensitivity of T cells to the cytotoxic effect of ionizing radiation, with defective cell-mediated immunity, and with nervous system disorders. The gene responsible for this disorder (the *Atm* gene) has recently been identified as being important in the regulation of cell division. Lymphocytes from patients with AT do not exhibit normal cell cycle arrest and do not rapidly accumulate p53 following irradiation. Patients with AT have a high incidence of T cell leukemias with aberrant chromosomal rearrangements involving T cell receptor (TCR) genes.

Certain types of severe combined immune deficiency (SCID) are characterized by an inability of lymphocytes to rearrange TCR and Ig genes due to a functional loss of a recombinase. There is an increased sensitivity of these lymphocytes to the killing effects of radiation. Two protein subunits, called Ku proteins (originally identified as a nuclear antigen in certain autoimmune diseases) mediate the rearrangement of Ig and TCR genes by binding to a 350 kDa protein (catalytic subunit) which functions as a DNA-protein kinase. This DNA-protein kinase activity is absent in SCID mice and in some forms of human SCID. The radiation sensitivity of SCID cells is corrected by transfecting the DNA-protein kinase

catalytic subunit, thus implicating this pathway in both Ig/TCR rearrangement and radiation sensitivity. Additional immunodeficient states such as Wegener's syndrome in humans, and the syndrome of 'wasted' mice are associated with radiation sensitivity. Studies of these abnormalities are likely to uncover more interactions between normal immune function and radioresistance.

RADIOLABELING

Robert E Cone, Department of Pathology, University of Connecticut Health Center, Connecticut, USA

The incorporation of radioisotopes into macromolecules has increased by 30 000-fold the sensitivity of immunoassays, so that picogram amounts of an antigen or receptor can be detected and quantified. Radiolabeled antibodies can be used to detect the primary binding of antibody to antigen, providing speed, sensitivity and measurements of affinity.

In addition, radiolabeled antibodies may be used to identify the site of a tumor or the presence and topography of molecules in the membrane of an intact cell. Similarly, radiolabeled antigens were used to demonstrate that B lymphocytes bind antigen specifically via cell surface immunoglobulin receptors.

Radiolabeling of soluble molecules

Most proteins are iodinated externally with ^{125}I or ^{131}I (iodide), although other radioisotopes have been used. Radioiodine is used to label proteins usually by oxidation of iodide to iodine (I_2) or I^- which covalently halogenates the phenolic ring of accessible tyrosine or histidine residues. Oxidation is accomplished chemically with chloramine T or enzymatically with lactoperoxidase. Proteins can also be radioiodinated chemically with the Bolton-Hunter reagent, ^{125}I -N-succinimidyl 3-hydroxyphenyl propionate, iodogen (3,3',4,4'-tetrachloro-3a,6a-diphenyl glycoluril) or iodine monochloride. Generally, γ -ray emitting radioisotopes are used to radiolabel proteins, but β -emitting ^3H , ^{14}C or ^{35}S are sometimes used. In particular, these β -emitting isotopes are used to label proteins or antigens containing carbohydrate groups by biosynthetic incorporation of radiolabeled amino acid or carbohydrate precursors of macromolecules. The radiolabeled proteins are analyzed by various procedures in which radioactivity is detected with appropriate instrumentation. Microanalytical polyacrylamide gel procedures will resolve radiolabeled proteins which may be detected by autoradiographic procedures. Radiolabeled ligands or antibodies binding to cells are visualized by autoradiography with light or electron microscopes. The specificity of binding of radiolabeled ligand to cells or antibodies is determined by competition with unlabeled ligand.

Radiolabeling of living cells

In addition to radiolabeling proteins in solution, radioisotopes have been incorporated into cytosolic and/or cell membrane proteins of living cells. Lactoperoxidase or insoluble iodogen have been used to radioiodinate accessible cell membrane proteins, based on the principle that the labeling agent cannot penetrate the cell membrane. Ten million lymphocytes provide approximately 5–10 μg membrane protein, of which 0.5–5 ng might be a particular species. Radiolabeling, in combination with immunochemical procedures, facilitates the rapid molecular identification of individual membrane proteins.

For example, radioiodinated cells are lysed with nonionic or bile salt detergents and radiolabeled proteins immunoprecipitated with antibody. These procedures permit the isolation and identification of as little as 0.1% of the radiolabeled proteins. Once isolated, the radiolabeled proteins are analyzed by standard microchemical procedures such as polyacrylamide gels and autoradiography. Cell surface

Figure 1 Biosynthetic labeling of cellular macromolecules. Cells are cultured 2–24 hr in complete cell culture medium or cell culture medium lacking the radiolabeled constituent (e.g., methionine for ^{35}S -methionine). The cells incorporate the radiolabeled precursor into macromolecules and after culture, the cells and culture medium are separated by centrifugation. Radiolabeled macromolecules are extracted from the cell or, if secreted, obtained from the cell culture medium. The radiolabeled macromolecules are then specifically isolated by immunoprecipitation.

radioiodination has identified the molecular properties of B and T cell receptors of antigen, major histocompatibility complex glycoproteins and differentiation antigens. Cell membrane glycoproteins can also be labeled vectorially with ^3H - NaBH_4 after oxidation of carbohydrate moieties. In addition, cellular proteins can be labeled by biosynthetic incorporation of ^3H , ^{14}C or ^{35}S -labeled amino acid precursors of protein or ^3H , ^{14}C -sugars as precursors of carbohydrates. Some proteins can also be labeled by incorporation of ^{32}P catalyzed by various kinases.

After these cells are biosynthetically labeled (see Figure 1), radiolabeled proteins are isolated immunochemically, and their structure determined by microanalytical procedures. In addition, the loss of vectorially-labeled membrane proteins by cultured cells and the increase in biosynthetically radiolabeled proteins can be taken as a measure of the turnover of cytosolic or membrane proteins.

RAT, INBRED STRAINS OF

David L Gasser, Department of Genetics, University of Pennsylvania School of Medicine, Philadelphia, USA

Immunological investigations can be greatly enhanced by the availability of rat models. A number of inbred strains are available for such studies, and there is a growing body of genetic information about these strains. This entry summarizes what is known about the derivation of the most commonly used inbred strains, and provides references for genetic data that have been accumulated so far.

The common strains of laboratory rats belong to the species *Rattus norvegicus*, so named because some of their ancestors were observed in the Norwegian peninsula as they migrated from Asia into western Europe. The laboratory mouse (*Mus musculus*) and the laboratory rat are both members of the family Muridae in the order Rodentia, so the adjective 'murine' could be applied to either mice or rats (although in practice it usually refers to mice). In fact, the rather close relationship between mice and rats is very important to investigators who work with rats, because the wealth of information on the genetics of the mouse frequently provides useful guidance in rat studies.

Many of the rat strains in use today were originally inbred at the Wistar Institute in Philadelphia or the Crocker Institute of Cancer Research at Columbia University. The early investigators who were active at the Wistar Institute included Drs Henry Donaldson, Helen Dean King and Margaret Reed Lewis. One of the noninbred lines which they maintained was known as 'the Wistar rat'. Rats from this colony were sent all over the world, beginning as early as 1911. Inbred strains directly descended from these Wistar rats include AS, BUF, KYN, LEW, LOU, MNR, OKA, SHR, W, WAG, WF and WKY. Several other inbred strains also originated at the Wistar Institute, including PA, WKA and BN. The BN strain is especially interesting in that it was derived from wild rats, and is therefore useful whenever a strain is needed that differs as much as possible from other laboratory strains. Drs Frederick D

Bullock, Maynie Rose Curtis and Wilhelmina F Dunning at the Crocker Institute for Cancer Research worked for many years on the susceptibility of rats to the induction of sarcomas. In 1919, Dr Curtis initiated the inbreeding of the Fischer (F344), Zimmerman, Marshall (M520) and August (AUG) rat strains, which were named after commercial breeders who supplied the first mating pairs. The Copenhagen (COP), ACI, ACP, ACH and A990 strains were also initiated by these investigators. Many additional inbred strains were derived subsequently in numerous laboratories around the world. Genetic relationships among various inbred strains have been investigated by comparing genotypes at polymorphic markers. A tentative genealogic tree of 13 inbred rat strains was constructed on the basis of genotypes at 264 arbitrarily primed polymerase chain reaction products by Canzian and colleagues. In general, these results confirmed that the Wistar-derived strains form a cluster that is different from the Crocker Institute-derived strains, and that BN is quite different from both clusters.

The inbred strains developed by these and other pioneers have been used throughout the world for a variety of genetic and immunological studies. As new genetic loci were identified, sometimes independently in different laboratories, conflicting nomenclature systems were reported in the literature. These problems have not been fully resolved, but there is more uniformity in recent publications than occurred in some of the older literature. During the late 1970s, investigators working on the immunogenetics of the rat agreed to adopt a system of nomenclature in which genetic loci encoding surface antigens would be designated by 'RT' followed by an appropriate number. It was agreed that the first locus in the series, RT1, would be the major histocompatibility complex. The status of RT1 genetics has been reviewed by Butcher and Howard (1986) and the RT1 types of many strains are shown in Table 1.

The second locus in the series, RT2, was originally designated AgC, and by linkage similarities involving serum esterase loci appears to be homologous to the mouse Ea-1 locus. RT3 is a blood group locus that was formerly designated AgD. The histocompatibility loci RT4 and RT5 were previously designated H-2 and H-5, respectively and unfortunately most of the common inbred strains have not been characterized for these loci. The RT6 antigens (formerly designated ART-2, AgF, Pta and RT LY-2) are expressed on T lymphocytes in peripheral lymphoid tissues but are absent from thymus and bone marrow. The RT7 antigens (previously designated ART-1 and RT LY-1) are expressed on all thymocytes and peripheral T lymphocytes, while RT9 is a blood group locus linked to RT2, and all strains tested so far except WKA have the a allele. A monoclonal antibody which defines RT10 has been reported.

The study of immunoglobulin allotypes in rats was greatly facilitated by the development of the LOU/C strains, which have a unique susceptibility to the development of immunoglobulin-secreting tumors. Nomenclature conflicts have occurred in this field as well, but a uniform system in agreement with World Health Organization (WHO) guidelines is now in use. Allotypes of many common strains are shown in Table 1.

In addition to the above antigens, a variety of other loci of immunogenetic importance have also been characterized. These include tubular basement membrane antigens, the rat homolog of the CD4 lymphocyte antigen, W3/25 and interleukin 3 (IL-3).

Immunologically unique features of some rat strains are summarized in Table 2. The BB rat is not included in Table 1, as it has not been rigorously inbred. This is a spontaneously diabetic population of rats that was first obtained from a noninbred Wistar-derived stock maintained at the Bio Breeding Laboratory of Canada, Ltd, in Ottawa, Ontario. As this model has become increasingly popular, a good deal of inbreeding has undoubtedly occurred, but its genotype has not been reported at many polymorphic markers.

Rat strains have also been characterized for a large number of polymorphic biochemical markers. These include aconitase, aldehyde dehydrogenase, two alkaline phosphatases, two α -amylases, twelve esterases, fumarate hydratase, α -glycerophosphate dehydrogenase, glyoxalase, hemoglobin, leucine aryl-aminopeptidase, peptidase, pepsinogen, 6-phosphogluconate dehydrogenase, and seminal vesicle proteins. Many of these genes have been mapped by the use of rat/mouse somatic cell hybrids. Although the genetic map of the rat is not nearly as complete as

that of the mouse, a great deal of progress has been made. Investigators who wish to map additional genes will benefit from the large numbers of microsatellite polymorphisms that have already been mapped. A growing collection of the oligonucleotides needed for these tests is available from Research Genetics, Inc. (Huntsville, AL, USA).

In some experiments, it is important to know whether sublines of the same strain have diverged from one another. This question has been examined by Matsumoto and colleagues by testing numerous sublines of the SHR and WKY strains for polymorphic variants. The SHR sublines varied at six of the 30 loci that were tested, and the WKY sublines differed at 15 of the 30 loci. Many strains and substrains were also surveyed for their genotypes at 39 loci by Bender and colleagues. These investigators observed variation at only WAG sublines, but there was variation at two of the loci among 13 sublines of BN, at three of the loci among four WF sublines, and at four of the 39 loci among five sublines of BUF. Twelve LEW sublines showed no variation at any of the 39 loci, but LEW/Mol differed from the other LEW strains at eight of the loci. Investigators should therefore be aware that there is a varying degree of subline diversity among inbred strains, and that this may or may not affect any given experiment.

Historical background

In the late nineteenth century, Metchnikoff first suggested that phagocytic leukocytes were important in host defense against infectious pathogens. After noting that leukocytes move toward bacteria and ingest them, he induced local recruitment of macrophages and demonstrated protection of the host against otherwise lethal doses of bacteria. However, Metchnikoff's concept of recruitment and activation of leukocytes, the cellular theory of immunity, sparked intense opposition from the humoralists who supported the theories advanced by Koch and others for an exclusive role of circulating antibodies in protective immunity. Indeed, proponents of the humoral theory of immunity considered the inflammatory reaction and the accompanying macrophages to be harmful rather than beneficial to the host, setting back the study of cellular mechanisms of immunity for decades.

Not until the 1950s and 1960s did a revival of interest in the mechanisms of cellular recruitment and activation occur as their importance in transplantation, delayed hypersensitivity and immunodeficiency was recognized. Moreover, investigators soon realized that inflammatory cell infiltrates were not merely exudative, but rather dependent on an active migration of leukocytes from the circulation to the site of inflammation. Intense investigation of the mechanisms involved in leukocyte adhesion and recruitment, particularly within the past decade, has revealed that these events are not only very complex, but importantly also provide potential targets for therapeutic intervention.

Leukocyte recruitment in inflammation

Recruitment of circulating leukocytes to a site of tissue injury, infection or antigen deposition is essential to the evolution of an inflammatory response. The inflammatory response, characterized by altered vascular permeability, the release of inflammatory mediators, and the mobilization and infiltration of leukocytes, serves to sequester and eliminate pathogens. As the leukocytes phagocytose and degrade the inflammatory agent, they, in turn, release additional inflammatory mediators that orchestrate additional recruitment and activation of leukocytes. If these recruited leukocytes succeed in eliminating the

immunologic challenge, the inflammatory response subsides and the tissue repair begins. Failure to eliminate the antigen, however, results in continued recruitment and activation of leukocytes, responsible for the development of chronic inflammatory lesions. These lesions may account for destruction of the host's own tissues.

In order for leukocytes to accumulate in an inflammatory site, circulating leukocytes must: 1) adhere to nearby vascular endothelial cells, and 2) migrate between cells and through the basement membrane toward chemotactic signals in the tissue site where they 3) become immobilized (migration inhibition) and activated to phagocytose, secrete cytokines and/or proliferate as they carry out their inflammatory functions. Thus, recruitment of leukocytes to a specific location is not random, but involves an ordered series of events.

Mechanisms of cell adhesion

The first cells to appear at an inflammatory focus are neutrophils which arrive rapidly after injury, followed by mononuclear cell egress shortly thereafter (**Figure 1**). Stimulation of leukocytes by substances immediately released at the injury site such as complement fragments (C5a), bacterial products (*N* formyl peptides (fMLP) and lipopolysaccharide (LPS)), cell-derived chemotactic cytokines (chemokines) and other inflammatory mediators (leukotrienes (LTB₄)) results in increased leukocyte margination and adherence to the vascular wall. Originally thought to be passive participants in these events, endothelial cells are now known to actively contribute to leukocyte adhesion. Adherence of phagocytes to endothelium, basement membranes and matrix constituents is a complex, reversible event which is augmented during inflammation. When circulating phagocytes encounter an inflamed postcapillary venule lined with activated endothelial cells, they become tethered and commence a transient adhesive rolling motion (**Figure 1**). Rolling is initially mediated by adhesion molecules of the selectin family, which are glycoproteins expressed on the surfaces of both the endothelial cells (E-selectin (CD62E) and P-selectin (CD62P)) and leukocytes (L-selectin (CD62L)), and their corresponding carbohydrate ligands on the target cells (L-selectin targets on endothelial cells: GlyCam-1, CD34 and MadCAM-1).

Figure 1 Leukocyte adhesion and recruitment. Leukocytes (N, neutrophils; M, monocytes; T, T lymphocytes) adhere to endothelial cells through cell surface adhesion molecules, leave the circulation by directed migration towards chemotactic stimuli, and enter the tissues where they secrete cytokines which recruit additional cells.

Rolling of leukocytes along the endothelium slows their movement through the circulation, allowing them intimate contact with the vessel wall where the leukocytes may be exposed to additional pro-inflammatory stimuli.

If sufficient stimuli are encountered, the weak selectin-mediated adhesion is replaced (due to shedding of L-selectin) by a more secure binding which precedes transendothelial migration (diapedesis) (Figure 1). This process is partially mediated by the integrins, a multi-membered family of cell surface glycoproteins each consisting of a noncovalently associated α and β subunit (Figure 2). The leukocyte β_2 (CD18) integrins interact with ligands displayed on other leukocytes and/or vascular endothelium, including members of the immunoglobulin superfamily, intercellular adhesion molecules 1 (ICAM-1, CD54) ICAM-2 (CD102), ICAM-3 (CD50) and vascular cell adhesion molecules (VCAM). Integrins,

particularly of the β_1 (CD29) family, also interact with extracellular matrix molecules (laminin, collagen, fibronectin) encountered in basement membranes and in tissues (Figure 2). Leukocyte-endothelial adhesion is augmented by the inflammatory cell-derived cytokines, interleukin 1 (IL-1), tumor necrosis factor α (TNF α), and interferon γ (IFN γ), as well as bacterial lipopolysaccharides (LPS), which can induce and/or activate integrin expression to facilitate leukocyte migration into local areas of immune reactivity. IL-1 and TNF α also stimulate endothelial cells to produce chemotactic cytokines of the chemokine superfamily of proteins, further promoting inflammatory cell recruitment (Figure 3). Chemokines, in turn, facilitate the upregulation of integrins on leukocytes. Thus, endothelial cells not only are targets of regulatory cytokines, but reciprocally produce these polypeptide mediators.

The importance of the adhesion molecules in leukocyte recruitment and host defense is underscored in transgenic mice in which the genes for selectins, integrins, or ICAM-1 and VCAM have been inactivated via homologous recombination with a mutant gene (knockouts) (Table 1). Genetically engineered deletions of integrin α chains or the β_1 chain of the integrins are embryonically lethal, demonstrating their additional critical roles in embryogenesis (Table 1). Mice lacking selectins develop normally, but have leukocytes with impaired adhesive and migratory capabilities. Likewise, null mutations of the β_2 chain result in an adhesion deficiency, and this deficiency causes manifestations similar to a genetic disease recognized in humans, leukocyte adhesion deficiency (LAD). Leukocytes from these patients have a defect in synthesis of CD18, with diminished leukocyte aggregation, adherence and chemotaxis. Consequently, these individuals display markedly diminished inflammatory responses with inadequate phagocytosis of microorganisms, resulting in recurrent, life-threatening infections.

In addition to integrins, adhesion molecules termed homing receptors (CD44) are important in directing lymphocyte-high endothelial venule (HEV) binding (addressins) central to lymphocyte recirculation and homing. Within an inflammatory site, areas of activated endothelium facilitate lymphocyte recruitment analogous to high endothelium in lymphoid tissues. In this regard, HEV-like structures which express VCAM-1 have been demonstrated in areas of chronic, but not acute, inflammation, consistent with the presence of IFN γ which promotes this HEV phenotype. Moreover, memory T cells express increased levels of adhesion molecules including CD2, CD44, LFA-1 ($\alpha_L\beta_2$) and VLA-4 ($\alpha_4\beta_1$) which favor their adherence and enrichment

Figure 2 Leukocyte integrins and their ligands. In addition to selectins and members of the Ig superfamily, leukocytes express a plethora of integrin molecules which promote adhesive interactions with endothelium, extracellular matrices, other leukocytes and also infectious microorganisms. Shown are representative leukocyte integrins and their ligands.

at sites of secondary immune responses. Increased expression of CD44 is also found on neutrophils and monocytes, and antibodies to this receptor inhibit accumulation of these cells in inflammatory sites. Thus, homing receptors appear to cooperate with leukocyte integrins in mediating the large increase in transendothelial migration seen during inflammation.

Chemotaxis

To enter the inflamed tissues, adherent leukocytes have to cross the vascular endothelial lining and migrate along increasing concentrations of biochemical signals emanating from the site of injury. This locomotion (chemotaxis) may be initiated, augmented or directed by a variety of chemotactic stimuli such as humoral components (C5a) and coagulation products (thrombin), and those which are released by microorganisms (fMLP), platelets and other sources. Early events in inflammation trigger platelet aggregation and the release of platelet-activating factor (PAF), platelet-derived growth factor (PDGF), platelet factor 4 (PF4) and transforming growth factor β (TGF β) (Figure 1), all of which are potent inducers of leukocyte mobilization. Neutrophils, the first leukocytes to arrive at the site, contrib-

ute to complement activation (C5a), and also release chemoattractants (chemokines, PAF, TGF β), thereby amplifying inflammation and promoting monocyte accumulation. Monocytes, in turn, influence subsequent events by generating numerous pleiotropic products (IL-1, TNF α , chemokines, PAF, TGF β) which promote leukocyte-endothelial cell adhesion and recruit additional cells (Figure 1). These leukocyte-derived products have an enormous cascading impact on the evolution of an inflammatory or immune response.

Among these amplification products is the superfamily of nearly 30 chemotactic proteins, the chemokines (Figures 1 and 3). These small (8–10 kDa) proteins contain four cysteine residues in highly conserved positions, and have been subdivided structurally into two families based on the arrangement of the first two cysteines which are adjacent in β chemokines (C-C), but interrupted by a single amino acid in the α chemokines (C-X-C). Most α chemokines preferentially elicit and activate neutrophils to destroy foreign agents, while β chemokines mobilize mononuclear cells, enabling a progression of cell recruitment into an inflammatory site. Secreted by a wide variety of myeloid and non-myeloid cells including neutrophils, monocytes, endothelial cells, fibroblasts, and some tumor cells in response to

Figure 3 Chemokines and their receptors. Chemokines are represented by two subfamilies based on the arrangement of their first two cysteines, which are adjacent (C-C) in β chemokines and separated by a single amino acid (C-X-C) in α chemokines. Polymorphonuclear neutrophils (PMNs) express type A and B receptors for α chemokines, and mononuclear leukocytes (MNLs) express different combinations of the five β chemokine receptors which have been identified to date.

Table 1 Consequences of gene targeting (knockout) of adhesion molecules

Null mutation	Phenotype of homozygotes
<i>Selectin family</i>	
E-selectin (CD62E)	Normal phenotype
L-Selectin (CD62L)	Normal phenotype ↓ recruitment ↓ lymphocyte homing
P-Selectin (CD62P)	Normal phenotype ↓ recruitment
<i>Integrin family</i>	
α_3 (CD49c)	Day 1 postnatal lethal
α_4 (CD49d)	Embryonic lethal
α_5 (CD49e)	Embryonic lethal
β_1 (CD29)	Embryonic lethal
β_2 (CD18)	Similar to LAD
<i>Ig superfamily</i>	
ICAM (CD54)	Normal phenotype ↓ recruitment
VCAM-1	Embryonic lethal

proinflammatory factors, chemokines may also be produced in response to other tissue insults. Disruption of the cytoskeletal–nuclear architecture triggered by cellular stresses such as cell deformation, hypoxia,

ischemia–reperfusion and particulate deposition activates the nuclear transcription factor NF κ B to signal chemokine expression in the initiation, amplification and maintenance of inflammatory sequelae.

Chemokines and other chemotactic factors are recognized by specific cell surface receptors. Receptor numbers vary from a new hundred for TGF β , which is chemotactically active at femtomolar concentrations, to nearly 100 000 for fMLP and C5a (C5aR, CD88), active in the nanomolar range. Two α chemokine receptors, which belong to a superfamily of seven transmembrane G protein-coupled receptors, have been characterized on the surface of neutrophils: the type A receptor selectively binds IL-8, while the type B receptor binds all α chemokines which contain the sequence motif Glu-Leu-Arg (ELR) near the N-termini (IL-8, NAP2, GRO α , β , γ , and ENA-78) (Figure 3). The family of receptors for β chemokines is much more complex with at least five β chemokine receptors (CC CKR1–5) identified on mononuclear cells (monocytes, lymphocytes) and on basophils and eosinophils, each with varying specificities for different subsets of β chemokines. Interestingly, a chemokine receptor expressed on the surface of erythrocytes has broad specificity for both α and β chemokines, and may act as a scavenger receptor to remove chemokines from the circulation that might otherwise interfere with local chemotactic gradients. Occupancy of chemokine receptors, other than the erythrocyte chemokine receptor, transduces signals coupled to guanine nucleotide-binding (G) proteins which initiate a sequence of complex biochemical and cellular events. These events culminate in polarization of the cell with a redistribution of receptors and cytoskeletal elements (actin, myosin) towards the leading edge, extension of a lamellopod in the direction of the attractant (motile phenotype), and the initiation of directed movement toward the signal.

Migration inhibition, activation and resolution

Chemotactic signals are naturally self-limiting, since they have a narrow range of optimal concentrations for chemotactic activity. When chemotactic factors are present at high concentrations, they tend to activate target cells, resulting in dramatic changes in cellular physiology and in the repertoires of adhesion molecules displayed on the cell surface. Since the release of chemoattractants from a proinflammatory site results in a concentration gradient away from the site, leukocytes first encounter low, chemotactically active concentrations and as they migrate up the gradient, the cells reach concentrations which

activate other functions and inhibit motility. This migration inhibition, assuring leukocyte persistence at the site of inflammation, is also due to a downregulation of receptors for certain chemotactic ligands. When leukocytes, newly recruited to the source of a chemotactic signal, are not subsequently activated, they may undergo apoptosis, a process here serving to minimize unneeded leukocyte accumulation. However, upon exposure to relevant activation and differentiation signals, such as IFN γ or LPS, the cells are rescued from apoptosis, undergo maturation, and lose their ability to migrate. Under the influence of the activation signals, the leukocytes are directed to carry out their specific functions of proliferation, phagocytosis, cytokine secretion, and/or cytotoxicity necessary for host defense.

Clearance of the inciting stimulus leads to resolution of the inflammatory response, whereas persistence of the stimulus favors excessive recruitment of inflammatory cells with the potential for leukocyte-mediated tissue damage. In chronic inflammatory sites, lymphocytes constitute a substantial proportion of the infiltrating leukocytes. Moreover, once activated, the lymphocytes exhibit remarkable selective migratory behavior due to their specific adhesion molecules and chemotaxis receptors. Release of chemotactic ligands by these cells, including β chemokines selective for monocytes, appears to direct responses associated with delayed hypersensitivity and chronic inflammation. Consequently, excessive, self-perpetuating recruitment is the basis of many chronic autoimmune, allergic and inflammatory diseases. In contrast, deficiencies in leukocyte recruitment lead to recurrent life-threatening infections. Thus, regulated leukocyte recruitment from the bloodstream to sites of inflammation is an essential component of host defense. Consequently, the adhesion molecules, their ligands and the chemokine family have become key targets in identifying novel therapeutic approaches to control recruitment in aberrant inflammatory responses.

RELATIVE RISK

Glenys Thomson, Department of Integrative Biology, University of California, Berkeley, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

A genetic marker association with a disease is demonstrated if a statistically significant difference is found in marker allele (or genotype) frequencies between ethnically matched unrelated patients and a group of unrelated control individuals. ABO blood group associations with certain diseases are well established, however the associations so far are consistently weak. In contrast, many strong associations of the HLA system with disease have been found. Association studies are increasingly relevant for mapping purposes in all disease studies. Association data have been used as a follow-up to linkage studies to further localize the disease-predisposing gene in a number of monogenic traits, and also to detect the role of candidate genes in complex diseases. To perform an association study between a disease and, say, a particular HLA antigen, or other genetic marker, a 2×2 table of antigen presence or absence versus disease presence or absence is set up as follows. Traditionally, the class antigen presence includes individuals who are homozygote and heterozygote for the marker allele, or HLA antigen, but also see below.

Marker allele			
Disease	+	-	
+	<i>a</i>	<i>b</i>	<i>N</i> ₁
-	<i>c</i>	<i>d</i>	<i>N</i> ₂
	<i>M</i> ₁	<i>M</i> ₂	<i>T</i>

The number of patients studied is *N*₁, the number of control individuals is *N*₂.

The most commonly used measure of the strength of an association between a disease and a marker allele is the relative risk (RR), or relative incidence ratio of Woolf (1955). The relative risk is simply estimated by the cross-product ratio of the entries in the 2×2 table of association, i.e.

$$RR = x = \frac{a \cdot d}{b \cdot c} \quad (1)$$

(Strictly, this measure in a retrospective study as described here is the odds ratio (OR), but when the incidence of the disease in the population is low, this is equivalent to the relative risk as defined in epi-

demiology for prospective studies.) A relative risk higher than 1 (a positive association) is seen when an antigen is more frequent in the patients than in the controls, whereas a risk below unity (a negative association) reflects a decreased frequency in the patients.

Under the null hypothesis of no association of the genetic marker with disease, the expected RR is 1, and observed values of the RR follow a chi-squared distribution with 1 degree of freedom, as follows

$$\chi^2 = (ad - bc)^2 T / (M_1 M_2 N_1 N_2) \quad (2)$$

Deviations of an observed RR value from the chi-squared distribution indicate a statistically significant association. For more details on statistical issues, including combining samples, see Svejgaard *et al* (1974).

In cases where an antigen, or marker, is absent or present in all patients or when sample sizes are small, the formula given by Haldane in 1955 should be used:

$$RR = x = \frac{(a + 1/2)(d + 1/2)}{(b + 1/2)(c + 1/2)} \quad (3)$$

For a number of HLA-associated diseases large relative risks are observed, for example in the case of ankylosing spondylitis the relative risk for B27 in Caucasians is 69.1, while for insulin-dependent diabetes mellitus (IDDM) the relative risks for DR3 and DR4 are 3.8 and 9.0 respectively (see Thomson, 1988).

Two possibilities exist to explain a marker-disease association. The first is that disease susceptibility is directly influenced by the presence of the marker allele, e.g. class II HLA-DRB1, DQA1 and DQB1 associations with IDDM. The second is linkage disequilibrium (nonrandom association) between the marker allele and a disease predisposing locus, e.g. the association of HLA class I A3 with hemochromatosis in Caucasians. In either case, the 'disease' locus may have alleles necessary for disease, or alternatively all genotypes at the locus may be disease susceptible, with different degrees of penetrance. Significant linkage disequilibrium values are usually not expected for loci with recombination distances greater than 2%, and sometimes less than this distance.

All subjects must be of the same homogeneous ethnic origin. Otherwise, spurious associations may result from a stratification effect if one of the subgroups had a higher frequency of the disease and the marker allele than did the rest of the population. Using family-based association studies, where the parental marker alleles not transmitted to an affected child in simplex families form the 'control' population, ensures that only associations of marker genes linked to a disease gene will be detected (for details, including statistical tests, see Thomson, 1995).

Multiple alleles at a genetic marker locus may show associations with a disease. To test this, it is preferable to test all k alleles simultaneously in a $k \times 2$ contingency table of number of alleles observed in patients and controls, than to perform multiple tests on each allele separately. Genotype specific effects can similarly be determined.

RENAL INFECTIONS

Guy Neild, Institute of Urology and Nephrology, UCL Hospitals, University College London, London, UK

The principal infections of the kidney and urinary tract occur in either the renal parenchyma (pyelonephritis) or in the bladder (cystitis). Other, or connecting, parts of the urinary tract may be specifically involved as in urethritis, prostatitis, epididymitis, or as part of a more widespread process, e.g. tuberculous ureteritis.

Patients with renal disease may be prone to urinary infection because of anatomic or pathological abnormalities which lead to stasis of urine (e.g. retention of urine in the bladder), or are more prone to infections in general because of 1) uremic immunosuppression, 2) concomitant immunosuppressive treatment (e.g. transplant recipients), 3) malnutrition, 4) iron overload (in patients after multiple blood transfusions), or 5) concomitant systemic disease, such as diabetes mellitus.

Definition

Urinary tract infection (UTI) is the presence of microorganisms in the urine (bacteriuria). Significant bacteriuria is considered as the presence of at least 10^5 colony-forming units (CFU) ml^{-1} of freshly voided urine. Symptomatic infection is associated with

inflammation and a white blood cell count higher than 10 cells mm^{-3} in the urine (pyuria, leukocyturia).

Epidemiology

Significant bacteriuria is found in about 1–2% of girls and 3–5% of adult women but seldom occurs in males. The incidence rises dramatically in old age, occurring in 25–50% of patients in geriatric institutions.

Etiology and pathogenesis

Urine is an excellent culture medium and contains sufficient nutrients to support bacterial growth to a density of 10^7 CFU ml^{-1} . Ideal conditions, of urine pH 4–7 and concentration of 300–800 mosmol kg^{-1} , are common. Bacteria most commonly enter via the urethra (ascending infection) or may enter via the bloodstream. Ascending infections, which account for the great majority of cystitis and pyelonephritis, are mainly due to organisms of the normal bowel flora – principally *Escherichia coli* (75% or more).

Predisposing factors are shown in Table 1. Bladder

Table 1 Predisposing factors for urinary tract infection

Cystitis	Pyelonephritis
Urinary stasis	Normal kidney
Outflow obstruction	Pregnancy
Impaired bladder contraction	Stones
Reflux into ureter or diverticulum	Diabetes
	Previous episodes
Foreign body	Abnormal kidney
Bladder stone	Scars (from previous reflux/infection)
Bladder tumor	Obstruction
Instrumentation	Duplex kidney
Catheter	Malformed (dysplastic) kidney
	Vesico-ureteric reflux

outflow obstruction is a major factor and may be due to bladder neck stenosis, urethral stricture or prostatic enlargement. The particular susceptibility of women is due partly to the short urethra and its proximity to the bowel.

The virulence of an organism is related to its ability to adhere to epithelial cells. Less virulent organisms may be pathogenic when the kidney is not normal, e.g. with vesico-ureteric reflux. The epithelial cell receptors for the majority of uropathogenic *E. coli* strains are glycolipids of the globo-series, which interact with adhesins on the bacterial surface. The adhesins are filamentous appendages called fimbriae. The two main types are distinguished by whether their binding to red cells is inhibited by mannose or not. The receptor glycolipids are antigens in the P blood group system with the phenotype P1 as the major binding sites. *E. coli* express both O and K antigens and the pathogenic strains are associated with relatively few serotypes of these two families.

There are a number of host defense mechanisms against UTIs. The bladder luminal surface is covered with a glycoprotein mucin layer. Disruption of this layer allows bacteria to colonize the epithelium. Bacterial washout by the normal urine flow and bladder emptying is a major defense mechanism. Urinary antibodies (immunoglobulin G (IgG) and secretory IgA) are formed against the O and K serotypes, and with pyelonephritis a systemic antibody response to O antigens occurs.

Clinical infection

Acute pyelonephritis

This is associated with fever, malaise, loin pain (which may be bilateral) and bacteruria and leukocyturia. There may also be symptoms of cystitis. In nor-

mal kidneys the organisms are *E. coli*, coagulase-positive *Staphylococcus*, *Streptococcus faecalis* and *Klebsiella*. The presence of other gram-negative organisms (*Pseudomonas*, *Proteus*) would suggest pre-existing disease or a stone.

Other acute parenchymal infections

Rarely, septicemia may lead to microabscess formation in the kidney (usually *Staph. aureus*). Occasionally, with very severe infection, or particularly associated with diabetes, there may be necrosis of the renal papillae (papillary necrosis). Rarely subacute or chronic infections may develop, particularly associated with pre-existing abnormalities of the kidney, and the abscess may extend to form a mass (renal carbuncle) or point through the capsule of the kidney to form a perinephric abscess.

Chronic pyelonephritis

Vesico-ureteric reflux with or without infection may cause scarring of the kidney, and the scarring varies with the degree of reflux. Much of the scarring may have occurred in the fetal or neonatal period, although further scarring in childhood is associated with UTI. In later life progressive damage and renal failure may occur in the absence of both UTIs and reflux and the term reflux nephropathy is now preferred for such cases, rather than the former term chronic pyelonephritis. Ureteric reflux is now recognized as a common inherited disease (autosomal dominant).

Other chronic infections

Complete obstruction may lead to severe infection in the renal pelvis (pyonephrosis) and loss of the kidney. Tuberculosis may involve the renal parenchyma, and this is generally associated with a ureteritis and cystitis. Obstruction with stone disease may be associated with a chronic granulomatous pyelonephritis (xantho-granulomatous pyelonephritis). Malakoplakia is a rare chronic infection of the renal substance which may simulate a renal tumor. It is associated with an inability of macrophages to kill *E. coli* successfully.

Cystitis

Cystitis is associated with frequency and urgency of micturition and painful micturition (dysuria). Bacterial infection is usually due to *E. coli*. Chronic cystitis with pyuria but cultures that are reported as 'sterile' is highly suggestive of tuberculous infection. In some women recurrent symptoms of cystitis occur in the absence of significant bacteruria and pyuria (acute urethral syndrome). The cause is unknown but

may be due to fastidious organisms (such as *Gardnerella vaginalis*) or organisms that are considered as part of the normal urethral flora.

Urethritis

Urethritis is associated with dysuria and a urethral discharge. Infection from *Neisseria gonorrhoeae* should be considered; nongonococcal infections (non-specific urethritis) include *Chlamydia trachomatis* and *Ureaplasma urealyticum*.

REOVIRUS, INFECTION AND IMMUNITY

Amy Hodson Thompson, Lucille London and Steven D London, Department of Microbiology and Immunology, Medical University of South Carolina, Charleston, South Carolina, USA

Mammalian reoviruses are the prototype members of the *Orthoreovirus* genus of the Reoviridae family of segmented, double-stranded (ds) RNA viruses. Reovirus virions are nonenveloped and consist of two concentric protein capsids. While originally isolated from the respiratory and gastrointestinal tracts of humans, reovirus (reo – respiratory and enteric orphan virus) infections do not appear to be a source of major symptomatic respiratory or enteric disease. However, they are ubiquitous in the environment and the majority of the human population acquires a reovirus-specific antibody response in infancy or early childhood. Reovirus infection of rodents provides an excellent model for the study of viral pathogenesis and host immune responses at both systemic and mucosal sites.

Characteristics of the organism and its antigens

The mammalian reoviruses are classified into three serotypes based on neutralization and hemagglutination-inhibition tests. The prototypical strain(s) of the three reovirus serotypes are shown in Table 1. The reovirus genome contains ten discrete dsRNA segments which are resolved into three class sizes by polyacrylamide gel electrophoresis (four small, three medium and three large). Each segment is translated into a unique mRNA which codes for a unique structural or nonstructural viral protein. With the exception of the S1 gene, each of these RNAs appear to be monocistronic and produce a single primary gene product. These viral proteins are also resolved into

Table 1 Prototypical strains of mammalian reoviruses

Serotype	Prototype strain(s)	Source
Reovirus type 1	Lang (type 1/L)	Human GI tract
Reovirus type 2	Jones (type 2/J)	Human GI tract
Reovirus type 3	Dearing (type 3/D) Abney (type 3/A)	Human GI tract Human respiratory tract

GI, gastrointestinal.

class sizes (σ , small; μ , medium; λ , large). The major components of the inner protein capsid of reovirus are $\lambda 1$ and $\sigma 2$, with $\lambda 3$ and $\mu 2$ being minor components. Sigma 3 and $\mu 1C$ (a 72 kDa cleavage product of the $\mu 1$ protein) are the major outer capsid proteins. Twelve spikes extend from the inner to outer protein shells and are composed of five molecules of the $\lambda 2$ protein. The vertices of the 12 spikes extend to the outer capsid and are each associated with 2–4 molecules of the $\sigma 1$ protein. Figure 1 illustrates the structure of reovirus virions and the relationship of the viral genome and structural proteins. While morphologically similar, the three serotypes of reoviruses have varying levels of homology at the genetic level. RNA hybridization studies show that reovirus 1/L and reovirus 3/D are approximately 70% related, while reovirus 2/J is only 10% related to the other serotypes.

The segmentation of the reovirus genome has facilitated the making of reassortant virions. Simultaneous infection of tissue culture cells *in vitro* with two reovirus serotypes results in the generation of

Figure 1 Reovirus virion structure and genome.

reoviruses which can have gene segments derived from either parent. The origin of individual gene fragments from reassortant clones can be determined by comparison of the pattern of dsRNA migration in polyacrylamide gel electrophoresis. The use of reassortant clones has allowed unique biological properties of particular serotypes to be mapped to individual reovirus genes and proteins. For example, by analyzing reassortant clones, the $\sigma 1$ protein has been found to be the viral hemagglutinin as well as the target of serotype-specific neutralization antibodies.

The primary pathway for reovirus penetration of host cells involves receptor-mediated endocytosis, fusion with lysosomes and degradation of two of the outer capsid proteins ($\sigma 3$ and $\mu 1/\mu 1C$), which results in the formation of intermediate subviral particles (ISVPs). In the gastrointestinal tract, ISVPs can be directly formed in the lumen of the small intestine and this form of the virion appears to be required for adherence to specialized absorptive cells (M cells) overlying the organized lymphoid follicles (Peyer's patches) of the gut. Full activation of viral transcriptase activity requires further digestion of outer capsid proteins in the cell to form cytoplasmic viral cores. Newly synthesized positive strands are capped and are used as messenger RNA for protein synthesis as well as templates to synthesize complementary negative strands in nascent progeny viral particles.

Viral spread and pathology

The mucosal routes of reovirus entry into the host are via the gastrointestinal and respiratory tracts. After entering Peyer's patches via M cells, reovirus 1/L spreads to the mesenteric lymph nodes (MLNs)

and the spleen. Reovirus 3/D infection of the gut is more localized, with infectious virions detectable only in the gut and MLNs. High inoculum doses of reovirus 1/L ($\sim 10^{10}$ PFU) by the oral or intravenous routes results in site-specific viral replication in the ileum with the resultant generation of ileitis. In contrast, intravenous infection with similar doses of reovirus 3/D induces duodenitis, jejunitis and ulcerative colitis, with the ileum being spared. Studies with reassortant clones suggest that the $\sigma 1$ protein is the major viral determinant of site-specific intestinal disease. Respiratory reovirus infections of rodent lungs may involve a similar mechanism of viral entry into organized lymphoid nodules via M cells overlying bronchus-associated lymphoid tissue. In addition, reovirus also replicates in alveolar type I epithelial cells of the lung which is associated with the generation of pulmonary pneumonia. Although the details of viral spread following respiratory infection have not been delineated, it is likely that the virus spreads from the lung to the lung-associated lymph nodes, then to the bloodstream, in a manner similar to the events following reovirus infection of the gastrointestinal tract.

In addition to mucosal routes of infection, experimental models of reovirus infection using alternate routes of infection have been used to study particular aspects of viral pathology and viral immunity. Reovirus-specific immune responses can be stimulated in adult, immunocompetent mice after inoculation through a number of routes including intraperitoneal, intradermal, subcutaneous, and by direct inoculation in the footpads. Studies utilizing typical viral inoculation doses of $\sim 10^7$ PFU are not associated with pathological responses in adult mice (via systemic or gut routes of immunization). In contrast

to reovirus infection of immunocompetent adult mice, intracerebral infection of neonatal mice results in reovirus serotype-specific central nervous system (CNS) pathology. In neonatal mice, intracerebral inoculation of reovirus 1/L results in a nonfatal ependymitis followed by hydrocephalus. In contrast, intracerebral infection of neonatal mice with reovirus 3/D results in the development of a lethal encephalitis. Studies utilizing reassortant viruses have demonstrated that the S1 gene product ($\sigma 1$) determines the specificity of infection for neuronal versus ependymal cells. In addition to the intracerebral route, reovirus 3/D also produces a fatal encephalitis after footpad inoculation via spread to the CNS following local replication in muscle tissue. While reovirus 3/D does not result in encephalitis after oral inoculation, a murine isolate (reovirus 3 clone 9) does produce encephalitis after oral inoculation. The use of reassortant viruses have demonstrated that the M2 gene product ($\mu 1$) is the determinant of viral replication and systemic spread from the gastrointestinal tract.

In addition to the infection patterns previously described, infection of neonatal mice with any of the three reovirus serotypes can result in hepatic and pancreatic involvement. Hepatic infection leads to zones of necrosis and hemorrhage, and reovirus 3/D infects the mucosal cells of the bile duct, leading to chronic obstructive jaundice. Reovirus infection of acinar cells of the exocrine pancreas results in cellular injury and an inflammatory infiltration which can progress to extensive necrosis. Infection of endocrine areas of the pancreas by reovirus 3/D (insulin-producing β islet cells) and reovirus 1/L (insulin-producing β islet cells as well as other islet cell types) results in cellular injury, and may also induce an autoantibody response through upregulation of major histocompatibility complex (MHC) expression. More recently, a reovirus type 2-induced diabetes-like syndrome in neonatal mice has been described which is partially mediated by immune mechanisms. In this model, immunosuppressive treatment reduced or prevented the development of diabetes-like syndrome.

Infection of neonatal mice with reovirus 1/L or 3/D can result in a 'runt syndrome' characterized by small size, reduced growth rates and an oily hair effect (coat hair stuck together in irregular tufts). It is thought that this syndrome is caused by severe malabsorption due to coexisting pancreatic and hepatobiliary disease (reovirus 3/D infection), and in the case of reovirus 1/L, additional infection of the growth hormone-producing cells of the anterior pituitary. Because of the impact of reovirus infection on many organ systems in rodents, and the presence of

reovirus-specific antibody in humans, it has been hypothesized that reovirus may be involved in similar human disease patterns. However, attempts to detect the presence of reovirus in human tissue have not been successful, and it appears at this time that reovirus does not play a significant role in human hepatic disease.

The availability of severe combined immunodeficient (SCID) mice has more recently demonstrated the innate pathogenicity of reovirus infections in the absence of functional B and T lymphocytes. While infectious virions are typically cleared within the first 2 weeks after inoculation in immunocompetent mice, young adult SCID mice infected with reovirus 3/D develop a chronic infection of multiple organ systems. SCID mice infected with reovirus 1/L develop a more severe infection with persistent high virus titers in multiple organs and the development of severe hepatitis, which is frequently lethal within the first 3 weeks of the infection.

Table 2 lists the uses of reovirus in probing the causes of viral spread and pathology.

Immune responses of the host

As is common with viral infections, reovirus has been shown to elicit vigorous humoral and cell-mediated immune responses. Serum antibodies specific for reovirus are common in human and animal populations and this demonstrates the ubiquitous distribution of reoviruses in the environment. The predominant specificity of reovirus-specific antibodies is against the outer capsid protein $\sigma 1$. However, serum antibodies to other viral proteins are also elicited. While reovirus-specific antibodies to the $\sigma 1$ hemagglutinin protein are predominantly serotype specific, reovirus-specific monoclonal antibodies (mAbs) against other external capsid proteins have demonstrated serotype nonspecific neutralizing and/or hemagglutinin inhibition abilities. In the case of reovirus 3/D, a panel of mAbs has identified distinct neutralization and hemagglutination inhibition domains. Similar domains have not been identified for reovirus

Table 2 Uses of reovirus to probe causes of viral spread and pathogenesis, delineate immune mechanisms and provide models of human disease

Induction of autoimmune diabetes

I/L. Reovirus-specific mAbs can inhibit virus attachment to host cells, or, after binding, inhibit internalization and intracellular proteolytic uncoating to the ISVP form. Systemic routes of reovirus infection also elicit viral-specific cytotoxic T lymphocytes (CTLs) as well as T cell-mediated delayed-type hypersensitivity (DTH) reactions. While reovirus-specific CTLs are predominantly serotype nonspecific, the reovirus-induced DTH response is serotype specific and is determined by the S1 gene product. Reoviruses can also induce both antigen-specific and antigen-nonspecific immunosuppression. The administration of nonreplicating virions by the intravenous or oral routes results in T cell-mediated suppression of the reovirus-specific DTH response *in vivo*. Reovirus 3/D inhibits mitogen-induced T cell proliferation, as well as T cell responses specific for unrelated viruses, via its interaction with a subset of reovirus 3/D receptor-bearing CD8⁺ T lymphocytes.

The ability of reovirus infection to elicit a number of pathological conditions in neonatal or immunocompromised mice provides a model for the study of the protective nature of viral-specific humoral and/or cell-mediated immunity. The administration of reovirus-specific polyclonal antisera protects neonatal mice from reovirus 3/D-induced encephalitis. Studies utilizing reovirus-specific mAbs of varying isotypes and specificities, and analysis of the effect of these antibodies on virus spread and replication in the CNS, have shown that their protective effect can be mediated through inhibition of primary replication, prevention of neural spread and inhibition of growth within the spinal cord. Further studies have shown that a single antibody may not work in all capacities, and also that isotype and avidity (above a certain threshold) does not determine which features any single antibody will possess. Protection against reovirus-induced encephalitis in neonatal mice can also be transferred from immune dams to neonates either transplacentally or by suckling, demonstrating the importance of maternal immunity in protection of neonates from infectious pathogens. In neonatal mice, adoptive transfer of reovirus-immune splenocytes as well as the passive transfer of reovirus-specific antibodies has demonstrated humoral and cell-mediated immune protection against reovirus-induced myocarditis.

While the generation of reovirus-specific T cell responses in systemic tissues is not unexpected, the ability of reovirus to elicit a gut mucosal infection via M cell entry into Peyer's patches has provided a valuable model to analyze viral-specific immunity in the context of the gastrointestinal tract. Gut mucosal application of reovirus generates a virus-specific B cell response in Peyer's patches that is dominated by

immunoglobulin A (IgA) memory cells. In addition, the gut mucosal application of reovirus results in the appearance of virus-specific CTLs in both Peyer's patches and the intestinal epithelium. Frequency analysis of CTLs occurring in Peyer's patches and peripheral lymph nodes 6 days and 6 months after gut mucosal stimulation has demonstrated that a persistent gradient of precursors is established, with higher frequencies present in Peyer's patches. These results suggest that, for enteric viruses, the generation of a CTL response in Peyer's patches may be important in preferentially repopulating mucosal tissues with effector CTLs, which could result in the local containment of infections in the gut. The ability of adoptively transferred reovirus-specific CD8⁺ CTLs from the intestinal epithelium to protect neonatal mice lethally challenged with reovirus 3/D demonstrates the *in vivo* relevance of viral-specific T cell immunity in the gastrointestinal tract. The adoptive transfer of reovirus-immune Peyer's patch lymphocytes before infection protects SCID mice from persistent viral replication in multiple tissues and also from hepatitis. Reovirus infection of the lower respiratory tract results in an infiltration of T and B lymphocytes, including reovirus-specific CTLs, and provides a model for the study of the inter-relationship of respiratory-mucosal immunity with gastrointestinal immunity and other components of the common mucosal immune system.

Vaccines

The ability of reovirus to enter Peyer's patches via M cells suggests that members of the Reoviridae family may prove useful as mucosal vaccines if they could be engineered to carry heterologous B and/or T cell epitopes. Such an approach may be feasible since both *Rotavirus* and *Orbivirus* (bluetongue virus) virus-like particles (produced by the expression of multiple viral capsid proteins in insect cells via a baculovirus expression system) are reported to be highly immunogenic in a number of animal species. Additionally, studies of the reovirus 3/D receptor, using an anti-idiotypic approach, have identified a method of inducing immunity to pathogens which is independent of *in vivo* immunization with pathogenic agents. In these studies, the immunization of mice with anti-idiotypic antibodies specific for an idiotypic marker of a major neutralization domain-binding mAb has been found to induce reovirus-specific B and T cell immunity *in vivo*. Thus, while reovirus infections are not associated with significant human disease, these approaches may be useful for the generation of vaccine strategies against other pathogens. In the Reoviridae family, such an

approach may be useful for the design of vaccine strategies for avian reovirus infections which are a significant source of morbidity in the commercial poultry industry.

REPRODUCTIVE TRACT INFECTIONS

Morris D Cooper, Department of Medical Microbiology and Immunology, Southern Illinois University, School of Medicine, Springfield, Illinois, USA

Nancy M Khardori, Department of Internal Medicine, Southern Illinois University, School of Medicine, Springfield, Illinois, USA

The reproductive tracts of the male and female are anatomically distinct and present different sites for microbial colonization and pathogenesis. Primary infections of the reproductive tract are preceded by colonization of the tissue. A variety of microbial agents are frequently associated with the infections. These include *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*, *Ureaplasma urea-*

lyticum, *Treponema pallidum*, mycoplasmas, human papillomavirus (HPV), herpes simplex virus (HSV), and the gram-negative enteric bacilli. Human immunodeficiency virus (HIV) certainly enters the host by way of the reproductive tract but will not be dealt with here because of its diverse and multiorgan clinical manifestations.

Neisseria gonorrhoeae

The gonococci are oxidase-producing gram-negative diplococci that cause sexually transmitted infections including urethritis and cervicitis. The local complications of the infection are salpingitis and pelvic inflammatory disease in the female and epididymitis and urethritis in the male. Disseminated gonococcal infection (DGI) occurs in 0.5–3% of infected patients. The gonococci have many virulence factors which contribute to their pathogenesis. Pili attach to receptors on the mucosal epithelial cells which line the reproductive tract of humans. Their expression is under genetic control and has a high degree of antigenic variability. In experimental infections of volunteers with nonpiliated gonococci approximately 80% did not develop active infections. Other surface-exposed molecules involved in the biological activity of the gonococcus are proteins I, II and III, lipooligosaccharides and peptidoglycan. 1) Protein I (PI) is a major outer membrane protein and functions as a porin. It has two structural subtypes which are designated IA and IB. Isolates express only one subclass of PI. However, antigenic variation allows for the further division of the IA and IB into other serotypes. 2) Protein II (PII) consists of several different proteins (PII a–h). Individual strains may possess as many as three different PIIs. These proteins are involved in attachment and the production of bactericidal antibodies and have a high degree of antigenic variability with rates approaching frequencies of 10^2 to 10^3 . 3) Protein III (PIII) is antigenically conserved and functions as a site for blocking antibody attachment. 4) Lipo-oligosaccharide (LOS) is present in the outer membrane and frequently is excreted in the form of blebs in actively dividing gonococci. This molecule is toxic for epithelial cells and has a particular affinity for ciliated epithelial cells. LOS disrupts tight junctions and the intact ciliated epithelial cells are sloughed intact from the epithelial surface following exposure to LOS. 5) Peptidoglycan is an integral component of the cell wall of these gram-negative organisms and is responsible for epithelial cellular cytotoxicity. These components contribute to the virulence of the organism and enhance its pathogenicity to mucosal tissue (Figure 1).

The ability of gonococci to evade immune surveillance resides in their extraordinary ability to undergo phase and antigenic variation. This variation leads to frequent changes in expression of the antigenic composition as no single serotype predominates. Therefore, the host is unable to mount an effective protective immune response. At this time there is no vaccine available against gonococcal infection and the potential for developing one is not close at hand.

Chlamydia trachomatis

Chlamydia are gram-negative bacteria which have a unique developmental cycle. *C. trachomatis* is the only reproductive tract pathogen. The *C. trachomatis* serovars D–K and L_{1–3} are involved in urogenital infections and cause in excess of 50 million cases of genital infection worldwide, including urethritis, mucopurulent cervicitis, and salpingitis (serovars D–K), as well as lymphogranulovenereum (LGV) (serovars L_{1–3}).

The chlamydia infect primarily columnar epithelial cells where the organisms undergo a unique replicative cycle. Multiplication occurs in intercytoplasmic vacuoles where they are energy parasites and use ATP produced by the host cell. The cell wall contains the major outer membrane protein (MOMP) which is responsible for the rigidity of the cell wall since chlamydia lack peptidoglycan. These molecules are responsible for the species-specificity of the organisms. The cell wall also contains a lipopolysaccharide (LPS) (Figure 2).

Although nonspecific host responses to *C. trachomatis* and its antigens exist, specific immune responses (both humoral and cellular) appear to be involved in modifying infection or conferring immunity to reinfections. The presence of serovar-specific antibody has been documented in women with upper genital tract infection but correlation between the humoral immune response and resistance to infection has been difficult to make. The role of the cell-mediated response is even less well understood in humans than in many animal models. In experimental infection both responses are involved in the resolution of infection. Most of the immune response involves local mucosal immunity as the infection is restricted to the epithelial layer of the cervix, endometrium and fallopian tubes. However, it is generally accepted that mucosal immunity to chlamydial genital infection does not exist and recurrent infections are common. T Cells are recruited to the area of infection and through the release of inflammatory cytokines there is host cell-mediated damage to the mucosa.

Although no vaccine is available for clinical use, a number of laboratories are evaluating vaccine components of *C. trachomatis* for their efficacy in inducing a protective immune response.

Treponema pallidum

T. pallidum is the etiological agent of syphilis. It is a long spiral-shaped rod encased in a protoplasmic cylinder. It has a peptidoglycan layer and is motile by means of an axial filament. The fact that this bacteria

Figure 1 Immunobiology of gonococcal infection of the human fallopian tube mucosa. Gonococci attach to the microvilli on nonciliated epithelial cells and are internalized by a phagocytic mechanism that results in a membrane-bound vesicle. This process takes approximately 24 h. At the same time, the gonococci liberate from their surface two molecules (lipo-oligosaccharide and peptidoglycan) that are toxic to the ciliated epithelial cells and they slough as a result of this action. Gonococci continue to migrate through the epithelial cell and by 72 h after infection they have begun an orderly exocytosis from the epithelial cell. At this point in the infection, the gonococci are present in the lamina propria where they can encounter a variety of immunocompetent cells to initiate both B and T cell responses as well as the increased production of cytokines (e.g. TNF α). (Reproduced from Cooper and Moticka (1996) by copyright permission of Blackwell Science.)

cannot be cultured on artificial media has hampered studies to characterize the organism and study the immune response to the infection. No toxin production has been documented.

After infection with *T. pallidum*, polymorphonuclear leukocytes are attracted to the site where treponemas are killed. Activated macrophages also phagocytose and kill *T. pallidum*. Specific responses to treponemal infection involve both T and B cells. The initial humoral response is the production of antibodies which are nonspecific for *T. pallidum*. These are detected by serological tests such as the Venereal Disease Research Laboratory (VDRL) or the RPR (rapid plasma reagin) tests which are used to screen for syphilis.

By the time of the primary infection (chancre), specific humoral and cell-mediated immune mechanisms have been activated. Treponema-sensitized lymphocytes and activated macrophages are present in the lesions and antitreponemal antibody is detectable in serum. This leads to a decrease but not elimination of the treponemas. In the absence of treatment

incompletely understood events occur and a generalized infection called secondary syphilis occurs. The time and appearance of disseminated lesions suggest that there is a hematogenous spread throughout the body. The development of systemic immunity modulates the appearance and severity of the lesions. The infected individual has high nonspecific as well as specific antibody titers. However, delayed-type hypersensitivity (DTH) is usually absent.

Eventually the host suppresses the infectious process sufficiently and lesions are no longer apparent. This leads to a period of clinical latency. By this point, cell-mediated immunity is now present. Immobilizing treponemal antibody is present but it is difficult to demonstrate a protective humoral immune response. Even during latency, *T. pallidum* can be isolated from both human and experimentally infected animals. The spirochetes may be sequestered in an immunologically privileged site, e.g. the central nervous system. The infection may remain latent for the remaining natural course of the disease or manifest itself as tertiary syphilis.

Figure 2 Immunobiology of chlamydial infection of the human fallopian tube mucosa. Elementary bodies (EBs) attach to the microvilli of epithelial cells prior to invasion of the epithelium. In some cases, where EB aggregates are large, a local cytotoxicity is seen. The chlamydia have a normal developmental cycle in the epithelial cells but do not usually penetrate the basolateral portion of the cell. The EBs cause a lesion in the luminal surface of the infected epithelial cells and are released where they are capable of infecting other cells. (Reproduced from Cooper and Moticka (1996) by copyright permission of Blackwell Science.)

Since the natural history of the disease is unique and much remains to be understood about the biology of the spirochete, discussions regarding the development of a vaccine are premature.

Human papillomavirus

The human papillomavirus (HPV) belongs to the family Papovaviridae and up to 100 types have been recognized. The HPVs are naked viruses with a double-stranded DNA genome. Clinically they cause genital warts or condyloma acuminata affecting the mucosal lining of the genital tract as well as cutaneous sites. Warts are generally benign, self-limiting tumors which may regress spontaneously. All layers of the epithelium are represented in the wart and the basement membrane is not breached. The virus enters one or a few cells in the epithelium (basal germinal layer) presumably through a traumatic process. The virus replicates exclusively in the nucleus and cell growth is stimulated.

Several human and animal papillomaviruses are

associated with naturally occurring cancers. There is a long latency period with the need for a number of cofactors for the progression of the papillomas to malignancy. This is consistent with a multistep mechanism of carcinogenesis. It is speculated that papillomavirus infection leads to 'immortalization' of the cells (the resulting warts show abnormal mitosis in the suprabasal layers of the epithelium). However, a second event (ultraviolet light, X-irradiation, cellular mutations, etc.) is required for the development of the invasive tumor. More than 90% of the cervical cancers contain HPV DNA, usually types 16, 18 or 31. These same HPV types are found in the precursor lesion or cervical intraepithelial neoplasia. The detection of HPV mRNA in cervical cancer tissues indicates that HPV genomes is expressed in these tissues. Many epidemiological investigations demonstrate a close relationship between HPV infection and cervical cancer.

Warts increase in number and size in conditions that suppress T cell functions (i.e. pregnancy and organ transplantation). Histological examination of

regressing warts indicates the presence of a cell-mediated immune response. Viral antigens which have been obtained from clinical lesions have been used to study humoral and cell-mediated immune responses to HPV infections with limited success. There is no vaccine currently available for HPV.

Herpes simplex viruses type 1 (HSV-1) and type 2 (HSV-2)

There are several features which distinguish herpes viruses from other viruses. The genome is a linear double-stranded DNA ranging from 125 000 to 250 000 base pairs. The virion is composed of the DNA-containing core; an icosahedral capsid, which is about 100 nm in diameter and exhibits 162 morphological units (capsomeres) on its surface and an outer lipid-containing membrane or envelope. These viruses use both the nucleus and the cytoplasm of the host cell for their replication.

The pathology and epidemiology of herpes virus infections depend on the mode of viral replication, associated cytotoxicity as well as their capacity to cause latent infections. Clinically many of the infections caused by HSV-1 and HSV-2 are indistinguishable. Despite the fact that these strains are predominantly isolated from different anatomical sites, it is clear that strains of either type can initiate and establish infection at either genital or extragenital sites.

HSV rarely causes severe disseminated disease in adults, except when cell-mediated immunity is compromised. Among infected individuals who have no known immunologic defects, the responses to infection typically range from no clinical signs and symptoms to localized lesions. Mild to moderate systemic symptoms followed by periodic recurrence of localized lesions may occur. Asymptomatic genital infections are responsible for a significant number of transmissions. Genital HSV infections are a significant public health problem. It is estimated that 1 in 4 Americans are infected with HSV. Cell-mediated immune deficiency rather than antibody synthesis is associated with increased incidence of disseminated disease caused by HSV. It is likely that cell-mediated effector mechanisms are more important for preventing the spread of infections. Recurrent localized herpetic lesions can occur in the presence of high antiviral antibody titers. Despite this fact, antibodies are important. Many interrelated issues occur between cell-mediated immunity and the humoral immune response that regulate immediate antimicrobial effector responses.

It has been suggested by studies on protective immunity to HSV infections that the envelope glycoprotein antigens have the most likely potential to be

protective. However, it has been difficult to predict which antigens are most important in inducing protective cell-mediated responses. Some of the viral glycoproteins expressed by HSV may not only induce immune responses but also modulate effector mechanisms in ways that have not been precisely defined. Immune responses to viral antigens can, in some instances, cause as much or more damage in affected tissues as the cytopathology associated with viral replication.

Live attenuated as well as subunit HSV vaccines have been studied. The disadvantage of live vaccines is that even an attenuated HSV strains can establish a latent infection. The study of subunit vaccines revolves around the myriad of viral proteins, which is the best immunogen for protective immunity and methods to present them to the host. Therefore, the promise of an effective vaccine is not immediately apparent.

Other reproductive tract pathogens

Urethral colonization by gram-negative enteric bacilli, such as *Escherichia coli*, cause bacteriuria with no inflammation. The nonsexually transmitted diseases of the reproductive tract are usually caused by enteric organisms, e.g. *E. coli*, but can often be polymicrobial. The uropathogenic strains of *E. coli* possess pili that allow ready adherence to urogenital epithelial cells.

The mucosal surfaces which are exposed to the external environment are under a continual state of bacterial colonization. Local immunity is generated primarily by the secretory immune system and is characterized by the secretion of immunoglobulin (Ig) classes in levels different than in serum. The mucosal immune system of the reproductive tract has a different compartmentalization to that of other mucosal systems. In the genital mucosa there is a lack of organized tissue (i.e. Peyer's patches) and specialized cells (i.e. M cells). These differences in the construction of the local immune apparatus may account for the difficulty in generating local protective immunity against many reproductive tract pathogens. A better understanding of the local mucosal system in reproductive tract tissue will aid in the development of effective protective immune responses to the infections which predominate in the reproductive tract.

REPTILIAN IMMUNE SYSTEM

Rashika El Ridi, Zoology Department, Faculty of Science, Cairo University, Cairo, Egypt

Reptiles evolved from primitive amphibians nearly 300 million years ago during the Carboniferous period. They sprang from a basic stock, the long-extinct order Cotylosauria or 'stem reptiles'. A side-branch of stem reptiles led to the turtles and tortoises: order Testudines = Chelonia. The closest surviving descendants of the cotylosaurs are the tuatara that live on a few islands off New Zealand. Descended from ancient forms related to the tuatara is the much more successful order of the Squamata comprising the lizards (suborder Lacertilia) and snakes (suborder Ophidia = Serpentes). Stem reptiles also gave rise to other lines. One of these lines led to the crocodilians and modern birds; another led to the mammals. Reptiles are not only the closest ancestors of the birds and mammals, but are also the first vertebrates to exhibit the change from free-living larvae, as in fish and amphibians, to an embryo completely protected by an amnion similar to that found in avian and mammalian embryos. Therefore, study of immune processes in modern-day reptiles holds the promise of offering significant clues to the origin of certain facets of the immune response.

Reptiles are moderately abundant in the tropics, but less common in temperate zones and absent from cold climates. They are often said to be 'cold-blooded' like fish and amphibians as opposed to the 'warm-blooded' birds and mammals. This means

that reptiles lack the ability to regulate their metabolic heat for the production of sustained body warmth and a constant temperature. So, their temperature changes with that of their surroundings, hence the name poikilotherms, and they depend on an external source, rather than their own metabolism, for body warmth, i.e. they are ectothermic. Consequently, the structure and functional activity of several reptilian organs, including those of the immune system, are greatly modulated by environmental conditions.

Lymphoid organs and cells

The yolk sac is the first and major hematopoietic organ in reptilian embryos. Later in development, blood cell formation occurs in fetal spleen and fetal liver. Hematopoiesis in bone marrow starts near the end of embryonic development and persists throughout life. The thymus, the first organ to become lymphoid during reptilian ontogeny, is a bilateral organ lying on either side of the neck in lizards and immediately anterior to the heart in snakes; it is usually multilobulated in turtles. The thymic primordium originates as dorsal outgrowths of pharyngeal pouches II and III in lizards, IV and V in snakes and III and IV in turtles that detach from the pharyngeal wall and appear as a condensation of epithelial cells

surrounded by mesenchyme, with no capsular device yet formed. Thymic lobes increase in size and fibroblasts condense around the organ to form a distinct capsule. The epithelial thymic rudiment is then invaded by bloodborne large, basophilic, undifferentiated cells, which divide and mature into large, medium and small lymphocytes. A complete demarcation into cortex and medulla is apparent just before hatching (or birth). Later on, the thymus lobes show a peripheral cortex loaded with lymphocytes, and central medulla with fewer thymocytes so that the epithelial groundwork is easily discernible. Numerous macrophages and large and small, round, oval or elongate myoid cells are seen in the medulla and corticomedullary junction; cross-striations similar to those of skeletal muscle are evident in some myoid cells. Dendritic-like cells, with numerous labyrinthine processes forming gap-like junctions with the neighboring lymphocytes, are frequent in the medulla of the turtle *Mauremys caspica*. These cells lack Birbeck granules and the extensive membrane-membrane contacts like those reported for mature interdigitating cells of mammalian lymphoid organs, but often contain abundant cell debris and dense bodies, suggesting a certain degree of phagocytic activity. It is important to note that the thymus appears so well developed only in reptiles collected from the field, or maintained in the laboratory under suitable conditions of temperature, photoperiod and feeding, during optimal, species-specific, seasonal conditions (Figure 1). Otherwise, the thymus shows various degrees of degeneration, whereby the number of lymphocytes in the cortex and medulla greatly decreases and numerous myoid cells and epithelial cysts are observed. Reptilian thymic cysts range from minute intracellular structures to formations over 0.1 mm in diameter. They probably represent foci of cellular degradation segregated from surrounding thymic parenchyma by a continuous layer of epithelial cells. Involution continues with persistence of the adverse environmental conditions. Cortical epithelial cells degenerate and dendritic cells are absent. Eventually, the thymus may transform into fibrous tissue and become scarcely detectable. This involution is totally reversible, as in suitable seasonal and other ambient conditions rebuilding of the thymus begins and progressively proceeds to a mammalian-like picture and organization. The issue of whether the degenerated epithelial cells found in involuted thymus are eliminated and substituted by a new cell population, or recover with the advent of optimal seasonal conditions, remains unresolved as yet; nor have the waves of thymocyte production in the rejuvenating thymus been investigated.

The spleen in reptiles is the most important peri-

Figure 1 Development profile of thymus in: (A) lizards; (B) snakes and (C) turtles the year round.

pheral lymphoid organ. Histogenesis of the spleen commences with a thickening of the dorsal mesogastrium. The splenic rudiment then buds into the body cavity; later, blood sinuses develop as separate cavities in the mesenchyme, and spleen acquires its characteristic form by development of the capsule. The spleen in lizards, snakes and tortoises becomes lymphopoietic much later than the thymus, which is fully differentiated before any lymphocytes appear in the splenic rudiment. However, thereafter the spleen shows intense hematopoietic and lymphopoietic activity. After hatching and in adult life the spleen usually reveals well-developed and clearly defined white pulp, arranged around central arterioles, and red pulp, composed of blood sinusoids and cell cords. In the white pulp the framework of reticular cells contains macrophages, dendritic cells predominantly located in the periphery of the white pulp, and numerous densely packed lymphocytes. There is evidence to indicate that 50–70% of reptilian splenic lymphocytes are thymus derived (T-like cells) and are located in thymus-dependent juxta-arteriolar areas. The remaining lymphocytes are surface immunoglobulin (sIg) bearing, homologous to the B cells of aves and mammals. In lizards and tortoises, 25–50% of splenic lymphocytes are sIgM⁺, and 5–20% sIgY⁺. The sIgY⁺ lymphocytes coexpress sIgM. Germinal centers and nodules typical of mammalian secondary lymphoid organs are lacking in reptiles. As in the thymus, the “ideal” spleen architecture is only observed in reptiles living in optimal conditions. Otherwise, the splenic lymphoid aggregates regress in size, and the number of T-like cells sharply diminishes. A significant proportion of sIg⁺ lymphocytes survive even in animals exposed to rigorous environmental conditions (Figure 2). This suggests that reptilian T- and B-like cells differ in their sensitivity to environmental factors. The drastic depletion of splenic T-like cells is, however, reversible (Figure 2). It is indeed now established that the lymphoid elements of adult reptiles atrophy and regenerate, in a periodic manner, with the cycle of the species-specific adverse and optimal seasons.

Gut-associated lymphoid tissue (GALT) develops only after hatching in lizards, snakes and chelonians. Although reptiles do not possess tonsils, Peyer's patches or an appendix, numerous lymphoid aggregates occur in the mucosa and submucosa along the gut in most reptiles and consist of lymphocyte populations which exhibit differential sensitivity to seasonal conditions. In the lizard *Chalcides ocellatus*, esophageal lymphoid aggregates diminish considerably in size and number 1) during autumn and winter as compared with spring and summer, 2) after adult thymectomy, and 3) following hydrocortisone treat-

Figure 2 Number of splenic T-like (■) and B-like (□) cells of the lizard, *Chalcides ocellatus*, the year round. (Adapted from El Ridi R and Kandil O (1981) Membrane markers of reptilian lymphocytes. *Developmental and Comparative Immunology* 5(Suppl 1): 143).

ment, suggesting they consist essentially of T-like lymphocytes. Conversely the lymphoid accumulations of the small and large intestine are resistant to seasonal changes, adult thymectomy and hydrocortisone treatment, thus implying they are constituted essentially of B-like cells and that GALT in reptiles is a major reservoir of B cells. Additionally, adult splenectomy in lizards does not impair immune antibody responsiveness to foreign erythrocytes, and the nearly GALT-less lizards *Agama stellio* and *Chamaeleon chamaeleon* produce but a negligible amount of specific antibodies when confronted with various mammalian erythrocytes or human serum albumin, via the intraperitoneal, intramuscular or subcutaneous routes, and whether or not the antigen is incorporated in Freund's adjuvant. These findings indicate that the humoral immunological tasks in reptiles are shared between the spleen and GALT, and support the possibility that part of the GALT represents a bursa of Fabricius equivalent. T- and B-like cells constitute essentially 75–90% and 10–25% of peripheral blood lymphocytes (PBLs) of adult lizards, snakes and tortoises, with wide, season-dependent variations. In conclusion, despite the absence of true lymph nodes, the reptilian lymphoid system is homologous to that of mammals, from which it differs, however, by its exceptional sensitivity to ambient conditions.

T cell functions

Mitogen responsiveness in reptiles was first described in *Alligator mississippiensis* by Cuchens and Clem,

whereby PBLs were shown to respond by powerful proliferation to concanavalin A (Con A) and lipopolysaccharide. Significant Con A-mediated mitogenesis is consistently observed in thymocytes, spleen cells and PBLs of lizards and snakes. Acute graft-versus-host reaction is readily induced in newly hatched (or born) turtles and lizards following intraperitoneal injection with spleen cells from adult allogeneic donors. Reptilian lymphocytes are also able to respond powerfully to alloantigenic cells in the mixed leukocyte reaction (MLR). Significant responses are obtained in 50–90% of random MLR cultures performed, depending on the species examined, culture conditions and putative major histocompatibility complex (MHC) gene differences between responder and stimulator. Data gathered in several species suggest that the lymphocyte activating determinants in MLR are not extremely polymorphic in reptiles. Most importantly, seasonal and other environmental parameters, including captivity, malnutrition, etc., have an extremely strong impact on reptilian T cell functions. Deterioration in these ambient factors is paralleled by significant impairment, up to complete abrogation, of the different aspects of T cell responsiveness. So, in inadequate seasonal and laboratory conditions mitogen and MLR responsiveness is abolished (Tables 1 and 2). The severe impact of ambient factors on T cell functions, together with the putative low polymorphism of reptilian MHC class I/II loci, may explain why chronic graft rejection was thought to be the rule in reptiles. But in optimal seasonal conditions, a significant proportion of lizards and snakes reject skin allografts in the acute manner typical of mammals (Table 3). Anamnestic responses characterized by an earlier onset and a more rapid rejection time are invariably observed. These findings indicate that reptiles display the major functional markers of the

^aTypical manner of primary skin allograft rejection in lizards *Chalcides ocellatus* ($n = 48$) and snakes *Psammophis sibilans* ($n = 48$) during spring and summer, respectively. Under nonoptimal seasonal and environmental conditions, skin allograft rejection is invariably chronic. Adapted from Farag and El Ridi (1990) and Afifi *et al* (1993)

MHC. These MHC markers were furthermore shown to be functionally linked in the snake *Psammophis sibilans*, as animals which reject skin allografts acutely manifest strong MLR and cell-mediated lympholysis (CML) to donor leukocytes, while animals which reject their skin allotransplant in a chronic manner do not react significantly to the donor leukocytes in MLR or CML. Genetic studies of the antigens inducing graft rejection, MLR and CML should be performed to examine whether these functionally linked markers are genetically linked as well. Some anti-chicken MHC sera (one against MHC class I α chain, two against heterodimer) immunoprecipitate putative class I molecules of 40, 45 and 90 kDa from iodinated *Psammophis sibilans* blood cells. The precipitation of the snake bands is immunogen inhibitable. Additionally, a 19 kDa snake band is recognized by snake alloantisera and by rabbit sera directed to chicken and human MHC class I complex or β_2 -microglobulin; the immunoprecipitation of this band is inhibited by chicken or human β_2 -microglobulin, but association with a class

I α chain has not been shown. However, the polymerase chain reaction was used by Grossberger and Parham to isolate clones with class I MHC sequences from lizards and snakes. All the sequences show the expected evolutionary relatedness. A small number of amino acid residues are conserved in the class I heavy chain sequences. These invariant residues are found symmetrically clustered in the first two domains contributing to intra- and interdomain contacts, but none are present at the peptide-, T cell receptor- or CD8-binding positions.

Antibody production

Reptiles synthesize at least two classes of immunoglobulins. An 850–900 kDa Ig related to mammalian IgM consisting of five disulfide-bonded 7S subunits, each of which is composed of two heavy (H) and two light (L) chains. The molecular mass of the H and L chain is approximately 70 and 21–23.5 kDa, respectively. The second Ig is of lower molecular mass (180 kDa) and shows a close antigenic relationship to the 7S Ig of birds and amphibians, but only a distant relationship to mammalian IgG. Thus, it has been termed IgY, and current evidence indicates that it is the evolutionary ancestor of mammalian IgG and IgE as well. IgY consists of two disulfide-bonded H chains and two L chains of, respectively, 50–63 and 21–26 kDa. The H (or ϵ) chain typically possess one variable and four constant (C) region domains. A truncated (120 kDa) IgY, lacking the two C-terminal domains, is found in some reptiles, particularly turtles.

All existing groups of reptiles are capable of powerful humoral immune response to a variety of antigens: bacteria, protozoa and heterologous erythrocytes and proteins. Primary antibody production is detectable after a lag period of 5–15 days and peaks at 20–60 days postimmunization, depending on the species, antigen type, route and dose, environmental factors (season, temperature, feeding) and hormonal status. Antibody titers then wane gradually. In several reptilian species a secondary response is demonstrable, characterized by a shorter latent period, a significantly higher peak level, and persistence for a long period of time. This indicates that immunologic memory is present in reptiles. It is important to note that immunologic memory is maintained through adverse seasonal conditions, as a very strong anamnestic antibody response can be induced in reptiles in adverse seasons, provided the animals have received a primary immunization in optimal environmental conditions.

Thymectomy of adult lizards has revealed that the thymus is a source of T helper cells that control the

kinetics and magnitude of the humoral immune response. This finding is supported by season-related circumstantial evidence. In fact, under adverse seasonal conditions, reptiles appear as adult thymectomized, do not possess T cells in the peripheral lymphoid organs and are unable to display primary antibody responses, despite the persistence of the majority of B cells in spleen and GALT. Thus, antigen recognition and binding (by B-like cells) occur normally, yet the subsequent proliferative and differentiating events are inhibited, and no serum antibody is detectable. This lack of antibody formation may well be attributed to an absence of T cell help and/or T cell-derived lymphokines, and appears not be due to an inherent inability of the lymphocytes to synthesize or release Ig as a result of low body temperature or malnutrition, as powerful secondary antibody responses can be elicited in reptiles, even during winter.

Mechanisms of changes in reptilian immune system

Body temperature is a salient factor regulating the performance of reptilian immunological functions. It must be noted in this regard that reptiles, in contrast to fish and amphibians, have become restricted in the temperature range over which physiological activities, including immune responses, can occur. Photoperiods, humidity and nutrition are also critical modulators of reptilian immune processes. Endogenous rhythmic factors that are not as yet characterized appear also to control immune reactivity independently of external conditions. Thus, it was not possible to induce thymus regeneration in winter reptiles even if they were maintained in optimal environmental conditions, including the species-specific preferred temperature.

Studies in lizards and turtles have documented that the impact of seasonal and other environmental factors on the immune system is mediated by fluctuations in levels of circulating corticosteroids and sex hormones. Therefore, reptiles represent unique natural models for studying the interrelations of the neuroendocrine immune systems in vertebrates.

RESPIRATORY AND CARDIAC INFECTIONS

Andrew Fogarty and John Macfarlane, City Hospital, Nottingham, UK

Historically, infections of the cardiorespiratory system have resulted in substantial morbidity and mortality. This has been diminished but not eradicated by the introduction of antibiotics. Despite the continuing evolution of more sophisticated antimicrobial drugs, infections, particularly of the respiratory tract, are a major cause of hospital admission and death. Recent studies suggest that the annual incidence of community acquired pneumonia is 2–4 per 100 population in the UK while bacterial endocarditis has an estimated yearly incidence of 11 cases per 100 000 population in an urban area in the USA. There is a degree of overlap both in the type of organism that infects the respiratory tract and the heart and also in the host response to this challenge. However, the differing anatomy makes it more appropriate to consider each system in turn. Overall there is a greater prevalence of respiratory infections.

Respiratory infections

These are divided into two anatomically separate categories. First, there are those of the upper respiratory tract, which extends from the nose to the vocal cords. These include the common cold (coryza), sinusitis, pharyngitis, laryngitis and epiglottitis. Secondly, there are infections of the lower respiratory tract. These may affect the large airways (bronchitis), the alveoli and parenchyma (pneumonia) or the pleura space, leading to an empyema. The source of infection is variable. Droplet inhalation is the most frequent although pathogens may be introduced to the lung by alternative routes, such as the aspiration of pharyngeal contents as seen in neurological conditions leading to bulbar palsy and defective swallowing, haematogenous spread as in miliary tuberculosis or staphylococcal septicemia, and direct extension from surrounding tissues. In patients with comorbid illness, impaired host responses or damaged respiratory tract, organisms normally regarded as nonvirulent can become pathogenic and cause

infection. This is common in some immunocompromised conditions such as the acquired immune deficiency syndrome (AIDS).

The commonest cause of pneumonia encountered in the community is the bacterium *Streptococcus pneumoniae*, followed by *Mycoplasma pneumoniae* and influenza virus (see Table 1). The diagnosis is made clinically and with the aid of investigations such as chest radiographs (Figure 1), an elevated white cell count and the growth of an organism on culture of sputum, respiratory secretions (Figure 2) or blood. Indirect techniques such as complement fixation or indirect immunofluorescence tests are

used to detect infection by some organisms e.g. *Mycoplasma*, *Legionella*, *Chlamydia* and influenza virus, while pneumococcal capsular antigen can be detected in sputum, urine, pleural fluid and blood. Isolation of an organism is helpful in assessing the appropriateness of treatment, but in practice most cases are treated empirically on a 'best guess' policy as many laboratory results appear too late to aid initial clinical management.

Cardiac infections

The commonest infection of the heart affects the valves. Previously damaged valves when exposed to bloodborne infection may become colonized by microbes. The organisms involved are listed in Table 2. Untreated, the consequence of progressive destruction of the valve with associated thrombus formation and risk of embolization can be fatal. Even with prompt antibiotics and valve replacement surgery the

outlook is still uncertain. The myocardium is vulnerable to infection, leading to myocarditis. Viral infection, particularly by coxsackievirus B and echovirus, can lead to myocardial damage, possibly secondary to the immune response elicited. Infectious pericarditis is usually of viral etiology but can be secondary to tuberculosis which, if untreated, leads to typical calcification seen on radiography.

Immune responses of the host

The host has a variety of mechanisms developed to prevent infection of the respiratory tract. These include a number of physical barriers, such as the filtration of large particles by nasal hairs and the branching structure of the bronchial tree causing impaction of inhaled particles which are subsequently removed by the epithelial ciliary action. The epithelium is coated with a layer of secretions, including surfactant which has antibacterial properties, immunoglobulins, complement and mucus which also acts as a physical barrier to pathogens. All components of the immune system have a role in protecting the respiratory system. The principal phagocytic response initially comes from the resident alveolar macrophages and also neutrophils that are recruited by the inflammatory response via the complement system to concentrate in areas of infection. The lymphocytes appear to coordinate the antigen-specific immunity, while the role of other components, such as eosinophils, mast cells and dendritic cells, are not yet fully understood. All antibody subtypes are found in the lung although immunoglobulin A (IgA) predominates in the bronchial secretions.

Clinically, the importance of the immune system is illustrated during its impaired function secondary to disease. Thus patients with generalized abnormalities of immunoglobulin production such as asplenic states, agammaglobulinemia, and myeloma are prone to recurrent bacterial sepsis. This particularly involves encapsulated microorganisms such as *Streptococcus pneumoniae* and some strains of *Haemophilus influenzae*, leading to repeated sinusitis, pneumonia and bronchiectasis. IgA deficiency may be asymptomatic although there can be an increase in upper and lower respiratory infections. Neutropenia increases the risk of many infections, especially those by gram-negative enteric bacilli (GNEB), such as *Escherichia coli* and *Pseudomonas aeruginosa*. An impaired T helper cell response, as associated with human immunodeficiency virus (HIV) infection, results in a greater frequency of opportunistic infections such as *Pneumocystis carinii*, a protozoan that

colonizes normal lung. These patients have a higher frequency of sinusitis, pneumonia and tuberculosis.

Evasive strategies by the organism

The ability of any pathogen to evade the host response continually evolves as the species adapts in response to its environment. To avoid opsonization and phagocytosis various strategies have developed. *S. pneumoniae* and *H. influenzae* type B both possess a polysaccharide capsule that provides greater resistance to phagocytosis. Other factors affecting the virulence of the different serotypes of *S. pneumoniae* include the production of the lytic enzymes pneumolysin and autolysin and also the presence of certain cell surface antigens. The roles of these molecules are currently poorly understood but they will have significance in the design of pneumococcal vaccines. The development of microbial resistance to chemotherapeutic agents is another response of the pathogen to environmental pressure, often due to the widespread use of antibiotics. This leads to changes in the structure of the microbe, preventing antimicrobial action. The mechanism varies. For instance, erythromycin resistance can arise when methylation of the ribosomal RNA, the site of antibiotic action, prevents antibiotic binding and hence activity, while in *Staphylococcus aureus* the production of a β -lactamase destroys penicillin and other antibiotics.

Vaccines

The development of vaccines has focused upon those organisms that cause respiratory rather than cardiac infections due to the greater prevalence of the former and thus the greater benefit of disease prevention. The two most often used are the pneumococcal and the influenza vaccine. The pneumococcal vaccine is a polyvalent compound covering the 23 most common of the 80 serotypes. In healthy adults under the age of 55 it is over 90% effective in preventing infection although in an immunocompromised population, particularly at risk of infection, the benefit is less clear. Current recommendations include those for whom the risk of contracting pneumococcal pneumonia is unusually high or dangerous. The influenza virus is constantly changing antigenically and any vaccine needs to be redesigned annually to provide immunity against this antigenic variation. Inactivated virus is used and leads to the development of serum antihemagglutinin and neuraminidase antibodies.

In the target population, the elderly and infirm, it is only 30–40% effective in preventing clinical influenza illness, although it also provides benefit by

reducing the severity of disease and its complications. Current recommendations for usage include nursing home residents and those with chronic underlying conditions such as diabetes, alcohol abuse and renal, cardiac or respiratory disease. A newer capsular conjugated polysaccharide vaccine against *H. influenzae* type B has proved highly effective in preventing meningitis in young children but also may have a role in conditions that predispose to infections with encapsulated bacteria (see above). The live attenuated BCG vaccine protects against tuberculosis infection although its usage is being re-evaluated. Other vaccines preventing respiratory disease are the attenuated live virus vaccines against measles and rubella that are standard for young children in the UK.

RETROVIRAL VECTORS

David M Nelson and **Richard A Morgan**, Gene Transfer Technology Section, Clinical Gene Therapy Branch, Human Genome Research Institute, National Institutes of Health, Maryland, USA

Viral vectors have become one of the most widely used agents for gene transfer studies. These vectors have received so much attention primarily because they are more efficient at mediating gene transfer than other methods such as electroporation, transfection, lipofection, and particle acceleration. They act like Trojan horses to carry and deliver therapeutic transgenes into target cells. Viral vectors have been made based on retrovirus, adenovirus, adeno-associated virus (AAV), Epstein–Barr virus (EBV), herpes simplex virus (HSV), and alphaviruses including Semliki Forest virus and Sindbis virus.

Of these, retroviral vectors have received the greatest attention.

Retroviral vectors are retroviruses which have been genetically engineered to deliver therapeutic genes rather than retroviral genes to target cells. Retroviral vectors are particularly attractive because the transgenes they carry integrate into the target genome and can potentially provide permanent gene expression. Other viral vector systems have disadvantages in that they do not integrate (adenoviruses, EBV), are more pathogenic (adenoviruses, EBV and HSV), require helper viruses which are difficult to

eliminate (AAV), may be toxic to target cells (EBV, adenovirus and alphaviruses), or require transient production strategies which are subject to variability (AAV, adenovirus and alphaviruses). For these reasons, retroviruses have been the vector of choice in most of the clinical gene therapy trials to date.

Retroviruses

Retroviruses are characterized by RNA genomes which go through a DNA intermediate during replication. Retroviruses have been found throughout evolution including invertebrates and vertebrates. Retroviruses have been divided into three subfamilies based on the diseases they cause: lentivirinae, spumavirinae and oncovirinae. Of these, the oncovirinae have the simplest genomes, are the best understood, and are the most widely used as gene transfer vectors. Specifically, most retroviral vectors are based on murine type C oncoviruses such as the Moloney murine leukemia virus (Mo-MuLV).

The prototypical murine type C retroviral particle

The retroviral particle contains two copies of the RNA genome. Both RNA molecules are about 8 kb, are polyadenylated, and are positive (+) stranded, meaning they are templates for translation. These two RNA molecules are packaged in a core of retroviral proteins along with integrase, ribonuclease H, and reverse transcriptase (Figure 1). The retroviral core buds off from the producing cell, taking the

Figure 1 The prototypical mammalian type C retrovirus particle.

phospholipid bilayer with it to serve as the virus envelope. Most, but not all, cell surface proteins are excluded from the viral envelope during the budding process. A retrovirally encoded envelope protein (env) is incorporated into the phospholipid bilayer of the virus which determines the host range. This retroviral particle is highly unstable and has a half-life of around 4–8 h at 37°C *in vitro*. The half-life of murine retroviral particles *in vivo* in primates, including humans, is in the range of a few minutes due to complement and antibody-mediated inactivation. The virion is about 100 nm in diameter.

The retroviral life cycle

The retrovirus particle attaches to the target cell via a specific receptor which binds to the env glycoprotein on the viral surface. Upon binding to the receptor, the env protein undergoes a conformational change in which the fusion peptide of the env protein is thrust into the lipid bilayer of the target cell membrane. Membrane fusion results, leading to release of the viral core into the cytoplasm of the target cell. Lentiviral cores can traverse the nuclear membrane but the oncovirus cores can not. This is the reason that lentiviruses are capable of infecting nondividing cells whereas oncoviruses, including most retroviral vectors, can only infect replicating cells (they enter the nucleus as the nuclear membrane breaks down during cell division). The RNA genome is reverse transcribed into DNA as it is transported to the nucleus. The double-stranded retroviral DNA is called the provirus and it integrates randomly into the host genome after it has been replicated. Integration is mediated by host factors and the integrase enzyme from the retrovirus. The provirus then behaves like any other endogenous genetic element and is maintained through cellular division by passage to half of the progeny cells. Transcription from the integrated proviral promoter generates retroviral mRNA, allowing the life cycle to begin again.

It should be noted that reverse transcriptase lacks proofreading activity and results in a number of genetic rearrangements including point mutations, frameshifts, deletions, homologous recombinations, and nonhomologous recombinations. These mutations are responsible for generating wild-type viral diversity and may have undesirable consequences, albeit at a low frequency, in gene transfer studies.

The retroviral genome

The construction of retroviral vectors requires an understanding of which viral components are required *in cis* and which can be supplied *in trans*. The retroviral genome is approximately 8 kb in length, most of which can be deleted to make vec-

tors. The *trans*-acting elements can be deleted and are the gag, pol and env genes located in the middle of the genome. The gag gene encodes protease and structural proteins (including capsid, matrix and nucleoprotein), pol is reverse transcriptase (which includes the integrase function), and env is the envelope protein. All three of these genes are necessary for production of infective virions but can be supplied as 'helper' functions in packaging cells.

The only retroviral elements required in *cis* are the two long terminal repeats (LTRs), the packaging site (ψ), and the reverse transcription initiation sites found in the terminal portions of the provirus. The 5' LTR acts as the promoter and enhancer while the 3' LTR contains the poly-A signals, both are necessary for transcription of the retroviral mRNA. The ψ site located just downstream of the 5' LTR is the binding site for the gag polyprotein which packages the RNA into the viral core. These *cis*-acting elements need to be included in all retroviral vector designs.

Retroviral vectors

The first step in making retroviral vectors is to engineer a 'packaging' cell line. Most of the early packaging cell lines have been based on the Moloney murine leukemia virus. Investigators constructed retroviral packaging cell lines to constitutively express the Mo-MuLV helper gag, pol and env proteins by stable transfection of gag, pol and env expression plasmids into murine fibroblasts (NIH3T3 cells). Cells engineered to constitutively express gag, pol and env secrete 'empty' virion particles into the media and are called 'packaging' cells.

The next step is to get these 'empty' virions to package recombinant retroviral vector sequences. The recombinant retroviral vector is made by cloning a transgene between the LTRs in a plasmid-based retroviral vector construct. Transfection of the retroviral vector plasmid DNA into packaging cell lines results in production of retroviral vector mRNA, packaging into the retroviral core, and secretion of recombinant viral particles into the culture media. Packaging cells secreting recombinant retroviruses are called 'producer' cells and the media containing the secreted retrovirus is generally called 'supernatant'. The supernatant can then be harvested, titered, and used to infect target cells.

A number of retroviral vector designs have been developed including single gene, multigene (with additional promoters, ribosome binding sites, or IRES sequences), splicing, reverse orientation, self-inactivating (SIN), and double copy vectors (Figure 2). All of these vector constructs are plasmids

Figure 2 Types of retroviral vectors. LTR; therapeutic gene (forward orientation); therapeutic gene (reverse orientation); dominant selectable marker gene; promoter; Internal Ribosome Entry Site; AAA retroviral mRNA (forward orientation); retroviral mRNA (reverse orientation).

which contain a prokaryotic origin of replication and a prokaryotic selectable marker (AmpR).

Single and multigene retroviral vectors

Single-gene vectors contain one transgene, often transcriptionally regulated by the 5' LTR, in a retroviral construct. Multigene vectors can also be made since retroviral particles can accommodate up to 7 kb of insert DNA without affecting production of recombinant viral particles. Expression of the upstream gene is usually regulated from the 5' LTR while the downstream genes are expressed from either additional promoters or internal ribosome entry sites (IRES). The advantage of internal promoters is that one can vary expression of the downstream gene by choosing between strong viral promoters for high expression (Rous sarcoma virus (RSV) or cytomegalovirus (CMV)), tissue-restricted promoters for tissue-specific expression (albumin), or inducible promoters for inducible expression

(tetracycline promoters). IRES sequences are derived from picornaviruses (either encephalomyocarditis virus or polio virus), are about 500 bp in length, and allow for ribosomes to initiate translation at internal start codons on polycistronic mRNA. The advantage of IRES sequences is that they make expression of the downstream gene dependent on expression of the upstream gene. A selectable marker gene is often used in this downstream position so that clones isolated after selection for the marker gene are guaranteed to express the upstream therapeutic gene. As many as three genes have been expressed from a single retroviral vector utilizing combinations of IRES and internal promoters. These tricistronic constructs seem to give consistently lower expression than the bicistronic constructs, but whether this is a translation or RNA stability issue remains unclear.

Splicing retroviral vectors

Expressing genes from the 5' LTR promoter can be suboptimal since the transgene is cloned about 600 bp downstream of the transcriptional initiation site. Based on the scanning model for translational initiation, one would predict that this would lead to inefficient translation of the transgene. To minimize this problem, splicing vectors have been engineered in which a partially used splice acceptor sequence is cloned just upstream of the transgene. In the spliced messages, the translational start site of the transgene is brought closer to the 5' end of the message, which should result in higher translation efficiency and expression of the transgene. These splicing vectors give consistently higher expression of transgenes compared to vectors without the splice acceptor.

Reverse orientation vectors

Reverse orientation vectors are constructed by cloning a transcriptional unit (including promoter, cDNA, optimal introns, and poly-A sequences) in the opposite orientation to the retroviral LTR transcript. The primary reason for doing this is that introns can be incorporated in the reverse orientation but not in the sense orientation and intron-containing constructs tend to give higher expression than constructs lacking introns. Introns in the sense orientation would be spliced out in the nucleus of the producer cell before the vector was packaged. Problems with reverse orientation constructs include promoter interference between the LTR and the transgene promoter and antisense effects leading to lower expression and titers. A second problem that has been observed is frequent deletion of all or parts of transgenes from aberrant splicing due to splice sites in the antisense transcriptional unit.

Self-inactivating (SIN) vectors

Two types of vectors were generated predominantly to address early safety concerns: self-inactivating (SIN) vectors and suicide vectors. SIN vectors have a deletion in the 3' LTR enhancer which renders both LTRs transcriptionally inactive in the target cell. These vectors were initially designed for safety reasons to prevent the 3' LTR from promoting or enhancing spurious transcription of a gene adjacent to the site of integration. The specific concern was inappropriate activation of a cellular oncogene. Early concerns about insertional mutagenesis, however, have proven unfounded due to the enormous size of the target genome, so these SIN vectors have not been used extensively. SIN vectors are currently used in reverse orientation constructs to prevent the problem of promoter interference and in cases where an internal promoter is preferred to the 5' LTR.

Double copy retroviral vectors

Double copy vectors are designed to provide two copies of a therapeutic gene in one retroviral vector by inserting the transgene into the U3 region of the 3' LTR. The process of reverse transcription copies this sequence segment such that, when the provirus is formed, the transgene appears in both the 5' and 3' LTRs. Having two copies of the gene should result in higher expression than a single copy, but these vectors have not proven better in most cases.

Retroviral vectors with and without selectable markers

Most of the gene therapy studies and clinical trials have used retroviruses containing dominant selectable marker genes such as drug-resistant markers. The most common selectable marker gene has been the bacterial neomycin phosphotransferase (neo) gene. Selectable marker genes have been used for selecting and characterizing retroviral producer cell clones and for enriching target cell populations for transduced cells. However, investigators have recently suggested that bacterial drug-resistant markers should be eliminated or replaced with natural human proteins less likely to elicit an immune response that would eliminate targeted cells *in vivo*. The ideal dominant selectable marker would be a human cell surface protein that is not normally expressed on the target cell. Cell surface markers would allow more rapid selection of targeted cells by immunomagnetic selection or FACS compared to drug resistance. Human CD24 and NGFR (p75, nerve growth factor receptor) are examples of human cell surface proteins currently used as dominant selectable markers.

Eliminating selectable markers altogether may have advantages because including two genes in one vector may lead to lower titers or reduced therapeutic gene expression by promoter suppression. For these reasons, many investigators are turning to 'simplified' retroviral vectors which lack dominant selectable markers. Work with simplified vectors had been limited by the laborious methods required to isolate, characterize and titer useful producer clones but recent efforts to simplify this process may encourage greater use of these vectors.

Packaging cell lines

Retroviral packaging cells are designed to supply the *trans*-acting proteins required for replication and packaging of the engineered retroviral vector construct. Engineering these packaging cell lines has been accomplished by stable transfection of gag, pol and env into suitable cell lines. Constitutive high levels of helper expression are ensured by selection for drug resistance genes which are linked to the gag, pol and env expression cassettes. Interestingly, the gag and pol proteins from murine retroviruses can be used with a number of different env proteins

(including nonmurine env proteins) to create 'pseudotyped' vectors with different host ranges. A series of increasingly safer generations of retroviral packaging cell lines have been engineered to prevent the generation of replication competent retroviruses (RCR, see below) (Figure 3, Table 1).

Evolution of retroviral packaging cell lines

The first generation The earliest retroviral packaging cells were constructed by stable transfection of a complete provirus from which only the ψ (packaging) site had been removed. These cell lines were prone to replication competent retrovirus (RCR) generation since only one recombination event was needed to restore wild-type virus. Examples of these first-generation packaging cell lines include ψ -2, ψ -AM, and PA12.

The second generation The second generation of retroviral packaging cells replaced the 3' LTR with the SV40e poly-A signal to reduce the probability of generating RCR. In addition, the helper genome 5' LTR was mutated to destroy the integrative ability of this helper genome. Thus, even if a defective helper genome happened to get packaged, it would not be

Figure 3 Evolution of retroviral packaging cell constructs.

Table 1 Retroviral packaging cell lines

<i>Envelope</i>	<i>Name</i>	<i>Generation</i>	<i>Parent cell</i>	<i>Resistance genes</i>	<i>Selectable media</i>

gpt, xanthine-guanine phosphoribosyltransferase; hph, hygromycin phosphotransferase B; dhfr, mutant dihydrofolate reductase; HSV-tk, herpes simplex virus thymidine kinase; bsr, blasticidin S resistance; phleo, phleomycin resistance; puro, puromycin resistance; XMAT, XMAT media containing xanthine, hypoxanthine, aminopterin, mycophenolic acid and glutamine.

capable of integrating into a target cell genome and making new virus. These packaging cell lines require two recombination events to generate helper virus and, if used with care, have proven relatively safe. In fact, the amphotropic PA317 cell line has been used extensively to generate supernatant for many clinical trials. Examples of the second generation of retroviral vectors include PE501 and PA317.

The third generation A third generation of retroviral packaging cell lines has been engineered in which gag and pol are expressed from one transcriptional unit while env is expressed from a second transcriptional unit. These 'split' packaging cell lines require three recombination events to generate RCR and are thus 'safer' than the second generation cell lines. Examples of split packaging cell lines include ψ-CRE, ψ-CRIP, GP+E86, GP+AM12, PG13, PG53, FLYA13, FLYRD18 and ProPak-A.

Mammalian type C retroviral packaging cells

Retroviral packaging cells can be categorized in terms of their host range. The three types of murine retroviruses are ecotropic (murine host range),

amphotropic (broad host range) and xenotropic (nonmurine host range). Only the first two of these have been used extensively for gene transfer studies. The host range is specified by the env protein on the viral surface which binds to a specific receptor on target cells. Interestingly, many of the receptors for retroviruses are membrane transport proteins.

Understanding receptor function has proven valuable in gene transfer studies for two reasons. First, one can directly test for the presence and levels of different receptors on target cells of interest. Receptor levels should be predictive of which pseudotyped vector should be chosen to achieve the highest gene transfer efficiency. Second, receptor biology has provided insights into upregulating receptor levels on target cells to increase gene transfer efficiency. For example, phosphate depletion prior to infection with PG13-derived vectors has been shown to increase gene transfer efficiency presumably due to upregulation of the 1+5 receptor.

The ecotropic receptor (ecoR or rec-1) is found on most murine cells with the notable exception of mouse hepatocytes. Rec-1 is a basic amino acid transport protein 622 amino acids in length with 14

transmembrane domains. The envelope proteins of the murine ecotropic retroviruses bind to this receptor. The cell lines GP+E86, ψ -2, ψ -CRE and PE501 are examples of ecotropic packaging cell lines.

The amphotropic receptor (Ram-1) is a sodium-dependent phosphate symporter. The gene for this protein was cloned from amphotropic MuLV strain 4070A and used to construct packaging cell lines. Almost all human gene therapy trials to date involve amphotropic pseudotyped retroviral vectors. Packaging cell lines with the amphotropic env gene include ψ -AM, ψ -CRIP, PA317, GP+AM12 and *pkat* AMPAC.

Another mammalian type C retrovirus is the gibbon ape leukemia virus (GaLV). The GaLV receptor (Glv-1) is also a sodium-dependent phosphate symporter with ten transmembrane domains. GaLV pseudotyped vectors cannot infect murine cells but seem to infect some human cells better than amphotropic vectors. Packaging cell lines incorporating the GaLV envelope protein gene include PG13 and PG53.

The reticuloendothelial viruses (Rev) are avian type C retroviruses that have also been used to make retroviral vectors. Both the reticuloendotheliosis virus strain A (Rev-A) and the spleen necrosis virus (SNV) have been used. One drawback is that Rev vectors only infect avian and not human cells. Therefore, investigators have used site-directed mutagenesis of the Rev env sequence to extend the host range to include human cells. One advantage of these vectors is that the packaging site does not extend into the gag coding sequence, thereby minimizing generation of replication competent retrovirus.

Pseudotyped vectors using the env gene from the feline endogenous virus RD114 have also recently been reported. The RD114 receptor remains unidentified but it has been mapped to the long arm of human chromosome 19. The host range of RD114 pseudotyped vectors has not been fully explored, but they do infect human hematopoietic cells with high efficiency. In addition, retroviruses containing the RD114 env are much more resistant to complement inactivation in human serum compared to murine amphotropic vectors. FLYRD18 is an example of an RD114-pseudotyped packaging cell line.

Type C retroviral vectors in human packaging cells Generating novel retroviral packaging cell lines has been one of the most active areas of retroviral vector research over the past few years. One problem with the commonly used murine-based retroviral packaging systems is that they generate vectors that are rapidly inactivated by serum from Old World primates (including humans). The prim-

ary mechanism is activation of the classical complement cascade initiated by binding of C1q to the retroviral surface protein p15e, although a natural human antibody to the α -galactosyl carbohydrate epitope has also been implicated. This will severely limit the efficacy of *in vivo* delivery of the murine-based vectors. To overcome this problem, investigators have engineered complement-resistant packaging cell lines in human rather than murine cells. Retroviruses produced from human cells (which naturally lack the enzyme responsible for producing the α -galactosyl structure) are resistant to serum inactivation and may be better suited for *in vivo* applications. The FLY packaging cell lines (FLYA13 and FLYRD114) derived from human HT1080 cells (human fibrosarcoma) and ProPak-A derived from 293 cells (human kidney carcinoma) are examples of human packaging cell lines.

Lentiviral and foamy viral vectors A major limitation of the type C vectors currently in use is that they are unable to infect quiescent cells. Many quiescent cells (including neurons, airway epithelia, hepatocytes and bone marrow stem cells) are attractive targets for gene therapy. Lentiviral retroviruses can, however, infect nondividing cells and investigators have begun to explore their use as gene transfer vehicles. The lentiviral virion core can traverse intact nuclear membranes whereas the type C virion core cannot. This feature has been attributed to karyophilic determinants in the two lentiviral proteins matrix (MA) and Vpr. Pseudotyped lentiviral packaging cells have been made by transient cotransfection of three plasmids. One 'helper' plasmid contained the human immunodeficiency virus (HIV) genome with deletions or mutations in the 5' LTR, packaging signal, envelope gene, and 3' LTR. The second plasmid contained either the murine amphotropic env or the VSV-G protein to make pseudotyped virus. The third 'vector' plasmid contained the transgene of interest. Supernatant from this three-plasmid transient packaging system was shown to infect nondividing cells including terminally differentiated neurons. Eventual human applications may require development of nonhuman (non-HIV) lentiviral vectors such as bovine immunodeficiency virus (BIV), equine immunodeficiency virus (EIV) or simian immunodeficiency virus (SIV).

The use of foamy viral vectors has also been proposed but work in this area is still preliminary. Foamy viruses are found in several animal species and are generally nonpathogenic. Foamy viral vectors may have some advantages over Mo-MLV-based vectors including a broader host range, a

larger packaging size, and more efficient transduction of nondividing cells.

Manipulation of retroviral vector titers

Most of the standard murine type C retroviral vectors can routinely produce titers of 10^5 – 10^7 antibiotic-resistant colony-forming units per ml of supernatant (CFU ml⁻¹). These titers are suboptimal for many gene transfer experiments requiring high multiplicities of infection (MOIs) for success. For this reason, investigators have explored a number of techniques to increase absolute or effective viral titer.

VSV-G pseudotyped vectors

The relatively low titers of retroviral vectors is, in part, due to instability of the retroviral env protein. Retroviruses, as mentioned above, have the ability to incorporate heterologous proteins into their envelope membranes. This observation has been exploited by incorporation of the vesicular stomatitis virus envelope glycoprotein (VSV-G), into retroviral vectors. VSV-G pseudotyped vectors can be concentrated by ultracentrifugation by as much as 3 logs up to around 10^9 CFU ml⁻¹. In addition, whereas env-containing vectors require interaction with a specific receptor, VSV-G interacts directly with a phospholipid component of the target cell plasma membrane. The result is that VSV-G pseudotyped vectors have an extremely broad host range including most vertebrate and many insect cells. However, one problem with VSV-G is that it cannot be constitutively expressed in cell lines because it causes cell fusion and syncytia formation leading to cell death. Therefore, the VSV-G protein must be made transiently in the retroviral packaging cell line by either transient transfection or inducible expression.

Temperature, centrifugation, lyophilization

As noted above, retroviruses are relatively unstable entities. Investigators have attempted to increase the stability of retroviral vectors by growing producer cells at 32°C instead of 37°C. Titers obtained at 32°C were found to be 5–15 times higher than titers at 37°C. This correlated to release of six vector particles per cell at 32°C but only two vector particles per cell at 37°C and is most likely the result of increased viral stability at 32°C. Investigators have also attempted to increase effective viral titer by centrifugation. The theory is that centrifugation can overcome the Brownian motion which normally limits retroviral movement to bring more viruses near the target cells. Transduction with centrifugation at $1000 \times g$ has been shown to increase gene transfer

efficiency in both adherent (fibroblasts) and suspension cells (lymphocytes) 3–10-fold. Lyophilization has also been tried as a method to increase viral titer. This method has not proven effective in generating higher titers but has demonstrated that titers can be maintained by lyophilization which may have important implications for large-scale production and widespread delivery of clinical retroviral vectors.

Safety

Replication competent retrovirus

One important safety consideration in packaging cell design is to minimize the likelihood of generating replication competent retrovirus (RCR). RCR can form when the vector construct is introduced into the packaging cell and recombination occurs to regenerate a wild-type retroviral genome on a single transcript. Recombination leading to development of RCR is extremely rare with the newer packaging cell lines. However, the presence of RCR can have devastating consequences. One study reported development of viremia and T cell lymphomas in three out of ten monkeys which had been transplanted with bone marrow cells transduced with RCR-contaminated vector stocks. The level of RCR given to these immune suppressed animals was extraordinarily high, however, and other immunologically normal monkeys infected with 10^9 ffu MLV showed no pathology up to 7 years later.

The probability of generating RCR has been greatly reduced in second- and third-generation packaging cell lines by minimizing sequence homology between helper and vector genomes, by removing the 3' LTR from the helper transcripts, and by splitting the helper functions on to multiple transcripts. Some of these 'split' packaging cell lines require three homologous recombinations to generate PCR and have proven extremely safe *in vitro* and *in vivo*.

Assays have been developed for the detection of RCR in preparations of retroviral supernatant. The two RCR assays most frequently used are the 'S+L-' assay and the 'marker rescue' assay. The marker rescue assay is more sensitive and involves mobilization ('rescue') of an integrated vector, usually containing a selectable marker such as neo, from a target cell line which lacks gag, pol and env. Therefore, the indicator cell line constitutively makes vector message but it does not make any retrovirus. Supernatant to be tested for RCR is used to infect the indicator cell line. If, and only if, the test supernatant contains RCR (with functional gag, pol and env) will the indicator cell line start producing retroviruses with the indicator vector sequences. Detection of the 'rescued'

indicator vector is determined by selection of target cells for drug resistance.

RETROVIRUS, INFECTION AND IMMUNITY

Thomas F Schulz, Department of Medical Microbiology and Genitourinary Medicine, The University of Liverpool, Liverpool, UK

Classification and ultrastructural appearance

Retroviruses are enveloped viruses that contain two copies of a single-stranded RNA genome. Their characteristic feature is an RNA-dependent DNA polymerase, termed reverse transcriptase, which allows the virus to reverse transcribe its RNA genome 'backwards' into a DNA copy, hence the name retrovirus. This DNA copy becomes integrated into the host genome during retroviral infection and serves as the template for the transcription of viral genes and the production of viral proteins (see below).

Retroviral genetic information can be transmitted by two distinct mechanisms. 'Horizontal' or infectious transmission occurs when the virion fuses with uninfected cells. Retroviruses which utilize this mechanism of infection are known as exogenous retroviruses. 'Vertical' transmission occurs when germline cells become infected and the integrated viral genome is then transmitted to subsequent generations as an endogenous genome. The term 'vertical' transmission is also used to describe an exogenous infection of the fetus occurring *in utero* or perinatally. Both exogenous and endogenous retroviruses are found in many species (see Table 1 for some examples). Retroviruses are conventionally classified as oncoviruses (subdivided morphologically into B-type, C-type, D-type viruses), lentiviruses, and foamy (spuma) viruses. B- and D-type viruses bud from the cell membrane with their cores already assembled in the cytoplasm whereas C-type viruses, lentiviruses

and foamy viruses assemble their cores during the budding process. Mature lentiviral particles differ from C-type viruses by the conical shape of their core (the C-type core has a more spherical shape).

A-type particles are intracellular, retroviral core-like particles which are occasionally seen in some tissues or cell lines. In cells infected with D- or B-type retroviruses they occur in the cytoplasm and represent intracellular B- or D-type particles. In contrast, intracisternal A-type particles are localized in the endoplasmic reticulum and have been described in a strain of diabetic mice, in some human cell lines, in preterm placenta of some primates, including humans, as well as in short-term cocultures of biopsies from patients with Sjögren's disease.

Genomic structure and function

Common features

All retroviruses share a basic pattern of genomic organization but differ in other features which are characteristic for individual groups of retroviruses. As shown in Figure 1, all retroviral genomes are flanked by two identical elements, called LTRs (long terminal repeats). An LTR is itself subdivided into three domains: U3, R and U5. The U3 region contains promoter and enhancer elements which control retroviral transcription. Transcription starts at the beginning of R in the 5' LTR and terminates at the end of R of the 3' LTR. Thus the R region is represented twice in the viral RNA genome, hence R for repeat, whereas the U regions are unique to either

Table 1 Examples of retroviruses

	Feline syncytium-forming virus	FSFV
	Hamster foamy virus	HFV

the 5' end (U5) or the 3' end (U3). Reverse transcription of the viral RNA is initiated by a tRNA primer which is hydrogen-bonded to a region of the genome known as the primer binding site (PBS), localized between the end of the 5' LTR and the beginning of gag. Reverse transcription then proceeds towards the 5' end of this LTR and then jumps to the 3' end of the same or another viral genome. The resulting linear DNA copy is flanked by two LTRs and is then integrated into the host genome.

The core structural proteins of replication-competent retroviruses are encoded by the gag gene, the viral enzymes reverse transcriptase, proteinase and integrase are encoded by the pol gene, and the two envelope proteins by the env gene (Figure 1). The gag and pol gene products are translated from a single full-length viral RNA as a precursor polyprotein which is then cleaved by the retroviral proteinase to yield the individual proteins. In the case of murine leukemia virus (MLV), this common precursor is produced by occasionally suppressing the stop codon at the end of gag. For the other retroviruses 'ribosomal frameshifting' is required to change the reading

frame between gag and pol. In the case of human T lymphotropic virus type I (HTLV-I), a similar frameshifting event occurs between the proteinase gene at the 5' end of pol and the reverse transcriptase gene.

Typically, gag encodes three proteins, although in some cases there are further processing products. The first of these, the matrix protein, is encoded at the N-terminus of the gag precursor protein and serves to anchor the core complex underneath the cell membrane, often by a myristylated N-terminal glycine residue. The second protein encoded by gag, the capsid protein, is the major structural core protein, whereas the third, C-terminal gag protein interacts with the genomic RNA and serves to dimerize the genomic RNA copies and to package them selectively in the viral particle. In the dimerized state the genomic RNA cannot serve as a template for translation.

For C-type viruses and lentiviruses, the cleavage of the gag-pol precursor, performed by the viral proteinase, takes place mostly after budding from the cell membrane. This cleavage is accompanied by the 'maturation' of viral particles, as visualized by electron microscopy. In contrast, B-type and D-type

Figure 1 Genome structure of a C-type retrovirus (MLV), a 'tax-type' retrovirus (HTLV-I), a lentivirus (HIV-1) and a foamy virus (HFV). Structural genes are represented by open boxes, auxiliary (regulatory) genes by hatched boxes. The three compartments of the LTR (U3, R, U5) are indicated by different patterns.

retroviruses assemble viral particles with mature core structures inside the cell. Retroviral core particles can be released from the cell in the absence of envelope glycoproteins or coated in envelope proteins from some other viruses. This feature allows the packaging of envelope-deficient virus mutants into the envelope proteins of another retrovirus and has been exploited in the construction of retroviral vectors targeted at cells expressing particular receptors.

The env gene encodes two proteins which are derived from a common precursor protein. One of them extends through the lipid membrane of the envelope and is therefore referred to as TM (transmembrane) protein. It anchors the second envelope protein, termed SU (surface protein) to the virion membrane. This anchorage is mostly mediated by noncovalent bonds, although in the case of some C-type retroviruses a proportion of the SU protein is covalently linked to the TM protein by disulfide bonds. In the case of tissue culture-adapted strains of human immunodeficiency virus type 1 (HIV-1) the interaction between the SU and TM proteins is weak and these viruses therefore shed their SU proteins easily.

The SU proteins mediate the attachment of virions to their target cells by binding the virion to the cellular receptor. Several retroviral receptors have been identified so far. The CD4 glycoprotein serves as the primary receptor for primate lentiviruses, including HIV-1 and HIV-2 (Table 1). HIV-1 and HIV-2 require additional 'coreceptors' to gain entry into cells, and recently several chemokine receptors (mainly CCR5, CXCR4, CCR3, CCR2b) have been shown to play this role. Binding to CD4 induces conformational changes in the HIV envelope protein complex which can then interact efficiently with one of these chemokine receptors. Sequence variation in several regions of the HIV SU protein determines the tropism of individual isolates, presumably by influencing the choice of coreceptor. For 'non human' retroviruses, the cellular receptors have been identified for ecotropic and amphotropic MLV, for Gibbon ape leukemia virus (GaLV), for bovine leukosis virus (BLV), and for avian leukosis virus (ALV). All are membrane glycoproteins. As for HIV, the different tropism, due to the use of different receptors, of ecotropic and amphotropic MLV is determined by minor sequence variation in an N-terminal domain

of the SU protein. Although this is not completely resolved, it seems as if in most instances retroviruses enter the cell by fusing with the cell surface membrane. This is in contrast to some other envelope RNA viruses, e.g. influenza, which require the lower pH of endosomes to trigger the fusion event with internal (endosomal) membranes. The sequence responsible for the fusion ('fusion domain') is located at the N-terminus of the TM protein and is most likely hidden within the tri- or tetrameric envelope protein complex, until the fusion event is triggered by contact with the cellular receptor.

Characteristic features of individual groups of retroviruses

MMTV has a long U3 region in its LTR which, unusually, contains a protein-encoding region. This protein, mls (minor lymphocyte stimulating), has properties of a superantigen and stimulates B cells. Some retroviruses carry oncogenes in their genomes (see under *Neoplasia*). An example of this is Rous sarcoma virus (RSV) which carries the *src* oncogene between *env* and the 3' LTR.

The primate T lymphotropic viruses (HTLV-I, II, STLV) and bovine leukemia virus (BLV), as well as primate lentiviruses (HIV-1/2, SIV_{mac}, SIV_{AGM}, SIV_{MN}, SIV_{SM}) possess an extensive genomic region downstream of their envelope gene (Figure 1). In addition, the lentivirus group is characterized by a 'central region' between their *pol* and *env* genes (Figure 1). Both regions contain genes coding for control proteins which regulate viral transcription, processing of viral RNAs or maturation of viral particles. These control regions are translated from subgenomic, multiply spliced RNAs. Their mode of action can only be briefly summarized here.

Transactivating genes (*tat*, *tax*) The primate T lymphotropic viruses (PTLVs) and BLV as well as the primate lentiviruses (HIV-1, HIV-2, SIVs) produce nuclear activating proteins which act by enhancing transcription from the viral LTR. The Tat of primate lentiviruses acts by binding directly to the nascent viral RNA at a region termed *tar* (for *tat* responsive) which is localized in the R region of the viral LTR and promotes transcription. PTLV and BLV Tax achieve their effect through interaction with cellular transcription factors of the CREB, NF κ B, SRF families. By binding to these transcription factors Tax also affects the expression of cellular genes: it enhances the expression of the genes for interleukin 2 (IL-2), the IL-2 receptor α chain, granulocyte-macrophage colony-stimulating factor GM-CSF, *c-fos* and others and suppresses the gene for β -polymerase, a cellular DNA repair enzyme. The activation of some of these

cellular genes is thought to be important for the transforming properties of HTLV-I and the inhibition of β -polymerase may contribute to DNA damage and subsequent chromosomal aberrations commonly found in adult T cell leukemia/lymphoma, the malignancy associated with HTLV-I. So far, the effects of this kind have never been observed for the lentiviral *tat* protein.

Genes affecting RNA processing (*rev*, *rex*) Rev (primate lentiviruses) and Rex (HTLV-I/II, STLV, BLV) have a common mode of action and facilitate the export from the nucleus of unspliced viral RNA. They thus increase the generation of full-length genomic RNA (encoding Gag/Pol proteins), as well as singly spliced RNA (encoding Env), at the expense of multiply spliced RNAs which code for control proteins.

Other control proteins The Nef protein of primate lentiviruses, encoded between the second exons of *tat* and *rev* and the 3' LTR (in some cases partially overlapping with the latter) is important for efficient replication *in vivo*, but its function is poorly understood. Vif, found in all primate lentiviruses, is encoded upstream of the first Tat exon and required for the infectivity of cell-free virions. Vpu is only present in the HIV-1 genome and may play a role in the release of virus particles from infected cells. Vpx is found in HIV-2 as well as nonhuman primate lentiviruses and Vpr in HIV-1, HIV-2, SIV_{mac}, SIV_{sm}. Vpx plays a role during the nuclear import of the pre-integration complex. Vpr of HIV-1 and SIV_{AGM} is important for nuclear import and induces cell cycle arrest, whereas in HIV-2 these functions are split, and Vpr only causes cell cycle arrest.

Foamy viruses, the third major subfamily of retroviruses, also have a set of open reading frames downstream of the *env* gene, termed *bel* genes. The Bel-1 protein also serves as a transcriptional transactivator.

Retroviral antigens

All major structural proteins encoded by the *gag*, *pol* and *env* genes elicit antibody production and, in some cases, also a T cell response. Antibodies to *gag* proteins show some cross-reactivity among diverse retroviruses such as all strains of avian leukosis virus or gibbon leukemia virus and all murine C-type viruses – hence the designation *gag* for group-specific antigen. In contrast, antibodies to envelope antigens are more specific. Virus-neutralizing antibodies are directed against envelope antigens – both linear and

conformational epitopes have been shown to be 'neutralizing' epitopes in HIV, HTLV-I and BLV. The variable regions of the HIV envelope protein, in particular V1/V2 and V3, as well as its (conformational) CD-4-binding site and a region in the TM protein, are targets for neutralizing antibodies. In contrast to laboratory strains of HIV-1 which have been adapted to grow in established T cell lines, 'primary' HIV-1 strains are more resistant to antibody-mediated neutralization. Neutralizing antibodies to HTLV-I cross-neutralize all HTLV-I variants, but not (or much less efficiently) HTLV-II. The nonstructural regulatory proteins of HIV-1/2 and HTLV-I/II are also immunogenic although in patient sera antibodies to these antigens are found much less frequently than antibodies to structural proteins.

A cytotoxic T cell response to structural proteins has also been demonstrated for some retroviruses, e.g. HIV-1, HTLV-I, friend leukemia virus. In HIV-1 infection cytotoxic T cells are thought to limit viral replication during the early disease stages and to protect against primary infection. Immunization attempts against retroviral disease have been successful for feline leukemia virus and experiments with SIV_{mac} in macaques suggest that immunization with viral structural proteins may confer limited protection against infection. However, in the macaque model efficient protection against SIV infection has only been achieved using attenuated viruses from which some auxiliary genes (e.g. *nef*) had been deleted, but the mechanism of protection is still unclear.

Pathogenesis/involvement in disease

Whereas animal retroviruses have been known for a long time to cause a variety of diseases, including benign and malignant neoplasms, anemias, wasting syndromes, neurological disease and immunodeficiency states, the role of retroviruses as human pathogens has only been substantiated during the last 15 years. HTLV-I is etiologically associated with adult T cell leukemia (ATL) and tropical spastic paraparesis (see below). Although HTLV-II was originally isolated from patients with a T cell variant of hairy cell leukemia, its role in human disease has not been established. The two human lentiviruses HIV-1 and HIV-2 cause the acquired immune deficiency syndrome (AIDS). Foamy or spuma retroviruses are commonly found in several simian species, chimpanzees, cats, cattle and hamsters. There is no known association with disease in these animals. Infection of humans can occur through contact with animals

but is not passed on and proposed associations with human disease have not been substantiated.

The following examples of diseases caused by retroviruses are meant to illustrate some of the mechanisms by which retroviruses cause disease.

Immunodeficiency diseases/wasting/anemias

A number of retroviruses are known to cause immunodeficiency states. The closest analog to human AIDS is the disease caused in macaques by a number of simian lentiviruses. Simian lentiviruses have been found in several species (Table 1). SIV_{AGM}, SIV_{MN}, SIV_{SM} do not cause disease in their natural host but are pathogenic when inoculated into other monkey species. SIV_{mac} is pathogenic to macaques which, however, are not its natural host. SIV_{SM}, SIV_{mac} and HIV-2 are highly related and a simian virus from this group may be the ancestor of HIV-2 in humans and SIV_{mac} in captive macaques.

Many other species also contain lentiviruses. A wasting disease in sheep with some features of human AIDS is caused by visna virus. In goats and sheep caprine arthritis encephalitis virus (CAEV) causes arthritis, pneumonia and meningoencephalitis, and an infectious anemia in horses is due to equine infectious anemia virus (EIAV). A common feature of all lentiviral infections is the chronic, protracted course of the disease which affects many organ systems and the long latency of the virus in the infected host. During the early and late stages of HIV infection virus turnover is very high with 10^9 – 10^{10} virions produced and cleared, and a corresponding number of CD4⁺ T cells destroyed each day. This massive destruction of immune effector cells as a direct result of viral infection probably accounts for most of the damage to the immune system. In addition, immune mechanisms may contribute. Circulating immune complexes may play a role in the glomerulonephritis of equine infectious anemia and the thrombocytopenia purpura of AIDS patients. The phagocytosis and hemolysis of erythrocytes coated with viral antigen, antiviral antibody and complement is at the root of equine infectious anemia and an inflammatory response is responsible for lesions in the lungs and joints of animals infected with visna virus and CAEV. A T cell response to HIV-1-infected T cells may be involved in the destruction of this group of cells.

Some members of a subgroup of oncoviruses, D-type viruses, cause an immunodeficiency state in macaques which was referred to as SAIDS (simian acquired immunodeficiency syndrome). Five viral serotypes belonging to this group are known and have been termed SRV-1–5 (for simian retroviruses).

SRV-3 is also known as Mason–Pfizer monkey virus (MPMV).

In cats and mice, defective forms of feline leukemia virus (FeLV) and MLV have been shown to cause immunodeficiency disease with some features similar to human AIDS. These defective forms have small deletions and insertions in *env* (FeLV) or large deletions in *env* and *pol* (MLV) and are therefore replication defective, i.e. they require the presence of intact helper viruses in order to propagate their genome and package it into infectious particles. The diseases induced by these defective viruses differ in some respects from human or simian AIDS: the murine disease is accompanied by a rapidly progressive B cell hyperplasia and this and the immunosuppression may be T cell dependent. Exactly why these defective viruses are pathogenic is only incompletely understood. There is evidence that minor changes in the envelope gene may affect post-translational processing of the envelope protein core.

Neoplasia

Ever since P. Rous demonstrated in 1911 that cell-free tumor filtrates could transmit a chicken sarcoma, the list of animal tumors caused by retroviruses has continued to grow. Several pathogenic mechanisms have been elucidated over the last 20 years. Retroviruses can cause tumors by transducing oncogenes, i.e. cellular genes involved in the control of cell proliferation and differentiation. Cellular oncogenes, often in a mutated form, can be 'picked up' by retroviruses and become part of recombinant retroviral genomes. Oncogene-carrying retroviruses are usually replication defective since the foreign gene interferes with the normal retroviral life cycle and requires the presence of intact 'helper viruses' to package the oncogene-containing viral genome into viral particles. Other examples include Avian sarcoma virus (*fps*, *yes* oncogenes), feline sarcoma viruses (*fes*, *fms*, *sis*), avian erythroblastosis virus (*erbA*, *erbB*), murine sarcoma virus (*mos*, *Ha-ras*, *Ki-ras*), simian sarcoma virus (*sis*). In this situation the transduced oncogenes are under the control of viral promoters and enhancers and these viruses tend to cause rapidly appearing and progressing tumors.

However, retroviruses need not transduce host genes to cause neoplasia. In the case of avian leukosis virus viral integration occurs in the vicinity of the cellular oncogene *c-myc* and places this oncogene under the control of the retroviral 3' LTR. Mouse mammary tumor virus integrates preferentially in two genomic loci, termed *int-1* and *int-2*, and affects expression of these genes which resemble fibroblast growth factor. In the case of murine leukemia virus the situation is more complex: minimal differences

between the U3 regions of different virus strains (presence or absence of certain tandem direct repeats) seem to be important for leukemogenicity and tissue tropism, most likely by affecting the enhancer function of the viral LTR. An increased enhancer activity may affect the expression of cellular genes in whose vicinity the virus has integrated. Feline leukemia virus may use several of these mechanisms – in some cases integration near the *c-myc* locus and/or recombinant viruses carrying the cellular *c-myc* gene have been observed.

The only human neoplasia associated with a retrovirus is adult T cell leukemia (ATL) caused by HTLV-I. Although the majority of ATL cases are associated with HTLV-I, the existence of rare cases of HTLV-I-negative ATL, the long latency period between infection and the emergence of ATL, and the low proportion of seropositive individuals developing ATL indicate that other events may be involved. The oncogenic role of HTLV-I is related to the viral transactivating Tax protein, which, as outlined above, activates a number of cellular genes and may thus create a pool of proliferating cells. These cells are more prone to further genetic changes which may constitute the actual transforming event. The recently described inhibitory effect of Tax on the repair enzyme polymerase I may contribute to the likelihood of genetic 'accidents'.

Neurological disease

In humans, HTLV-I is etiologically associated with tropical spastic paraparesis (TSP/HAM), but TSP can occur in the absence of HTLV-I infection. The presence of large numbers of activated (HTLV-I infected and uninfected) T cells may play a role in disease development. However, the precise role of HTLV-I in the pathogenesis of this disease is not yet understood. Among lentiviruses both HIV and visna virus cause CNS lesions characterized by inflammatory and degenerative changes. For both viruses, macrophages and microglia seem to be important virus reservoirs in the CNS. A temperature-sensitive mutant of MLV also causes a neurological disease and this may be due to minor sequence changes in the envelope protein which interfere with the normal processing of the envelope in the endoplasmic reticulum and Golgi apparatus of neural cells.

Autoimmune disease

In addition to the 'autoimmune' mechanisms found in immunodeficiency and wasting disorders discussed earlier, murine leukemia viruses are thought to exacerbate the autoimmune disease of (NZB × NZW)F1 mice that resembles human systemic lupus erythematosus (SLE), as well as the necrotizing

arthritis and glomerulonephritis of SL/Ni mice. Retroviral particles have been observed in animal models of autoimmune diabetes, and a new endogenous avian leukosis virus gene locus has been found in obese chicken with spontaneous autoimmune thyroiditis. However, the pathogenic role of retroviruses in these diseases remains to be established.

RABDOVIRUS, INFECTION AND IMMUNITY

Paul-Pierre Pastoret and **Bernard Brochier**, Department of Virology-Immunology, Faculty of Veterinary Medicine, University of Liege, Liege, Belgium

Characteristics of the organism and its antigens

Characteristics of the family Rhabdoviridae

Rhabdoviridae are enveloped RNA viruses characterized by their shape (Gr. *rhabdos*, rod), and by the presence of helical nucleocapsids that are enclosed in a lipid envelope bearing surface projections. The genome is a single molecule of negative single-stranded RNA which is noninfectious and is transcribed into five mRNAs, each of which codes for a single protein. The gene order in the genus *Vesiculovirus* is 3'-N-NS-M-G-L-5', representing respectively the nucleocapsid protein N, the nonstructural protein NS, the matrix protein M, the envelope glycoprotein G, and a large protein L.

About 80 members of the family infect vertebrates, mostly mammals, but also fishes and reptiles, and several of the viruses which infect vertebrates also infect invertebrates. Others in the family infect plants and/or invertebrates. The family contains two genera: the genus *Vesiculovirus*, derived from the name of the virus causing vesicular stomatitis (VSV), a disease of domestic animals observed in the Americas, and the genus *Lyssavirus*, named after rabies (Gr. *lyssa*, madness).

The Indiana serotype of vesicular stomatitis virus is the type species of the vesiculoviruses, whereas rabies virus that of the lyssaviruses. In addition, a number of other viruses of vertebrates, invertebrates, and plants are placed within the family but have not yet been placed in a genus.

Certain rhabdoviruses have been isolated only from blood-sucking arthropods, but some of these

are believed to infect vertebrates on the basis of serological surveys.

Characteristics of lyssaviruses and their antigens

Among the Rhabdoviridae, lyssaviruses are of special interest. Rabies has been known for centuries as a disease of humans and of domestic and wild animals and for many years rabies virus was thought to be unique. It is now clear that antigenic variation exists within rabies virus isolates, and the existence of several distinct rabies-related viruses is now recognized.

The genome of rabies virus, which has been completely sequenced, contains 11 932 nucleotides. An infectious virus has been obtained from cDNA. The presence of a pseudogene between the G and L cistrons implies that rabies virus is evolutionarily intermediate in the Rhabdoviridae family; apart from that, the gene order is similar to that of the *Vesiculovirus* genus. The helical core of ribonucleoprotein (RNP) contains RNA complexed with about 1325 molecules of nucleoprotein N, 50–70 molecules of transcriptase L; and 700 molecules of phosphoprotein NS. The nucleocapsid structure is surrounded by a lipid envelope with about 1150 molecules of membrane protein M, through which project the surface spikes of the only transmembrane protein, the glycosylated G protein, present at 1350 molecules.

Purified N protein elicits group-reactive antibodies detectable by complement fixation, immunofluorescence and immunoprecipitation that react with rabies and the rabies-related viruses. The immune response against N protein plays a secondary protective role, notwithstanding the fact that it plays the role of a superantigen.

Figure 1 Drawing of the rabies virus (top) showing surface glycoprotein (G) projections (peplomers) extending from the lipid envelope that surrounds the internal nucleocapsid. Matrix (M) protein is shown lining the viral envelope and interacting with the cytoplasmic domain of the surface glycoprotein. The helical nucleocapsid core (bottom) comprises the ribonucleoprotein RNP (i.e., the single-stranded RNA genome plus nucleoprotein [N]), phosphoprotein (NS), and virion transcriptase (L) molecules. The membrane 'tail' of the virus represents the frequently observed irregular shape of particles budding from the plasma membrane of the infected cell. Reprinted after modification from *Rev Infect Dis* 10: (4): S771-S784, 1988, with kind permission of Professor William H. Wunner, Wistar Institute, Philadelphia, USA, and the publisher.

Purified G protein elicits neutralizing antibodies. Glycoprotein can, alone, elicit a protective immunity as has been shown by using a vaccinia virus recombinant containing the rabies virus glycoprotein gene. The antigenic determinants of the glycoprotein vary. Pathogenicity of rabies virus is partially related to the G glycoprotein since the introduction of a mutation at arginine 333 of this protein (selection of mutants resisting neutralization by appropriate monoclonal antibodies), renders the virus avirulent for mice and other species. The sequence of amino acids of the glycoprotein deduced from the nucleotide sequence contains residues that show analogies with sequences of curaromimetic neurotoxins from snake venom.

Rabies-related viruses have been described that can be distinguished from rabies virus using both conventional serums and monoclonal antibodies. In Africa, Lagos bat virus was isolated from fruit bats

(*Eidolon helvum*), Mokola viruses first from *Culicoides*, then from a child, and from shrews (*Crocidura* sp.) whereas Duvenhage virus was isolated from a man who died after having been bitten by an insectivorous bat. More recently, new viruses have been isolated from European insectivorous bats. Although closely related, they differ somewhat antigenically from Duvenhage virus.

Rabies virus infection and its epidemiology

The dog is the principal source of infection of humans where urban rabies exists. On a worldwide basis, the reservoir of rabies is often to be found in wildlife, for instance in Europe the red fox (*Vulpes vulpes*) is the main vector, whereas it is the striped skunk (*Mephitis mephitis*) or the raccoon (*Procyon lotor*) in the USA. Vampire bats (*Desmodus rotundus* for instance) are responsible for cattle rabies in Latin America. Rabies is usually acquired from the bite of

an infected animal, but aerosol transmission has also been described. The incubation period can range from a few days to several years but in most cases its duration is 2–3 months. The disease pattern may be of a classical ‘furious rabies’ or a ‘dumb’ or paralytic rabies.

Immune responses of the host

Genetic control of resistance to rabies

The first demonstrations that different strains of mice varied in their susceptibility to rabies virus were reported independently in 1940 by Johnson and Leach and Habel. This resistance is a dominant trait, controlled by one or two genes and not linked to the H-2 locus. The mechanisms involved are not elucidated. Several factors could play a role including differences between the multiplication rate of defective interfering particles. There is also a differential species susceptibility to rabies virus infection; the amount of infectious virus needed to reproduce the disease experimentally differs markedly according to the virus strain and the species.

Nonspecific immunity

Rhabdoviruses readily induce interferon production in the host and are fairly susceptible to interferon action as shown in various models of infection. Interferon production, which is temperature dependent, seems for instance to play a crucial role in the protection of the poikilothermic rainbow trout (*Salmo gairdneri*) against viral hemorrhagic septicemia. Interferon seems also to play a role in the protection against rabies virus infection. Interferon production could be involved in the protection conferred by the curative vaccination procedure discovered by Louis Pasteur.

A paradoxical phenomenon may be observed when using high doses of infectious virus for challenge infection. Animals infected with high doses resist challenge whereas animals infected with lower doses succumb. This paradoxical phenomenon may be linked to a better interferon response in the first case.

Specific immunity

Natural rabies infection is characterized by a variable incubation period, the absence of serological evidence of infection before onset of the disease, and the mostly fatal outcome of the disease when declared. Nevertheless, recovery from CNS infection can occur (albeit rarely) in both humans and other animals. Therefore information on the specific mechanisms involved in protective immunity has mainly been gained through vaccination studies.

Vaccination during the incubation period, if not repeated, leads to the so-called ‘early death phenomenon’, i.e. a reduction of the incubation period compared with infected control animals. The rabies virus glycoprotein alone can produce this phenomenon since it can be reproduced by using a recombinant vaccinia virus containing the rabies virus glycoprotein gene. Protection against rabies can be obtained by passive transfer of specific antibodies. Many questions remain to be answered, therefore, concerning the role of the different immunological mechanisms involved in the protection against rabies virus.

The importance of cell-mediated immunity in the protective mechanisms is not yet fully evaluated. There is an excellent correlation between antibody titers and protection; nevertheless vaccinated animals devoid of detectable neutralizing antibodies may resist a challenge infection which kills the control animals. Moreover, the protective mechanisms following postexposure treatment of humans with rabies vaccine involves T cells. Structural studies of B and T cell epitopes of the rabies glycoprotein will help to answer this question.

Evasive strategies by rabies virus

Rabies virus infection is characterized by a silent progression of the virus in the nervous system during the incubation period without any detectable humoral immune response. Moreover, infection can lead to asymptomatic carriers which excrete the virus, and the saliva from clinically normal animals may be infective for a few days before clinical disease. It is also noteworthy that viremia does not normally occur before the onset of clinical symptoms. Rabies virus has also been demonstrated in the brown fat of experimentally or naturally infected bats. Bats maintained in simulated hibernation retain a viable virus (multiplying at a very low rate or not at all) for weeks or months, and when returned to a warm environment, multiplication is initiated or increased.

Vaccines

Conventional vaccines

As far as antirabies vaccination is concerned, we must distinguish preventive vaccination and post-exposure treatment. The first human vaccination published by Louis Pasteur in 1885 was a post-exposure one. Postexposure treatment for humans nowadays requires several vaccine injections together with specific immunoglobulin injection when badly exposed. In veterinary medicine preventive vaccin-

ation is the rule. Most of the current vaccines confer partial or no protection against some rabies-related virus infections.

Conventional vaccines for human use Only inactivated vaccines have been licensed for humans. Although some countries still use vaccines produced in nervous tissues, these are not safe because of their myelin content; foreign myelin may be responsible for hypersensitivity reactions of the recipient leading to paralysis. Since rabies virus can be multiplied in cell culture, most of the vaccines used nowadays are derived in this way and are perfectly safe. They can be used both for preventive vaccination or for post-exposure treatment accompanied by serological control.

Conventional vaccines for domestic animals Attenuated virus vaccines have been widely used in the past for immunization of domestic animals; most of them were still pathogenic for some species and cases of vaccine-induced rabies were often reported. Humans exposed to attenuated vaccine strains for veterinary use are treated in the same way as after wild virus exposure.

New potent inactivated vaccines for veterinary use have now replaced attenuated vaccines. Rabies virus glycoprotein has been successfully produced in the baculovirus expression system and will serve as a source of inactivated subunit rabies vaccine. Anti-idiotypic immunization has also been tested with results showing that such a vaccination procedure would be ineffective. In contrast, DNA vaccination shows promising results.

Conventional vaccines for wildlife vaccination In Europe and North America emphasis is placed on the vaccination of the wildlife rabies reservoir to control rabies from the start. Wildlife such as red fox, striped skunk and raccoon must be vaccinated by the oral route using baits. Inactivated vaccines are therefore not useful and attenuated ones must be used. The most extensively used attenuated strain is the SADB19. Unfortunately, it is still pathogenic for several species such as micromammals and striped skunk, and ineffective for raccoons. A new attenuated SAD variant has been recently obtained by arginine 333 mutation. This is apathogenic for small rodents.

Recombinant vaccines

A vaccinia recombinant virus harboring the rabies virus glycoprotein gene has been constructed and shown to induce the synthesis of virus glycoprotein

in infected cells and to induce rabies virus-neutralizing antibodies and protection in susceptible animals. Active when orally administered, this recombinant is a good candidate for vaccination of wild animal rabies vectors. It is stable, perfectly safe for target and nontarget animal species and confers protection to most of the rabies vectors. This recombinant, after extensive experimental studies conducted under controlled conditions, has already been used in open field trials. The results obtained confirm its basic properties and potential interest for rabies eradication.

Rh ANTIGENS

Peter D Issitt, Transfusion Service, Duke University Medical Center, Durham, North Carolina, USA

In 1939, Levine and Stetson reported a case of erythroblastosis fetalis and recognized the causative role of the maternal antibody, to which they gave no name. In 1940, Landsteiner and Wiener described production of an antibody in rabbits and guinea pigs immunized with *Macacus rhesus* blood that reacted with the red cells of 85% of random humans. Between them, these observations represented discovery of the Rh blood group system that is now recognized as one of the most complex polymorphisms known in humans.

By 1996, 45 purportedly different Rh antigens had been named (see Table 1) and several potential additions are currently under investigation. As far as is known, the Rh antigens are present only on red cells. Because of early disagreement about the possible genetic control of Rh antigen production, two distinct terminologies, CDE and Rh-Hr, were used. In 1962, a third terminology that used numbers for the antigens was introduced to enable presentation of phenotypic data without genetic implications. Most recently, names unrelated to these terminologies have been used. Sometimes this occurred because the antigen was named before its place in the Rh system was recognized, at other times a numerical and an alphabetical term were introduced simultaneously. The hybrid terminology currently used is shown in Table 1.

The clinical importance of the Rh antigens was quickly recognized. First, the antigen D is by far the most immunogenic of all red cell antigens. If persons who lack D are transfused with one unit of D+ red cells, some 80% make anti-D. Before the introduction of Rh immunoglobulin (RhIg, see below), in the order of 20% of D– women who bore D+ children became immunized to D. Second, when hemolytic disease of the newborn (HDN) is considered, virtually 100% of *in utero* deaths are caused by anti-D (that is sometimes accompanied by other Rh antibodies), and of seriously affected live-born infants, some 97% are D+ children born to women whose antibodies are, or include, anti-D. Third, anti-

D and almost all other Rh antibodies detected by standard serological techniques are capable of causing (usually extravascular) *in vivo* destruction of antigen-positive red cells.

The terms Rh-positive (Rh+) and Rh-negative (Rh–) are used to describe persons with or without D on their red cells, respectively; the other 44 Rh antigens are ignored in the definitions of Rh+ and Rh–. Although considerably less immunogenic than D, other Rh antigens stimulate the production of immune antibodies via transfusion and much less frequently via pregnancy. Indeed, of all clinically significant antibodies to red cell antigens, that is those capable of bringing about accelerated *in vivo* clearance of antigen-positive red cells, some 50% define Rh antigens, even after anti-D is excluded from the calculation. In spite of this, immunization is sufficiently rare, i.e. approximately 0.5% of all transfusion recipients, that donor blood need not be matched to the recipient's phenotype, save for D, in nonimmunized patients.

The introduction of RhIg in the early 1960s dramatically altered the incidence of HDN. The product is a concentrated form of IgG anti-D that is injected into D– women either during or following a D+ pregnancy. Used in the correct amount and at an appropriate time, RhIg approaches 100% efficacy in the prevention of immunization to D in this setting. While there is no doubt that RhIg is effective, there is dispute as to its mode of action. Possible mechanisms include rapid clearance of D+ red cells from the maternal D– circulation; interference in the processing of D antigen in the presence of passively administered anti-D; and influence on the feedback mechanism between B and T cells, again in the presence of injected anti-D. It seems more likely that use of RhIg to prevent immunization to D in an Rh– patient accidentally transfused with Rh+ blood involves rapid clearance of the D+ red cells.

In addition to Rh system alloantibodies, some 40–50% of autoantibodies in patients with 'warm' antibody-induced hemolytic anemia have Rh specificity.

LW^a (previously Rh25) and Duclos (previously Rh38) are no longer considered to be Rh system antigens since their encoding genes segregate independently of Rh.

Rh13, Rh14, Rh15, Rh16 and Rh24 are considered obsolete since the reagents to define them are no longer available.

In about 3% of patients the autoantibodies react with a well-characterized Rh antigen, such as e, c, C or even, on rare occasions, D. More frequently, the causative antibodies have a more complex specificity and react with 'core' Rh antigens that are present on all red cells with a common Rh phenotype, but are lacking from red cells with 'deleted' Rh phenotypes, when some or all Rh antigens are absent, e.g. Dc-, D- and Rh_{null}. There is as yet no immunological explanation of involvement of the Rh system in such a high proportion of persons autoimmunized to red cell antigens.

At the molecular level, much has been learned since the red cell membrane components that express the Rh antigens were first isolated in 1982. In persons with D+ red cells two Rh genes, RHD and RHCE, are present. The term RHCE includes (at least) the alleles RHcE, RHcE, RHce and RHCE. In most D- persons, at least those of Caucasian extraction, RHD is deleted. Both RHD and RHCE appear to be organized into 10 exons over 75 kb of DNA. Exons 1-7 each encode 50-60 amino acids, exons 8-10 encode the 58 residues of the C-terminal end of the proteins. The fourth intron of RHD contains a 60 bp deletion as compared to RHCE. Both RHD and RHCE encode production of nonglycosylated, fatty acid acylated polypeptides comprised of 417 amino acids (the initiating methionine is then cleaved from the mature protein). Hydrophathy analysis forecasts that the polypeptides cross the red cell membrane 12 times, thus suggesting an, as yet unidentified, transporter function. There is considerable homology between the RHD- and RHCE-encoded proteins; of the 416 amino acids only 36 differ. The N- and C-termini of the proteins are highly conserved. At the N-terminal end, the first 42 amino acids encoded by RHD and RHCE are identical. At the C-terminal end, only four of the last 84 amino acids differ. Some amino acid differences in the proteins encoded by the various alleles of RHCE have been correlated with red cell Rh antigen expression; such changes are summarized in Table 2. The partial D situation, in which persons with some but not all epitopes of D on their red cells are able to make allo-immune anti-D, is also understood at the molecular level. Table 3 summarizes the situations in which gene conversion (exon swapping), gene deletion and point mutation can result in an RHD gene that fails to encode all epitopes of D.

Isolation of the nonglycosylated Rh polypeptides results in loss of antigen integrity. It is believed that *in situ*, the Rh polypeptides are part of a complex that includes noncovalently bound Rh-associated glycoproteins (that are coprecipitated with the nonglycosylated polypeptides) CD47, LW glycoprotein,

Table 2 Amino acid changes in the CcEe polypeptide and antigen correlates

Polypeptide carries	Amino acid at position

ⁱ Red cells give variable reactions with monoclonal anti-D ostensibly directed against epD1, 2, 5, and 6/7.

^j Red cells give variable reactions with monoclonal anti-D ostensibly directed against epD6/7.

^k Red cells give variable reactions with monoclonal anti-D ostensibly directed against epD5 and 6/7.

^l Gene is essentially an RHce allele converted by the replacement of exon 5 of RHce with exon 5 of RHD.

glycophorin B and a component that carries the antigen Fy5. These various components are encoded by genes unlinked to Rh and to each other. That the nonglycosylated proteins make the major contribution to Rh antigen structure is clear from a number of lines of investigation. First, family and linkage

studies have shown that the Rh locus is on chromosome 1. Second, somatic cell hybrid analysis and *in situ* hybridization have localized the RHD and RHCE genes to 1p36.1–p34. Third, similar studies have localized the genes that encode the Rh glycoproteins to 6p21–qter. Fourth, transfection studies

using RHD and RHCE cDNA resulted in Rh antigen expression by K562 cells. In a number of instances it has been shown that the Rh genotype, as determined by studies on DNA, does not correlate with Rh phenotype as determined by typing tests on red cells. It is clear that in rare instances RHD and/or RHCE can be present but not expressed.

The Rh_{null} phenotype represents total absence of all 45 Rh antigens, the red cells are also LW(a-b-), Fy:-5 and have reduced expression of the antigen U. The Rh_{mod} phenotype represents marked depression but not total absence of the Rh antigens. The Rh_{null} phenotype can arise due either to the inheritance of recessive unlinked modifier genes (X^{or}), or to recessive amorphic genes ($\bar{r}$) that are at the Rh locus. The Rh_{mod} phenotype arises due to the inheritance of recessive unlinked modifier genes (X^Q). Recent evidence strongly suggests that X^{or} and X^Q are mutant alleles of the genes that encode production of the Rh-associated glycoproteins. Thus, presence of RHD and/or RHCE genes in 'modifier' Rh_{null} and Rh_{mod} individuals (those genes function normally in the parents and offspring of such individuals) but lack or reduction of Rh antigen expression, indicates that presence of normal Rh-associated glycoprotein is also required for Rh antigen expression.

The Rh_{null} and Rh_{mod} phenotypes are associated with a condition known as the Rh deficiency syndrome. The red cells are stomatocytic, have slightly increased osmotic fragility, and have a perturbation of membrane lipid organization. At the clinical level, these changes are associated with a reduced *in vivo* red cell lifespan and an often well-compensated form of red cell deficiency hemolytic anemia. Although several red cell membrane defects of Rh_{null} red cells have been identified it is not clear that any of them is responsible for the accelerated rate of *in vivo* red cell clearance. First, the clinical effects of the Rh deficiency syndrome are completely cured by splenectomy. Second, Rh_{null} and Rh_{mod} red cells survive normally when injected into persons who have been splenectomized following injury. In other words, perhaps the hemolytic anemia of this syndrome relates simply to the altered shape of the red cells and the filtering action of the spleen. Thus the clinical syndrome associated with the lack of Rh antigens throws no light on the function of the Rh antigen-bearing membrane components. Indeed, no definite conclusions about the function of these components can yet be drawn.

RHEUMATOID ARTHRITIS, ANIMAL MODELS

Pritam Das and Chella S David, Department of Immunology, Mayo Clinic and Medical School, Rochester, Minnesota, USA

Rheumatoid arthritis (RA) is a relatively common and disabling form of inflammatory arthritis. The etiology of RA remains unclear, but it is postulated that in genetically susceptible individuals, an unknown antigenic agent is presented by a major histocompatibility complex (MHC) class II molecule to CD4⁺ T cells. These T cells then become activated and initiate an inflammatory cascade involving macrophages, synovial cells, cytokines and growth factors, which in turn cause joint inflammation and destruction. In recent years, considerable progress has been made at the molecular level in understanding the pathogenesis of RA. Although advances have been made in understanding the pathogenesis and genetic associations of RA, studies have so far failed to identify a putative infectious agent or antigenic peptide common to the development of RA.

Experimental animal models of RA have provided a valuable tool to dissect underlying mechanisms involved in the disease process. Numerous models of experimental arthritis are currently being employed to study RA. Disease can either be induced by immunization with a variety of antigens or arthritis has been shown to occur spontaneously in a wide variety of animals including mice, rats, guinea pigs, rabbits and monkeys. Although none of these animal models exactly mimic human RA, several of the disease models studied to date do possess similarities with RA (Table 1). Collagen-induced arthritis (CIA)

in the mouse has been intensely studied in the recent past and will be the focus of this article.

Collagen-induced arthritis: a versatile model

Immunization with type II collagen (CII), a major constituent of hyaline cartilage, was first demonstrated by Trentham and colleagues in 1977 to be arthritogenic in rats. In the years to follow, CIA has been induced in several animals including mice, goats and rhesus monkeys. One of the hallmark features of CIA is the production of CII-specific antibodies and CII-reactive T cells during the arthritogenic process, as seen in some patients with RA. Furthermore, the histopathological features of CIA resemble RA, with the formation of synovial infiltrates, that lead to pannus formation, marginal bone erosions and joint deformity.

Pathogenesis of murine CIA

Both humoral and cellular responses have been implicated in the pathogenesis of CIA. Antibodies against CII are detectable 9 days following immunization and an immunoglobulin M (IgM) response peaks within 2 weeks; peak IgG levels are attained at 4–5 weeks postimmunization. Anti-collagen IgG levels coincide with the onset of arthritis, suggesting a role for autoantibodies in the pathogenesis of CIA.

Table 1 Comparison between animal models and RA

	<i>Collagen arthritis</i>	<i>Adjuvant arthritis</i>	<i>Pristane arthritis</i>	<i>Cell wall arthritis</i>	<i>Antigen arthritis</i>	<i>Proteoglycan arthritis</i>	<i>RA</i>

Antigen?	Type II collagen	Mycobacterium?	?	Group A Streptococcal cell wall	Ovalbumin BSA	Proteoglycan (aggrecan)	?

Further, passive transfer of transient arthritis is seen with the transfer of sera from arthritic mice or rats to naive animals. More profound is the ability of sera from a human with polyarthritis to induce arthritis similar to CIA in mice. As with the passive transfer of murine antibodies against CII, this arthritis is also transient in nature. This is in sharp contrast to CIA where chronic arthritis develops, culminating in joint destruction. Thus, autoantibodies do play a role in the pathogenesis of CIA, but their specific role in disease induction is yet to be clarified.

Cellular responses to CII are also involved in the pathogenesis of CIA. T cells and specific T cell receptors are clearly involved in the initiation of CIA. Mice with genomic deletion of specific T cell receptors have been shown to be resistant to the induction of CIA (see later). Furthermore, treatment of mice with anti-T cell agents prevents CIA and athymic nude mice are resistant to CIA.

Immunogenetic regulation of CIA

The immunogenetic control of CIA in mice has been extensively studied, providing considerable knowledge regarding the predisposition to CIA in mice and other models. Susceptibility to CIA in mice has been shown to be dependent on the presence of a trimolecular complex including: 1) a susceptible MHC haplotype, 2) the presence of self-reactive T cells utilizing selected T cell receptor (TCR) V_{β} chains, and 3) arthritogenic epitopes on the collagen molecule. MHC genes have been mapped to the H-2A locus, using inbred, congenic and recombinant mouse strains. Mouse strains expressing the MHC haplotypes H-2^a and H-2^r are susceptible, while other haplotypes of mice are resistant to the induction of CIA. In addition, studies utilizing CIA-resistant B10.P (H-2^p) and CIA-susceptible DBA/1, B10.G (H-2^a) strains of mice have localized a critical restriction site on the H-2A β chain that is important in CIA susceptibility.

Comparison between sequences in the A β first domain of H-2^a and H-2^p genes has revealed amino acid differences at positions 85–89 which are critical in CIA susceptibility. This region of the A β molecule is suggested to be localized at the end of an α helix, important for interaction between the TCR, the MHC molecule and an antigenic peptide. This 85–89 amino acid stretch has been further analyzed in CIA susceptibility. H-2^p mice transgenic for an A β^p gene mutated to resemble the A β^a develop CIA, supporting the role of the A β gene in predisposition to CIA. While considerable progress has been made in identifying a critical role of the H-2A molecules in CIA susceptibility, recent work from our laboratory has demonstrated a protective role for the H-2E mol-

ecules in CIA. Experiments were performed using a recombinant mouse strain (B10.RQB3), which possesses functional H-2A^a and E α^k molecules, but lacks an intact H-2E molecule due to a nonfunctional E β gene. However, B10.RQB3 mice transgenic for a E β^d gene express an intact E β^d /E α^k molecule. Upon immunization with bovine CII to induce arthritis, these transgenic mice showed a marked decrease in both incidence and severity of disease. This protective phenomenon was shown to be dependent on specific E β molecules, where only the E β^d and E β^r were associated with protection while other E β genes have no effect on CIA. Further analysis of the E β^d molecules has revealed that the HV3 region of the first domain in this molecule probably contains critical elements involved in the protection phenomenon. Lymph node cells from B10.RQB3 and B10.Q (H-2^a) respond to a peptide (65–79) encompassing the HV3 region of the E β^d and E β^r molecules, while peptides from E $\beta^{b,k}$ and E β^p failed to induce a T cell response. Thus, a correlation exists between the T cell response to the HV3 peptides and protection of the corresponding H-2E molecule against CIA, implicating that these peptides bind to the H-2A molecules and thereby mediate the protection effect. H-2A polymorphisms also have been suggested to play a role in the E β -mediated CIA protection. CIA-susceptible B10.RIII (H-2^r) mice transgenic for E β^d fail to protect mice from CIA and fail to mount a T cell response when lymph node cells are challenged with the E β^d 65–79 peptide, implying that the E β^d mediated protection is targeted to the H-2^a molecule and not the H-2^r.

In addition to a susceptible MHC haplotype, T cells expressing specific V_{β} chains are also important in CIA susceptibility. TCR involvement was first implicated by the observation that SWR mice, which possess a susceptible haplotype (H-2^a) but have a genomic deletion of 50% of their TCR- V_{β} genes, remain resistant to CIA. When SWR mice were crossed to B10 mice, which are resistant to CIA due to their nonsusceptible MHC haplotype (H-2^b) but possess a normal repertoire of V_{β} genes, the F1 offspring developed CIA, demonstrating gene complementation. The influence of TCR- V_{β} s on CIA has also been demonstrated using TCR- V_{β} congenic mice strains. Products of the minor lymphocyte-stimulating (Mls) loci have been shown in part to regulate the expression of specific V_{β} TCRs by T cells. Mice which have a clonal deletion of T cells because of certain Mls loci (e.g. mammary tumor virus), show a reduction in the incidence of CIA. For example, CIA-susceptible B10.Q (H-2^a, Mls-1^b) have a normal TCR repertoire, while CIA-resistant BALB.D2 (H-2^d, Mls-1^a) do not possess T cells bearing $V_{\beta}6$, $V_{\beta}7$,

V β 8.2, or V β 9 TCRs due to clonal deletion. An F1 cross between these mice (H-2^{d/q}) has a deletion of T cells utilizing the specific V β genes mentioned above and shows a lower incidence of CIA. In summary, the absence of T cells expressing certain V β TCRs, either by clonal deletion via Mls gene products or genomic deletion, clearly affects susceptibility to CIA.

Susceptibility to CIA is also dependent on the source of type II collagen. Immunization with either bovine, deer or porcine collagen can induce arthritis in H-2^d and H-2^r mice. However, B10.RIII (H-2^r) mice are resistant to disease induction with chick CII. B10.Q mice are resistant when immunized with porcine CII but are susceptible to chick CII. These findings suggest that at least two different collagen epitopes have the capacity to induce disease. Identification of such arthritogenic epitopes on CII has been pursued using cyanogen bromide fragments. A 245 amino acid CB fragment (CB11) from chick type II collagen has been shown to induce CIA in DBA/1 mice. Additionally, autoantibodies directed against murine CII are predominantly restricted to determinants on CB11, suggesting this fragment may contain arthritogenic epitopes. Although synthetic peptides corresponding to amino acids 122–147 and 245–270 of the CB11 molecule have been shown to induce tolerance and/or inhibit CIA, the arthritogenic potential of these peptides to date have yet to be demonstrated.

Immunomodulation of CIA

CIA in mice and rats has provided an excellent model for the development of several novel therapies of arthritis. These include the use of CII oral tolerance, antibodies and agents that affect T cells, MHC molecules, and the TCR. Modulation of cytokine levels in arthritic mice has also proved to be fruitful in the therapy of disease. Therapeutic protocols to date for the treatment of CIA are presented in Table 2. All of the above-mentioned interventions are able to

modulate disease to some extent and a few of the listed agents are currently in clinical trials for human RA.

HLA-transgenic mice: new models for human RA

Genetic studies have linked predisposition in RA in humans to the MHC class II HLA-DRB1 locus. Analysis of HLA-DR alleles associated with RA have revealed that DRB1*0401 (Dw4) and DRB1*0404 (Dw14) confer genetic predisposition to RA, while DRB1*0402 (Dw10) does not. In addition, these alleles bear a similar amino acid sequence within the HV3 region (amino acids 67–74) of the DRB1 molecule, which prompted the 'shared epitope' hypothesis of RA susceptibility. The hypothesis states that a critical element in conferring an increased risk for RA susceptibility is possession of this common epitope within the DRB1 molecule. Linkage disequilibrium between certain DQ and DR genes has revealed a much stronger association at the DQ and DR locus in some autoimmune disorders. In RA, the DQ7 allele has been shown to be associated with a majority of DR4 alleles (in Caucasoid populations), whereas in Asian populations, DQ8 is in linkage disequilibrium with DR4. The above data support a role of HLA-DQ alleles in genetic predisposition to RA.

Based on these findings and studies on the role of H-2E in CIA, we had proposed that an extended DQ/DR haplotype is responsible for RA predisposition and that polymorphism of the HLA-DRB1 alleles dictates disease protection. The molecular basis of this protection is through the presentation of a DRB1 HV3 peptide by RA-associated DQ molecules. It should be noted that HLA class II-derived peptides indeed constitute a major fraction of naturally processed peptides bound to class II molecules. According to our hypothesis, the negative association of DQ8/DRB1*0402 haplotype with RA should be reflected in the capacity of the DQ8 molecule to present the HV3 peptide from the DRB1*0402 chain during thymic education and induce a T cell response (Figure 1). Alternatively, the lack of DQ8 restriction of HV3 peptides derived from DRB1*0401, *0404, or *1402 allele should correlate with the RA association of the respective Dw4, Dw14, or Dw16 subtypes.

To test this hypothesis, we used HLA-DQ8 transgenic mice which express a functional DQB1*0302/A1*0301 dimeric molecule in the absence of endogenous mouse class II molecules. HLA-DQ8 molecule expression in the peripheral blood lymphocyte (PBL) population is approximately 25%. These

Table 2 Therapeutic protocols used for treatment of CIA

Oral tolerance (native type II collagen or peptide)
H-2E β transgene, DR2 (DRB1*1502) transgene

Figure 1 Presentation of HLA-DRB1 HV3 peptides by HLA-DQ molecules shape T cell repertoire. During thymic selection, potential autoreactive T cells are deleted following presentation of the DRB1*0402 HV3 peptide by HLA-DQ8 molecules. Conversely, positive selection of the same autoreactive T cells occurs due to the low affinity of DRB1*0401 peptide for the HLA-DQ8 molecule. These T cells are then activated and expand in the periphery by presentation of a foreign peptide and subsequently (via molecular mimicry) cause autoimmune inflammatory disease.

mice also induced a specific selection of CD4⁺ T cells with a normal V_β TCR repertoire. Upon immunization with bovine type II collagen, HLA-DQ8 transgenic mice mount a strong immunoglobulin G (IgG) response specific for type II collagen as well as proliferate vigorously against bovine CII. Bovine CII-immunized DQ8 mice also develop a severe polyarthritis with massive inflammation and swelling in the affected joints. Histological analysis of joints in these mice indicated synovitis, mononuclear cell infiltration with eventual bone and cartilage erosions leading to joint deformation. These findings demonstrated for the first time that expression of the RA linked HLA-DQ8 molecule in class II-deficient mice confer susceptibility to the induction of CIA.

Immunogenicity of peptides encompassing the amino acid sequence 65–79 of the HV3 region of known HLA-DRB1 alleles was analyzed in HLA-DQ8 transgenic mice. Peptides derived from alleles not associated with RA, namely DRB1*0402 and DRB1*1103, showed the strongest response whereas alleles associated with RA susceptibility, for example, DRB1*0101 and *0401, were not stimulatory. These results showed that a correlation exists between peptides derived from the HV3 regions of DRB1 chains and nonassociation of the corresponding alleles with RA predisposition. Polymorphisms in the DRB1 alleles were further analyzed in the DQ8 mice. RA-protective DRB1*1502 (DR2) gene was introduced in arthritis-susceptible DQ8 transgenic mice. The DR2.DQ8 double transgenic mice were then immunized with bovine CII and monitored for arthritis. Arthritis incidence was significantly lower

in these mice as compared to DR2-negative littermates. A similar reduction of disease incidence was found in CIA-susceptible B10.RQB3 (H-2^u) mice transgenic for the DRB1*1502 gene. HLA-DQ transgenic mice were further investigated to study polymorphisms within the DQ molecules in CIA susceptibility. RA nonassociated HLA-DQ6 transgenic mice generate a weak response to CII and do not develop CIA upon immunization with bovine CII. In contrast, bovine CII-immunized double transgenic mice expressing HLA-DQ6 β and HLA-DQ8 $\alpha\beta$ genes (DQ6/8) develop mild arthritis with delayed onset and lowered incidence. These studies using HLA-transgenic mice demonstrate that polymorphism in the HLA-DRB1 alleles probably modulate predisposition to RA by shaping the T cell repertoire, whereas susceptibility to human RA may be determined by polymorphism in the DQ loci.

Human type II collagen (HuCII) is a candidate autoantigen involved in human RA. Since arthritis-associated human MHC haplotypes (e.g. DQ8, DR4) may recognize unique sets of determinants on HuCII, HuCII peptide determinants recognized by DQ8 transgenic mice were analyzed. Using a series of 27 overlapping peptides (20 mer) encompassing the residues 124–403 of HuCII (CB11 fragment), T cell responses were analyzed both in DBA/1 and DQ8 transgenic mice. Unique peptide determinants were identified in DQ8 transgenic mice, namely peptide residues 174–193, 194–213, 284–303 and 314–343 when compared to responses in DBA/1 mice. Oral administration of HuCII peptides as well as native CII have been reported to suppress CIA in mice and rats, and to be beneficial in human RA patients. DQ8

transgenic mice orally tolerized with bovine CII show a marked reduction in incidence, severity, and delay in onset of disease.

Summary

Although significant progress has been made in recent years in understanding the pathogenesis of RA, a cure for this debilitating autoimmune disease still awaits the human population. It is quite clear that animal models only mimic certain aspects of human RA, yet they have proved invaluable in both the dissection of immunopathological mechanisms and in the development of novel therapies for RA. Certainly, the availability of the recently developed HLA transgenic mice opens exciting new avenues to pursue in understanding the role of HLA molecules in RA and their potential use in the search for therapeutic treatments of RA.

Rheumatoid arthritis (RA) is a chronic multisystemic autoimmune disease of unknown etiopathogenesis. Several different mechanisms probably overlap on a defined genetic background in triggering and perpetuating the disease (Table 1).

The disease

Incidence

Rheumatoid arthritis affects about 1% of worldwide population. The incidence of this disease increases with age in females, whereas is unusual in men under 45. First-degree relatives of rheumatoid arthritis patients have increased risk of developing rheumatoid arthritis, and siblings of severely affected patients are at highest risk. Monozygotic twins have a concordance rate of about 12–15% but dizygotic twins have only about 3% concordance rate.

Clinical picture and diagnosis

Progressive, symmetrical joint destruction is the main clinical feature of rheumatoid arthritis. It is the consequence of autoimmune inflammation, described

later in this article. Rheumatoid arthritis, however, is a systemic disease, as shown by the involvement of skin and internal organs, and from the presence of fever and nonspecific laboratory findings of systemic inflammation. Diagnosis is currently based on criteria established by the American College of Rheumatology (Table 2).

Table 2 The 1987 revised criteria* for the classification of rheumatoid arthritis

1. Morning stiffness in and around the joints, lasting one hour before maximal improvement
2. Arthritis of three or more joint areas
3. Arthritis of hand joints
4. Symmetric arthritis: simultaneous involvement of the same joint areas on both sides of the body
5. Rheumatoid subcutaneous nodules
6. Abnormal amounts of serum rheumatoid factor
7. Radiographic changes including erosions or unequivocal bony decalcification localized in, or more marked adjacent to, the involved joints

*Four of seven criteria are required to classify a patient as having rheumatoid arthritis. Criteria 1–4 must be present for at least 6 weeks. Criteria 2–5 must be observed by a physician.

Table 1 Immunological abnormalities which have been described in rheumatoid arthritis

- Hyperactivity of B lymphocytes
- Production of autoantibodies
- Rheumatoid factor
- Antinuclear antibodies: mainly associated with early onset of pauciarticular juvenile arthritis (JA) and with the onset of uveitis
- Antiperinuclear and anti-rheumatoid arthritis nuclear antigens (RANA) antibodies. Both associated with EBV
- Anti-single-stranded DNA: present. Crossreactive between human and other species. No documented diagnostic or pathogenic significance
- Anti-double-stranded DNA: absent
- Abnormalities in the cytokine network
- Increased secretion of IL-1, TNF α , IL-6, IL-15, IFN γ
- T_H1 pattern of cytokine secretion from T lymphocytes infiltrating the synovium
- Abnormal immune responses to infectious agents
- Increased T and B cell responses to EBV antigens
- Retrovirus-mediated immune dysregulation
- Abnormal immune responses to heat shock proteins such as hsp60 and dnaJ
- Antigen-independent mechanisms
- Synovitis, once initiated, may be self-perpetuating
- Mutations in the p53 gene
- Role of the shared epitope
- Binding site for 'arthritogenic' peptides
- Responsible for selection and activation of 'arthritogenic' T cells

Treatment

Pharmacological approach Nonsteroidal anti-inflammatory drugs (NSAIDs) and low-dose corticosteroids are currently used for the symptomatic treatment of inflammation in rheumatoid arthritis. Second-line antirheumatic drugs such as anti-malarials, sulfasalazine, gold, D-penicillamine, azathioprine and cyclosporine are now utilized early in the course of disease to modify its clinical activity. These drugs may stabilize and improve functional activity, including reduction in tender and swollen joint counts and levels of acute phase reactants. The most effective drug available for preventing joint destruction is currently methotrexate. It is often used in combination with other drugs.

Immunotherapy The increasing knowledge of immune mechanisms involved in the etiopathogenesis of rheumatoid arthritis has led to several attempts to correct immune anomalies by immunotherapy. Most approaches have been based on the usage of monoclonal antibodies specific for certain receptors on immune-competent cells, such as CD4 and CD44. Other targets include inflammatory mediators. Anti-tumor necrosis factor α (TNF α) therapy appears particularly promising. Two alternative approaches, both of extreme interest but as yet at a very preliminary stage, are: 1) gene therapy by intra-articular DNA injection; and 2) oral tolerization to putative targets of the disease process, such as collagen and heat shock protein-derived peptides.

Genetics

HLA and rheumatoid arthritis

Many studies have described the strong association between certain subtypes of HLA-DR4/DR1 and rheumatoid arthritis. By comparing the sequences of the various RA-related alleles, it has been observed that a five amino acid stretch, QK/RRAA, is common among all HLA alleles correlated to rheumatoid arthritis (Table 3). The QKRAA sequence was called

'shared epitope', with the idea that it may be involved in the etiopathogenesis of rheumatoid arthritis (Figure 1). Interestingly, the 'shared epitope' seems to be influencing susceptibility to rheumatoid arthritis and also the severity and the outcome of the disease. Together, these observations show that HLA genes play an important role in the etiopathogenesis of rheumatoid arthritis, probably by providing a sort of 'prearthritic' immunological background on which the triggering factors may thrive.

T cell receptors

Recognition of an antigen presented by the HLA molecule is mediated by the T cell receptor (TCR). The genes encoding the α/β receptor consist of variable (V), diversity (D), joining (J) and constant (C) regions. During T cell development, germline genes encoding one for each V, D, J, C region rearrange to form the functional gene. The preferential usage of some of these combinations in rheumatoid arthritis may be related to recognition of a specific autoanti-

Figure 1 Three-dimensional representation of HLA class II molecule containing the antigenic processed peptide in the antigen-binding groove (light blue stretch, top of the figure). (See also color Plate 4.)

Table 3 Major sites of sequence polymorphism among DR β chain alleles associated with rheumatoid arthritis

Locus-allele	Serologic specificity	Determinant	Amino acid position						
			67	70	71	72	73	74	86
DRB1*0101	DR1	Dw1	L	Q	R	R	A	A	G
DRB1*0401	DR4	Dw4	L	Q	K	R	A	A	G
DRB1*0404	DR4	Dw14	L	Q	R	R	A	A	V
DRB1*0405	DR4	Dw15	L	Q	R	R	A	A	G
DRB1*0408	DR4	Dw14	L	Q	R	R	A	A	G
DRB1*1402	DR6	Dw16	L	Q	R	R	A	A	G

L, leucine; Q, glutamine; R, arginine; A, alanine; G, glycine; V, valine.

gen. To date, TCR repertoire studies in rheumatoid arthritis have shown that, in general, no specific TCR V gene is specifically associated with rheumatoid arthritis. Analysis of the antigen binding site of the TCRs from synovial fluid cells, as opposed to peripheral blood, has shown the presence of conserved amino acid motifs that may play a role in determining the affinity for the HLA-peptide complexes. TCRs bearing these motifs may have a higher affinity for the still undefined 'arthritogenic' peptide that triggers inflammation in the joint.

Proteasomes, transporters and other HLA-linked genes

Antigen processing and peptide transport may also contribute to the induction of abnormal cellular immune responses in rheumatoid arthritis. Allelic differences in the transporter genes, in linkage with specific HLA genes, could be responsible for the selection of a pathway of antigen processing and transport for the generation of peptides having auto-immune potential. For instance, TAP2*0101-1693.A, an allele of TAP-2, is significantly more represented in rheumatoid arthritis patients than in controls. Interestingly, the same allele has significant association with HLA-DR4 only in patients with rheumatoid arthritis. The prevalence of both TAP2*0101-1693.A and HLA DRB1*0401 alleles gives the highest relative risk for rheumatoid arthritis.

Immune abnormalities

Autoantibodies

Rheumatoid factors Rheumatoid factors are autoantibodies directed against the Fc fragment of the immunoglobulin G molecules and are found in approximately 70% of patients with rheumatoid arthritis. Rheumatoid factors produced in normal individuals, during lymphoproliferative or transitory inflammatory conditions, are structurally and functionally dissimilar from the ones produced by rheumatoid arthritis patients. They differ, in the first place, genetically. Rheumatoid factors produced during lymphoproliferative disorders are generally encoded by a set of variable region genes that are germ-line. Hence, these autoantibodies have not been developed by selective antigenic pressure. On the contrary, genes encoding rheumatoid factors derived from patients with rheumatoid arthritis show a wide range of variable region usage. These genetic discrepancies underline strong functional differences. Rheumatoid factors found in normal individuals are part of a family of natural antibodies that have low affinity for the self antigen. They are often polyspecific,

reacting with self and exogenous antigens. On the contrary, rheumatoid factors isolated from rheumatoid arthritis patients are often of high affinity for their target. B cells that express high-affinity rheumatoid factors are very effective in presenting immune complexed antigens to T cells, contributing therefore to the generation of a specific secondary immune response that may be part of the etiopathogenesis of the disease.

Other autoantibodies Autoantibodies other than rheumatoid factors are frequently found in rheumatoid arthritis patients. Their presence, in most cases, can be associated with polyclonal B cell activation, one of the immune abnormalities of the disease, rather than with a specific pathogenic pathway. Antiperinuclear factors and anti-rheumatoid arthritis-associated nuclear antigen (RANA) are specifically associated with rheumatoid arthritis and have been associated with Epstein-Barr virus (EBV) infection. Anticollagen antibodies constitute another family of autoantibodies that may play a role in rheumatoid arthritis by mediating joint damage through the activation of various inflammatory pathways.

Abnormalities of the cytokine network

Proinflammatory cytokine family Interleukin 1 (IL-1) is mainly produced by activated macrophages in response to inflammatory stimuli. IL-1 has both systemic and localized effects on the immune system. For its role in septic shock and as a pyrogen, it is considered as the endogenous pyrogen. At inflammatory sites, it induces T and B cell activation and proliferation, and release of proteolytic and chemotactic substances from macrophages, and has a stimulatory effect on osteoclasts, with consequent cartilage reabsorption.

TNF α is another potent proinflammatory cytokine. It is produced mainly by inflammatory cells, such as activated macrophages. T cells can also produce TNF α in response to antigenic stimuli. TNF α is a stimulator of T cell activation. It upregulates expression of interferon γ (IFN γ) and IL-2 receptor expression in T cells. It induces B cell activation and immunoglobulin (Ig) production. It has chemotactic properties. TNF α interacts with several other proinflammatory cytokines, including IL-15. This amplifying effect may be particularly relevant in the pathogenesis of rheumatoid arthritis.

Immunomodulatory cytokines IFN γ is a potent proinflammatory cytokine produced by T cells and natural killer (NK) cells. It has a stimulatory effect on many cells of the immune system. It plays a major role in controlling infection, in particular of viral

origin. It is also the cytokine primarily associated with T_H1 -type responses. The immunomodulatory cytokine which is the natural antagonist of $IFN\gamma$ is IL-4. IL-4 is produced by $CD4^+$ T cells and eosinophils and is a potent stimulator of B cell-mediated immune responses. IL-2 and IL-6 are both intermediate mediators. They modulate immune responses by acting on other immune cells and stimulating production of other cytokines. Their effects are mainly stimulatory and both cytokines are therefore implicated in the mechanisms of autoimmune inflammation.

Growth factors Transforming growth factor β (TGF β) is a cytokine produced mainly by macrophages and epithelial cells. It is a potent chemoattractant and a very effective inductor of wound healing and fibroblast proliferation. With the other cytokines in this group, its role in rheumatoid arthritis is probably restricted to the late pathogenic steps, when synovial hyperplasia occurs. TGF β also has an important role in mucosal immunity, by boosting specific IgA responses. Another cytokine of this group that has been significantly implicated in the pathogenesis of inflammation is granulocyte-macrophage colony-stimulating factor (GM-CSF). This growth factor is produced by T cells; it is a potent stimulator of inflammatory responses and is involved in processes related to hyperplasia and inflammation.

Balance between pro- and anti-inflammatory cytokines: the T_H1/T_H2 paradigm The control of the balance of immune response mediators secreted by differing T cell subsets is emerging as a major immunoregulatory mechanism. T Helper (T_H) cells have been subdivided into T_H1 , secreting mainly $IFN\gamma$ and IL-2, and T_H2 , secreting mainly IL-4. This subdivision, originally described in the mouse, has also been applied to humans. It has an important functional significance in the physiology of immune responses. T_H1 -type cells are generally involved in cytotoxic T cell-mediated responses, while T_H2 cells are elevated in allergic and parasitic diseases. An efficient immune response rests on a balance between the two cell types. Any alteration of this equilibrium would affect the quality of the immune response toward exogenous antigens, therefore favoring a possible loss of tolerance toward self antigens. In rheumatoid arthritis a T_H1 pattern is found. Proinflammatory cytokines are upregulated. IL-6, IL-1 β and TNF α stimulate the secretion of prostaglandins, collagenase and oxygen radicals, and sustain synovocyte proliferation. All these anomalies in the cytokine network are probably secondary to the trig-

gering events that elicit autoimmune inflammation, and they certainly represent an important part of the mechanism of amplification and perpetuation of the autoimmune damage.

Adhesion molecules

Any anomalous expression of adhesion molecules, or their ligands, could affect the normal pattern of migration of immune response cells to the synovium. ICAM-3, an adhesion molecule and a costimulatory signal for both resting and activated lymphocytes, is overexpressed in rheumatoid synovium. In parallel, adhesion ligands such as ELAM-1 and VCAM-1 are overexpressed on endothelial cells in rheumatoid arthritis patients. CD44, the ligand for hyaluronic acid, is also overexpressed in synovial fluid lymphocytes. These anomalies in leukocyte trafficking and homing are present in rheumatoid arthritis. They may be part of the disease pathogenesis.

Toward a comprehensive model for etiopathogenesis of rheumatoid arthritis

Infectious agents

To date, no convincing evidence has been provided for a single infectious agent fulfilling Koch's postulates as an etiologic agent for rheumatoid arthritis. Nevertheless, some interesting observations have been made that correlate some pathogens with rheumatoid arthritis. This is the case, for example, with EBV. Patients with rheumatoid arthritis have increased titers of unusual antibodies to EBV, such as antirheumatoid arthritis nuclear antigens (anti-RANA). EBV antigens have been identified in the synovium and as discussed later, EBV may also participate in mechanisms of abnormal reactivity to the 'shared epitope'.

Another family of viruses that some authors claim to play a role in etiopathogenesis of rheumatoid arthritis is represented by retroviruses, which might activate 'autogenes' that may trigger autoimmune disease. Bacterial antigens are believed to be triggers of various arthritides, such as Reiter's disease. In these diseases, chronic arthritis is associated with abnormal immune responses to bacteria such as *Shigella*, *Salmonella* or *Yersinia*. These responses can be detected at the synovial sites of inflammation, without demonstration of the intact microorganism in the synovial space. Bacterial antigens with autoimmune potential may be transported into the joint, and initiate, and/or sustain, abnormal immune responses. Among the possible candidates, special attention has been given to heat shock proteins. Bacterial heat shock proteins, including hsp65 and *Escherichia coli*

Figure 2 Multistep molecular mimicry mechanism.

dnaJ, are targets of specific humoral and cellular responses in patients with rheumatoid arthritis.

Role of the 'shared epitope': Binding and/or 'multistep molecular mimicry'?

Binding hypothesis One etiopathogenetic hypothesis takes into account the special binding properties conferred to the disease-related HLA alleles by the 'shared epitope' sequence. The QKRAA amino acid stretch is part of the third hypervariable region of the $\beta 1$ chain of the HLA molecule. This region is an interaction site both for the bound peptide and for the TCR. Recent data have shown that nonconservative amino acid substitutions in this region of the HLA molecule lead to strong differences in the HLA-peptide binding patterns. A first explanation for a role of the QKRAA sequence in rheumatoid arthritis may therefore be based on the idea that the presence of this sequence could affect the binding of still undefined 'arthritogenic' peptides in subjects

bearing the HLA alleles correlated to rheumatoid arthritis. Variations of the binding hypothesis support a role for the QKRAA sequence in binding to peptide transporters, or to a superantigen from viruses or bacteria.

Multistep molecular mimicry hypothesis HLA molecules not only bind the immunogenic peptide and present it to the T cell, but they can also be considered antigens themselves. Peptides derived from RA-related HLA molecules, and containing the 'shared epitope' sequence, may participate in mechanisms of T cell thymic selection and peripheral activation (Figure 2). Immature T cells are selected in the thymus on the basis of their ability to bind HLA-peptide complexes presented by the 'nurse' cells of the thymic epithelium. Peptides encompassing the 'shared epitope' sequence can be naturally processed and therefore are part of the peptide pool that positively selects T cells during fetal life. The

presence of HLA genes encoding for the QKRAA sequence provides the genetically predetermined background for the selection of potentially self reactive T cells. These T cells, previously quiescent, could be activated by the encounter with homologous peptides of exogenous origin. Interestingly, common human pathogens have been found that express the 'rheumatoid arthritis cassette' in the context of highly immunogenic proteins. This cassette is a target of specific immune responses in patients with rheumatoid arthritis. Upon generation of the QKRAA-driven abnormal T cell responses, the perpetuation and amplification of autoimmune inflammation is the last, and probably the most diverse, step of the process.

Antigen-independent mechanisms

In rheumatoid arthritis, the chronic granulomatous rheumatoid response is the late stage of inflammation that leads to destruction of the normal architecture of the joint. According to several investigators, this stage of rheumatoid arthritis is antigen independent. Several mechanisms related to chronic inflammation can indeed sustain the destructive process without necessarily requiring constant restimulation of T cells. Also, recent interest has come from the description in the rheumatoid synovium of mutations of p53, a tumor suppressor protein involved in the control of the cell cycle.

Pathogenesis of the destructive process in rheumatoid arthritis

Intermittent deposition into the joints of antigen-antibody complexes and sometimes infectious agents (often carried by the precursors of the synovial type A macrophages) leads over time to the release of cytokines and growth factors that cause fibroblast hyperplasia and angiogenesis. At the same time, T and B lymphocytes localize to the synovial space. The most damaging agents are the ones that induce secondary immune responses leading to intermittent immune complexes formation and/or stimulation of low-affinity T and B lymphocytes.

Rheumatoid factor B cells efficiently present antigens trapped in immune complexes. Once such cells undergo somatic mutation and localize to the joints, rheumatoid arthritis becomes severe and progressive. At this stage, synovitis is maintained by conventional immune and inflammatory responses to different environmental antigens. The progression to seropositive erosive arthritis may then occur more frequently in 'shared epitope' positive individuals, as this epi-

tope is present on different microorganisms that induce high-titer antibodies.

RHEUMATOLOGICAL DISORDERS

Stanley Naguwa and **Dick L Robbins**, Division of Rheumatology, Allergy and Clinical Immunology, Department of Internal Medicine, School of Medicine, University of California, Davis, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The myriad of rheumatological diseases encompass those that are primarily degenerative, secondary to infectious agents, metabolic or endocrine-based diseases, neoplasms, neurovascular disorders, bone and cartilage disorders, and miscellaneous disorders in addition to those which have an immunological basis. Those diseases with an immunological basis constitute a large percentage of the rheumatological disorders, and in many cases, the most severe. Currently our understanding of these diseases is limited. However, it is believed that in the majority of instances, environmental factors are coupled with immunogenetic factors which determine first, susceptibility for a particular disorder and, second, severity. It is clear that many specific major histocompatibility complex (MHC) class I and II susceptibility genes have been identified for various rheumatic diseases, and certainly other susceptibility genes which are not part of the MHC gene complex also exist. In short, these diseases are polygenic in their basis. Thus, different degrees of immunogenetic susceptibility coupled with environmental factors capable of triggering an immunological disease can lead to loss of tolerance, followed by cellular and molecular auto-reactivity, which in turn can result in clinical autoimmune disease.

Of the immunologically mediated rheumatological disorders, rheumatoid arthritis (RA), systemic lupus erythematosus (SLE) and Sjögren's syndrome are discussed in detail in other sections of this encyclopedia. The discussion which follows will center on other, less common immunologically-based rheumatological disorders.

Systemic sclerosis (scleroderma) and related disorders

Systemic sclerosis (SSc) is a diffuse connective tissue disease of unknown etiology which is characterized by fibrosis of skin and internal organs with associated autoantibodies and microvascular pathology. The peak ages of incidence are in the fifth and sixth decades of life, females, particularly women of child-bearing years, are affected more commonly than males. Related disorders include CREST syndrome, mixed connective tissue disease (MCTD) and undifferentiated connective tissue disease (UCTD).

Fibrosis of the skin and other organs, including

blood vessels, is a pathologic hallmark of this disease. The underlying pathogenesis of scleroderma is a widespread disorder of microvasculature which results in extensive, proliferative fibrosis. Microvascular lesions in arterioles and capillaries generally precede fibrosis and proliferative changes in vital organs such as the lungs, heart, gastrointestinal tract and kidneys.

Although the exact immunopathogenesis is poorly understood, this is an immunologically mediated disease; for example, autoantibodies abound in scleroderma. Several of these autoantibodies are listed in Table 1.

T cell abnormalities have also been described in scleroderma, suggesting a role for both T_H1 and T_H2 cells. In particular, T_H1 cell responses are present and there is an increased expression in serum of both interleukin 2 (IL-2) and IL-2 receptors and endothelial cell growth-inhibition factor (a T_H1 granzyme). Data also exist to suggest activation of T cells by collagen. This suggests a scenario whereby cytotoxic T cells could directly attack endothelial cells based on an autoreaction to vascular antigens including type IV collagen. Moreover, a role for T_H2 cells is also suggested by increased expression in SSc serum of CD30, IL-4, IL-10 and IL-13.

CREST

CREST syndrome is considered a 'benign' variant of scleroderma (C = subcutaneous calcification, R = Raynaud's phenomenon, E = esophageal dysmotility,

S = sclerodactyly, T = telangiectasia). It is most commonly associated with anticentromere antibody.

MCTD

MCTD shares clinical features of scleroderma, polymyositis and SLE, and represents an 'overlap' syndrome characterized by a very high titer of antibody to ribonucleoprotein and an absence of other antinuclear antibodies (ANAs). It has been considered to be a more benign CTD than scleroderma but many cases have evolved into typical scleroderma.

UCTD

Diffuse CTDs with shared features of more than one but with no specific ANA or other autoantibody profiles are termed UCTD.

Idiopathic inflammatory myopathy

The idiopathic inflammatory myopathies, which include polymyositis, dermatomyositis and inclusion body myositis, are inflammatory diseases of muscle which cause weakness, and less frequently pain, of the large proximal muscles of the trunk and limbs. The inflammatory lesion with primarily lymphocytes results in damage and subsequent attempts at repair of the muscles with release of the muscle enzymes creatine kinase, aldolase, aspartate aminotransferase and lactate dehydrogenase. The muscle damage also results in characteristic changes on electromyography.

Dermatomyositis is distinguished from polymyositis with its characteristic rashes. These include a heliotropic rash of upper eyelids, a violaceous rash over the finger joints (Gottron's sign) and erythematous rashes about the periarticular areas, neck and anterior chest (V sign) or back and shoulders (shawl sign). The skin manifestations may occur without evident myositis.

There are differences in the inflammatory process in the idiopathic inflammatory myopathies that may explain their differences in clinical presentation. In dermatomyositis, the lymphocyte infiltration is predominantly CD4⁺ cells localized to the perivascular area, with complement activation and deposition with a resultant vasculopathy. This may also be associated with a vasculitis of the gastrointestinal tract seen most often in childhood dermatomyositis.

Dermatomyositis may be associated with an antibody to Mi-2, a not yet fully characterized nuclear antigen. Patients possessing the anti-Mi-2 antibody usually present with acute onset of disease with good response to treatment with anti-inflammatory agents. Of the idiopathic inflammatory myopathies, derma-

tomyositis is associated with increased incidence of malignancies.

In polymyositis, the inflammation is characterized by CD8⁺ cells and macrophage invasion of the endomysium and there is cytotoxicity against muscle cells. A vasculopathy is not a prominent feature in polymyositis. A number of autoantibodies have been detected in polymyositis, primarily directed against aminoacyl-transfer RNA synthetases which function to bind amino acids to the transfer RNA. The Jo-1 antibody is directed against histidyl-tRNA synthetase; PL-7 against threonyl-tRNA synthetase; PL-12 to alanyl-tRNA synthetase; OJ to isoleucyl-tRNA synthetase; and EJ antibody to glycyl-tRNA synthetase. These antisynthetase antibodies identify a syndrome which includes polymyositis and increased incidence of pulmonary fibrosis, polyarthritis, Raynaud's phenomenon and mechanic's hands (with cutaneous thickening, roughening and fissuring). Patients possessing antibodies to signal recognition particle (SRP), an RNA-protein complex which functions in the recognition and regulation of the movement of newly synthesized proteins, have severe polymyositis that is unresponsive to usual treatment.

Inclusion body myositis (IBM) differs from the other idiopathic inflammatory myopathies in several ways. Clinically, there may be asymmetric involvement of both proximal and distal muscles, with a more frequent involvement of the muscles of swallowing. Like a patient possessing anti-SRP, IBM is very resistant to anti-inflammatory treatment. But it is the histopathology that defines inclusion body myositis. Though there may be endomysial inflammation, as seen in polymyositis, there may be at times only few inflammatory cells. However, characteristically, the biopsy specimens show 'rimmed vacuoles' with amyloid within or next to the vacuoles. Electron microscopy may demonstrate filamentous inclusions.

Though viruses have been suspected as the etiology for the idiopathic inflammatory myositis, at present the etiology is not known.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a disorder of recurrent arterial and/or venous thrombosis and thrombocytopenia associated with the presence of antiphospholipid antibodies (aPL). Although scattered case reports existed, the term APS was first used in 1985 with tentative criteria being proposed in 1987. Approximately 50% of these patients are considered to have the primary APS (PAPS) and 50% secondary APS (SAPS). SAPS seems to be clinically

indistinguishable from PAPS except for an association with SLE.

The major clinical findings include venous occlusion with deep venous thrombosis, often recurrent, which is complicated in one-third of patients by pulmonary thromboembolism. Other venous thrombotic phenomena include pulmonary hypertension, hepatic vein occlusion producing a Budd–Chiari syndrome and renal venous occlusion. Arterial occlusions are also common. The most common manifestations are either transient ischemic attacks or strokes, often recurrent, and the frequency exceeds that of other arterial events such as myocardial infarction or peripheral large artery occlusion with gangrene. Mesenteric, retinal and renal infarctions also occur and migraine headaches with aPL may precede fully expressed APS. Recurrent fetal loss in non-SLE patients represents the most frequent clinical presentation of PAPS in young women.

Serologically these individuals are characterized by having the lupus anticoagulant (LA), anticardiolipin antibody (aCL) and/or antibodies to other negatively charged phospholipids such as phosphatidylserine (PS), phosphatidylinositol (PI) and phosphatidic acid (PA).

aPL are a heterogeneous group of antibodies which occur in certain autoimmune diseases, especially SLE, PAPS, syphilis and other infectious diseases, and in normal individuals. Autoimmune aPL include the LA and aCL and, as mentioned above, are associated with thrombosis, recurrent fetal loss and thrombocytopenia. Although aPL are heterogeneous in their specificities, those that react with anionic phospholipids and β_2 -glycoprotein 1 (β_2 GP1) (β_2 GP1-dependent aCL) are associated with the clinical manifestations of APS. In addition to LA and aCL, antibodies to the other anionic phospholipids include antibodies to PS (aPS), PI (aPI) and PA (aPA).

APS patients have been reported with aPL of the immunoglobulin G (IgG), IgM and IgA isotypes. In addition, patients may have one isotype alone or a mixture of one or two of the others. The majority of APS patients have aPL of the IgG isotype, usually at moderate to high levels. Some patients with APS are IgM positive only, and some data suggest that IgA aPL associate closely with thrombosis, but this latter observation requires further analysis. Some of the problems with IgM and IgA aPL isotype determinations may be the frequency of false-positive results.

The distribution of IgG aCL subclasses in APS patients is unclear. For example, in some patients, IgG1 and IgG3 aCL are the predominant subclasses, but in others, IgG aCL subclasses are approximately

the same as that found in normal human sera. Moreover, both κ and λ light chains are present in the same proportions as found in antibodies in normal human sera.

The specificity and affinity of aPL may distinguish one antibody from another and may be important in their pathogenic roles in the APS. APS aPL show binding cross-reactivity with various anionic phospholipids. For example, aPL binding to cardiolipin have equivalent binding to other anionic, phospholipids. Thus, aCL in patients with APS cross-react with a variety of anionic phospholipids and β_2 GP1. This is in contrast to aCL in syphilis sera that bind to CL alone (β_2 GP1-independent aCL) and are not associated with the APS.

The specificity and function of aCL and LA antibodies are closely related but slightly different. In particular, both LA and aCL act as anticoagulants by inhibiting PL-dependent coagulation reactions *in vitro*. LA recognize the complex of lipid-bound (human) prothrombin and aCL interact with β_2 GP1 absorbed on to a phospholipid surface. Moreover, antibodies to β_2 GP1 (and/or to aCL– β_2 GP1 complex) and LA associated with antiprothrombin activity are better predictors of thrombosis and likely have a pathogenic role in thromboses occurring in APS. In this regard, antibody binding to PL membrane-bound antigen could alter the kinetics of PL-dependent reactions involving that antigen. Thus, autoimmune aCL require β_2 GP1 to exert their anticoagulant effect, and they appear to amplify the anticoagulant effect of β_2 GP1. LA associated with antiprothrombin activity could produce similar functional effects.

Factors resulting in the induction of aCL and other aPL are not well understood. For example, data exist to suggest the importance of T cell dependence and antigen drive, including MHC allele and Ig, variable region (V) heavy chain (H) gene restriction and T cell subset abnormalities. However, experimental PAPS can be induced by passive transfer of human polyclonal IgG and IgM aCL and mouse monoclonal aCL in naive BALB/c mice. Furthermore, APS and SLE can also be induced both clinically and serologically in naive BALB/c mice with a human monoclonal anti-DNA antibody bearing the pathogenic 16/6 idiotype (id). PAPS is also inducible in BALB/c mice following immunization with a human monoclonal aCL (H-3). Cytokine analysis in these mice indicates low production of IL-2, IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF). This suggests that aCL and APS may be induced by anti-idiotypic antibodies generated in naive mice in response to immunization with anti-DNA or aCL antibodies bearing pathogenic idiotypes. However,

other data argue against this because aCL can be produced in mice by immunization with β_2 GP1. In this case, aCL always appears before anti- β_2 GP1, excluding the possibility that aCL are directed primarily to β_2 GP1 or are induced by the formation of anti-idiotypic to anti- β_2 GP1. In addition, IgG aCL from patients with APS can induce aCL in mice (this latter observation is consistent with an anti-idiotypic response). Thus, it is possible aCL may be induced by proteins with high avidity for phospholipid such as β_2 GP1.

Although the way in which aPL mediate thrombosis is not known, data exist to support several potential mechanisms for the procoagulant effect of aPL. These include reducing endothelial cell production of prostacyclin (PGI_2), increasing tissue factor activity, decreasing activated protein C, and/or activated protein S, and/or antithrombin III activity, increasing platelet activating factor and/or thromboxane A_2 production, increasing adhesion molecule expression, and decreasing placental trophoblast implantation. It is likely that more than one, and possibly several, of these mechanisms are important for aPL to mediate a clinical hypercoagulable state.

Wegener's granulomatosis and other diseases associated with antineutrophil cytoplasmic antibodies

Wegener's granulomatosis is a disease in which a granulomatous vasculitis results in inflammatory lesions of the upper and lower airways, particularly the paranasal sinuses and the lung. Other organs which may be involved include the kidney, with disease ranging from mild focal glomerulonephritis to a diffuse necrotizing glomerulonephritis, the joints with frank arthritis, small vessel vasculitis of the skin, and ocular disease ranging from conjunctivitis to scleromalacia perforans.

The severity of the disease can range from very mild and limited to severe multiorgan disease, which, prior to cytotoxic therapy, was uniformly fatal. While the biopsy demonstrating a granulomatous vasculitis remains a gold standard in the diagnosis of Wegener's granulomatosis, the ability to make the diagnosis has been facilitated with the recent identification of an antibody to cytoplasmic antigens detected in ethanol-fixed neutrophils.

These antibodies identified by indirect immunofluorescence are seen in two primary patterns. One is a coarse granular cytoplasmic pattern (c-ANCA) and the second a perinuclear pattern (p-ANCA). Further research has identified proteinase 3 as the antigen causing the c-ANCA. The p-ANCA is a result of an antibody to myeloperoxidase. Depending on the

extent and severity of the disease, c-ANCA is seen with 60–90% sensitivity and greater than 90% specificity in Wegener's granulomatosis. c-ANCA is seen in much lower frequency in other vasculitis, as well as infectious diseases.

p-ANCA is less specifically associated with the disease and is seen in Churg–Strauss vasculitis, as well as other vasculitides and autoimmune diseases.

With the sensitivity/specificity of c-ANCA/antiproteinase 3 antibody in Wegener's granulomatosis, aggressive investigation as to its etiopathologic role has been undertaken. However, its definitive role remains to be elucidated. It is hypothesized that the antiproteinase 3 antibodies interact with surface proteinase 3 on granulocytes and endothelial cells, subsequently triggering the inflammatory cascade that results in the granulomatous vasculitis and inflammation. However, contrary to what one would conclude, neither the level of c-ANCA nor the change in c-ANCA levels predict severity of disease or changes in disease activity. Further studies are necessary to more completely define the role of the antineutrophil cytoplasmic antibodies in their associated disease states.

Spondyloarthropathy

The spondyloarthropathies are a group of arthritides which share common features and include ankylosing spondylitis, reactive arthritis (including Reiter's syndrome), enteropathic arthritis (the arthritis associated with inflammatory bowel disease), psoriatic arthritis and unclassified spondyloarthropathy.

The shared features include arthritis of the axial skeleton and particularly the sacroiliac joints, peripheral arthritis and enthesitis (the inflammation of the transitional tissue between ligament and bone and, similarly, tendon and bone). The inflammatory lesions may evolve with development of bony structures which may ankylose a joint through a yet undefined process. Also shared are extraarticular features, including inflammatory diseases of the eye, heart, lung, skin and mucocutaneous tissues, gastrointestinal and genitourinary tracts. Both conjunctivitis and anterior uveitis are seen in the eye. The skin is involved with the obvious psoriasiform rash, as well as the closely related lesion of keratoderma blennorrhagicum, and with oral ulcerations. Cardiac lesions include an aortitis which may lead to valvular insufficiency, particularly with long-standing disease and conduction disturbances with various forms of heart block.

Whereas pulmonary fibrosis in other rheumatic diseases more frequently involves the lower segments of the lung, those seen in the spondyloarthropathies

involve the upper lobes and may further compromise the patient's respiratory status, which may be affected by involvement of the costovertebral and costochondral joints. Lesions of the gastrointestinal tract that are seen with inflammatory bowel disease and dysentery may also be seen in other spondyloarthropathies without clinical symptoms. In addition to the urethritis seen in Reiter's subset of the reactive arthritis, there is an increased occurrence of prostaticitis in the spondyloarthropathies.

Immunologically, there is a definite association of the spondyloarthropathies with the MHC class I molecule HLA-B27, particularly in ankylosing spondylitis, where more than 90% of white patients possess this antigen. Recently, there have been advances which have better defined the role of HLA-B27 in the pathogenesis of the spondyloarthropathies. For example, transgenic rat and mice models exist whose cells express human HLA-B27 antigen with animal/human β_2 -microglobulin. When these genes are significantly expressed, the animals develop articular and extraarticular lesions similar to the human diseases.

Environmental influences have also been defined, as animals raised in sterile conditions do not develop disease but, when allowed to reassociate with their normally-raised litter mates, subsequently develop disease. Studies are ongoing to identify which of the common enteric bacteria poses the biggest risk for development of HLA-B27-associated disease.

The structure and sequence of the HLA-B27 molecules have also been recently defined. The peptide-binding region of HLA-B27 interacts with nonapeptides which may derive from gram-negative enteric bacteria. Of importance is that the HLA-B27 has the typical MHC class I molecular structure with parallel helical chains that form a peptide-binding groove

and a β -pleated sheet forming the floor. The HLA-B27 molecule itself possesses a similar sequence of amino acids to the enteric bacterial nonapeptide. The differences in the amino acid sequences of the currently identified nine different HLA-B27 molecules are being investigated to determine how they influence the risk for development of disease, as identified by epidemiologic studies.

Although there have been significant advances in the understanding of the immunology of the spondyloarthropathies, as yet it is unclear how a chronic inflammatory process develops and is perpetuated.

RHINITIS, ALLERGIC

AW Frankland, Department of Allergy and Respiratory Medicine, Guy's Hospital, London, UK

When hayfever is seasonal or environmental, it will almost certainly be allergic, but the first distinction must be made between infectious and noninfectious rhinitis. In both of these types nasal polyps may be present and the patient is often anosmic. Lack of smell (and taste) may be so insidious in onset that only when leading questions are posed from the doctor taking the history may these symptoms be mentioned. In noninfectious rhinitis that is perennial, it may be very difficult to decide whether there is an

allergic basis to the symptoms. A rational classification of symptoms is not always easy in rhinitis, which is a heterogeneous group of diseases with multiple etiologies.

History, skin tests and possibly cytology of the nasal smear when symptoms are present should allow a basic classification of the appropriate subgroups (Tables 1 and 2). The term used in the past when rhinitis was not obviously allergic or infective was 'vasomotor rhinitis', however the International

Rhinosinusitis	—	—	—	Neutrophil
Polyps	—	—	—	Neutrophil

Consensus Report on the Diagnosis and Management of Rhinitis decided this word should not be used. Clinical examination is not always helpful; the nasal mucosa, which may be described as looking 'typically allergic', should be more accurately described as looking pale and wet. Unfortunately allergic causes are not the only factors that may make the mucosa pale and swollen; indeed the nasal turbinates may be so swollen that they look like, but are not polyps – they are correctly described as polypoid. When a patient with allergic rhinitis has recently been sneezing, the mucosa looks red and congested and not unlike an infective rhinitis. A nasal airway that is obstructed may have had decongestive nasal sprays or drops used many times a day or for long periods, so that even if the condition causing the original nasal obstruction was allergic, the drop-treated mucosa is usually very red (the nasal cilia have been denuded), particularly on the nasal septum.

Causes of allergic rhinitis

Both the microenvironment indoors and also the environment out of doors have to be separately considered. All animals are strong sensitizers to the allergic-prone individual. Cats are stronger sensitiz-

ers than dogs, but all very small animals such as guinea pigs or hamsters can cause symptoms. Laboratory allergy is a significant problem since rats, mice, guinea pigs and rabbits in an animal laboratory setting, may quickly sensitize the allergic-prone individual.

There are many occupational allergic hazards which can give rise to allergic rhinitis and, more important, to the associated asthma. Workers dealing with castor beans (*Ricin* spp.), whether in the fields, during transport, at the dockside or in ships, are particularly at risk. They are such a strong sensitizers that they will cause allergic inhalent problems to the so-called 'normal' population when downwind from a castor bean factory or when actively working with the beans.

In a hospital setting, latex allergy occurs in 8–17% of health work personnel. Wherever latex gloves are in use in hospital there will be airborne latex allergen which may sensitize particularly the atopic individual.

It must be remembered that ingestants as well as inhalants may cause rhinitis. Traditionally, milk is supposed in some people to cause catarrh but this symptom is difficult to evaluate. Both the mediators of nasal allergy and also the resulting clinical symptoms including nasal obstruction can be measured

after provocation tests. However, the nose, which has its own neurogenic system and complicated blood supply, is exposed to so many stimuli, only some of these specifically allergic and only some from the external environment, that it is not surprising that rhinitis has many pathophysiological forms.

Hayfever on the increase

It is remarkable that in 1934 it was found that 3.5% of the Japanese population resident in southern California were found to have allergic rhinitis due to pollen, a disease that had never been recognized in Japan. However, in 1986 not only was the increase recognized, but an incidence as high as 33.3% for children aged between 6 and 17 years had been noted. The major allergen in Japan comes from trees – the Japanese cedar tree. The frequency of allergy to this particular pollen is more common in people living within 50–100 m of a motorway, compared with those living in the country who are surrounded by trees.

In the UK, it has been shown that the number of people consulting their doctors for seasonal hayfever almost doubled between 1970 and 1981. The increase is still continuing and is occurring in all age groups, but between 1961 and 1985 records on the content of the air over Central London have shown a decline in the cumulative grass pollen count. This is largely because fewer farmers make hay these days, and the grass is cut for silage before it flowers to produce pollen. The sown pastures are of ryegrass (*Lolium*) which is a poor pollen producer compared with the previously sown cocksfoot (*Dactylis glomerata*) and timothy grass (*Pleum pratense*). These grasses may be seen pollinating in the summer along uncropped roadside verges.

A decline in pollen concentration during the last two decades has been accompanied by an increase in air pollution. Hayfever is common, according to the Japanese, in people living near motorways. When pollen grains are collected from industrial areas it can be seen that they are coated with a variety of chemicals. It may be that for allergy to develop, additional factors are necessary rather than just the allergens. These same chemicals may act as irritants to the lining of the nose and lungs. Moreover, it has been shown that diesel exhaust particles have an adjuvant effect on the development of antibodies to pollen in mice.

The immune system and the allergic nose

Bone marrow-derived mast cell precursors prolifer-

ate locally due to stimulation by antigen-activated T cells. The precursors migrate to regional lymph nodes and acquire surface immunoglobulin E (IgE) under the regulation of helper T (T_H) cells. These mast cells reach the nasal secretions mainly by passive diffusion. Mucosal synthesis of IgE may also occur locally. The eosinophilia is probably due to ECF-A (eosinophil chemotactic factor of anaphylaxis) which is one of the degranulation products of mast cells, as is leukotriene B_4 (LTB_4). In effect, the manifestations of IgE-mediated hypersensitivity in the nasal mucosa are basically an inflammatory protection. It seems likely, however, that a vicious circle may be set up by mechanisms that depend on complement-activating IgG antibodies and perhaps both type I and type III hypersensitivity reactions participating in the development of nasal polyps. It is now clear that interleukin 4 (IL-4) plays a pivotal role both in the induction and the effector phase of the IgE-mediated allergic response.

Mediators and nasal allergy

Mediator release after nasal airway challenge with allergen has now been extensively investigated. Nasal lavage for the recovery of secretions on the surface of the nasal mucosa has made it possible to identify a postallergen challenge increase in a vast number of putative mediators of inflammation in humans. As well as experimental provocation tests, the inflammatory response of the nasal mucosa to natural exposure to pollen can also be measured. Much can be learned about the immediate (early) phase and the late (delayed) phase reaction so that a hypothesis can be generated of the involvement of different trigger cells during the different parts of the allergic reaction (Figure 1). It would seem that mast cells are the main source of histamine in the early phase, and basophils the main (but lesser source) in the late phase, during which there is no similar increase in prostaglandin D_2 . During the pollen season there is a large increase in the number of nasal mast cells, but perhaps there has been too much focus on these cells, and now membrane-derived mediators of inflammation are being studied following nasal allergen challenge. These include arachidonic acid products from the lipoxygenase pathway leukotrienes LTC_4 , LTD_4 and LTB_4 , and some of those from the cyclo-oxygenase pathway such as 5-hydroxyeicosatetraenoic acid (5-HETE) and thromboxanes. It is not yet certain whether platelet-activating factor (PAF) increases or decreases after allergen challenge. It is of interest that N - α -tosyl-L-arginine methyl ester (TAME)esterase, a nonspecific marker of inflammation, best reflects the symptomatology obtained at nasal challenge. This

Figure 1 Mechanism of allergic rhinitis. (Reproduced with permission from Durham SR Hypothesis on mechanisms of allergic rhinitis.)

suggests that plasma leakage is a crucial marker of the pathogenesis of a nasal allergy. This plasma leakage may contain many potent peptide mediators and augment the inflammatory response. Certainly bradykinin can be demonstrated in the nasal secretions and would explain the ongoing chronic nature of nasal symptoms both in challenge models and during natural exposure.

To understand the role of different mediators that generate the signs and symptoms of allergic rhinitis, provocation tests with the mediator in question have been done, and the symptoms monitored. The other way to elucidate the problem is to use specific mediator antagonists which should produce further clues as to the effects of the mediator itself. So long as the effect is on the receptor mechanism it will be relevant. This is certainly the case as far as histamine with the antihistamines is concerned. There are variable amounts of histamine in nasal secretions in normal as well as in allergic nasal secretions. During a nasal infection some bacteria will increase the histamine level. Even so, histamine still remains the only mediator that behaves consistently in terms of release with local challenge, as well as producing most of the major symptoms. Also, specific H_1 antagonists influence the symptoms *in vitro* and *in vivo*. It remains to be seen whether antagonists against other putative mediators such as leukotrienes, PAF and bradykinin will be found.

There is some evidence that a nonsedative antihistamine compound (cetirizine), which may act against the eosinophil cell and PAF, confers greater benefit to the patient. Clinically, when nasal obstruction is a major symptom in allergic rhinitis, antihistamines are not very helpful in providing relief. This would seem to depend on the complicated mechanisms sub-

serving the blood supply to the nasal mucosa. It must also be remembered that there are functional differences between mucosal and connective tissue mast cells. This mast cell heterogeneity has clinical implications in rhinitis. The nasal mast cells contain tryptase and are designated MC_T . Prophylactic topical corticosteroids greatly reduce the seasonal increase of nasal mast cells, probably by an action on the $CD4^+$ (helper) cells that secrete mast cell colony-stimulating factors such as IL-3. Nasal, as opposed to human lung, mast cells have not been observed to degranulate under provocation. Only recently has it been shown that Langerhans cells are present in the nasal mucosa especially in allergic rhinitis. Also it has been observed that 20–40% showed IgE positivity. Whether Langerhans cells plus IgE that binds to aeroallergens will give a clue to the pathogenesis of atopic dermatitis remains to be answered, but their presence in the nasal mucosa may serve as a model to study atopic dermatitis and the function of these cells.

Nasal blood vessels

In order to understand the pathological changes that occur in allergic and vasomotor rhinitis, it is necessary to consider in some detail the vasculature of the nose. It consists of four groups of blood vessels: 1) precapillary resistance vessels, 2) capillaries, 3) veins and venous erectile tissue with venous sinusoids, and 4) arteriovenous anastomoses. Transudation of albumin occurs in nasal inflammation. This very stable protein may give a more reliable estimate of the inflammation than the relatively unstable mediators. The venous erectile tissue may be filled with blood. This filling determines the state of con-

gestion of the mucosa which will regulate the nasal resistance to air flow.

Blood flow through the blood vessels is controlled by the autonomic innervation of the nasal mucosa. The nasal blood vessels receive a dense sympathetic innervation so that stimulation causes reduction in nasal blood flow and pronounced decongestion. The sympathetic tone of the nasal venous erectile tissue exhibits a cyclic reciprocal activity. The nasal mucosa seems to undergo a rest period every 2–4 h in humans. It is not surprising, therefore, that patients may state that one and then the other side of the nose becomes obstructed. The tickling sensation, sneezing and hypersecretion caused by allergen challenge is due to stimulation of the sensory nerve endings in the nasal mucosa with histamine from the mast cells being the main mediator.

Prostaglandin E_2 is formed in an allergic response but as it is a potent constrictor of nasal venous erectile tissue, it presumably does not reach this tissue. There is an increase in nasal secretion and glandular vasodilation which is caused by reflex activation of the parasympathetic nervous system so that unilateral stimulation produces a bilateral effect yet the vascular response remains local and unilateral. Nerve fibers containing vasoactive intestinal polypeptide (VIP) are richly distributed in the nasal mucosa. The fibers are especially numerous around seromucous glands and beneath the surface epithelium. Probably VIP is mainly involved in vasodilation of blood vessels serving the glands.

The neuromediator substance P seems to be involved in many of the inflammatory responses elicited in the nose in animals, but not at all in humans. Much more information is required about the anatomy and physiology of nasal blood vessels. It may be that prostaglandin E_2 , which is known to inhibit norepinephrine release from sympathetic nerve endings, has a role as a modulator of sympathetic tone to nasal blood vessels.

Treatment of rhinitis

Find the cause of the rhinitis and get away from the cause is easy advice to give, but often impossible to follow. There should be obvious causes of symptoms if they are strictly seasonal or environmental, as has already been mentioned. When the symptoms persist throughout the year the most likely cause is the major allergen of the house dust mite. Dust mites of the genus *Dermatophagoides* are the most important indoor allergens found worldwide in dust samples. The two major mite species are *D. pteronyssinus* (Der. p) and *D. farinae* (Der. f). Although monoclonal antibodies are available for groups I, II and

III antigens, most information is available about Der. p I. The fecal pellets are relatively large, 10–30 μm , and cause allergic conjunctivitis as well as allergic rhinitis and asthma. Airborne levels of Der. p I give a more appropriate idea of allergen level than are obtained in dust, where the highest concentrations are in the mattress and bedding. The allergens are also present in soft furnishing and carpets and especially toys. Many methods used to control house dust mite rhinitis have been amazingly disappointing.

Symptomatic treatment is now much more effective since the availability of nonsedative antihistamines. The most commonly used one is terfenadine, but others are available and there are some undergoing clinical trials. Antihistamine tablets are not very effective if the worst symptom is that of nasal obstruction. Antihistamine nasal sprays (azelastin) may be useful in rhinitis. Decongestants can be used sparingly for a short time, but the topical use of nasal sprays containing sodium cromoglycate or nedocromil sodium or the use of corticosteroids (Beconase, Rhinocort, Syntaris, Betnasol and Flixonase) usually give adequate relief. Patients must be told of the anti-inflammatory nature of these drugs – they do not give quick relief of symptoms.

Specific injection treatment is indicated when symptomatic treatment is not giving enough help, especially when symptoms are increasing in severity with time. The UK was the first to use this method of treatment in 1911, but since 1986 because the Committee on the Safety of Medicines decided that the treatment was both dangerous and also ineffective, their recommendations mean that the UK has virtually ceased to use this form of treatment. The pros and cons of such treatment have been well-reviewed in debate (Kay, 1989). More recently it has been shown that immunotherapy in a double-blind controlled trial does give benefit in severe summer hayfever uncontrolled by antiallergic drugs. In such studies it could be shown that immunotherapy may act by altering the T_H2 – T_H1 balance in favor of T_H1 responses. There is also a marked increase in interferon γ (IFN γ) mRNA expressing T cells which correlates with the beneficial clinical response to immunotherapy. Also IFN γ has the potential to inhibit IL-4-induced IgE expression and favors B cell IgG production.

Noninjection treatment including oral and topically applied allergens, acupuncture and other forms of treatment, are being increasingly used, but double-blind trials either have not been employed or give equivocal results.

RICKETTSIA, INFECTION AND IMMUNITY

Gregory A Dasch, Rickettsial Diseases Program, Department of the Navy Naval Medical Research Institute, National Naval Medical Center, Maryland, USA

Characteristics of the organisms and their antigens

The term rickettsia is often used indiscriminately to describe very small gram-negative bacteria with an apparent obligate requirement for growth within eukaryotic host cells and regular association with arthropods. The usage of rickettsia has even been broadened occasionally to include small bacteria associated with plants and other invertebrates. Even in the more narrow sense employed here, the group is highly heterogeneous, and contains exceptions to the general definition in that some species can grow without host cells and the arthropod association of others has not been proven. Rickettsiae belong to three families, the Rickettsiaceae, and the hemotropic erythrocyte-associated bacteria in the Bartonellaceae and Anaplasmataceae. Although the latter families contain species causing disease in humans (e.g. *Bartonella bacilliformis*) and some are of major veterinary economic importance (e.g. *Anaplasma marginale*), they have been less extensively studied than the Rickettsiaceae and are not further discussed.

The Rickettsiaceae include numerous species pathogenic for vertebrates. Nine different diseases of humans are caused by members of the genus *Rickettsia*. The louse- and flea-transmitted typhus group rickettsiae cause epidemic and endemic (murine) typhus, respectively. The genetically closely related tick-transmitted spotted fever group rickettsiae cause Rocky Mountain, Mediterranean (boutonneuse),

North Asian (Siberian), Japanese and Israeli spotted fevers. Mites transmit the spotted fever rickettsia causing rickettsialpox and the scrub typhus rickettsia causing tsutsugamushi fever. Some other species of *Rickettsia* have varied pathogenicity for vertebrates and potentially for humans but are largely maintained in nature by transovarial and transtadial passage in their host ticks. The major serotype-specific antigens of typhus and spotted fever group rickettsiae are large (>120 kDa) proteins which form regular crystalline arrays on the rickettsial surface. The lipopolysaccharides are also major immunogens, comprise a cross-reactive antigen which distinguishes these groups, and contain epitopes similar to those of selected *Proteus* strains used in the Weil–Felix agglutination test for rickettsial disease. In contrast, antigenically heterogeneous scrub typhus rickettsiae appear to contain no lipopolysaccharide and differ primarily in the properties of their immunodominant 54–56 kDa protein antigens. The etiologic agent of trench fever, *Rochalimaea quintana*, exhibits a distant genetic relationship to the typhus rickettsiae and has been used as a model for rickettsiae since it can be grown free of host cells. However, its antigens differ from those of the genus *Rickettsia*. *Coxiella burnetii*, the etiologic agent of Q (or query) fever, differs markedly from the other rickettsiae in its extreme resistance to physical and chemical agents. This may be partially due to its developmental cycle which includes formation of an endospore-like cell. In addition, both its major antigen, the phase I lipo-

polysaccharide, and some cell wall proteins appear to contribute to the physical stability of *Coxiella*. Rickettsiaceae also include pathogens of invertebrates such as *Wolbachia* and *Rickettsiella* as well as the important veterinary pathogens in the genera *Ehrlichia*, *Cowdria*, and *Neorickettsia*. *Ehrlichia sennetsu* and a newly discovered agent *E. chaffeensis* related to *E. canis* are also pathogenic for humans. The Ehrlichiae have a distant genetic relationship to the genus *Rickettsia* but their dominant surface protein antigens are different.

Immune responses of the host

Rickettsiae are remarkable in their proficiency in invading a variety of hosts and diverse cell types. A single organism invading the dermis is able to cause disease. They are transmitted efficiently both by arthropod bite and by scarification of arthropod feces at the bite site. They can also infect the host by aerosol exposure of the lung or contamination of the conjunctiva. The immune response that is generated is generally vigorous and prolonged, involving both humoral and cell-mediated immunity. Antibody is efficient in opsonizing these bacteria for destruction by macrophages although complement plus antibody is not bactericidal. In addition, antibody-dependent cellular cytotoxicity has been demonstrated for *Coxiella burnetii*. Macrophages activated by interferon γ and other cytokines are also able to destroy rickettsiae. Interferon γ and, to a lesser extent, both tumor necrosis factor and interferons α/β can limit the replication of rickettsiae in nonprofessional phagocytes. Passive transfer studies in animal models have demonstrated that cell-mediated immunity but not antibody alone is important in protective immunity. In mice, T-independent and dependent antibody responses to infection have been demonstrated. Specific T helper cells also respond actively to rickettsial antigens in elaborating interferon γ . Natural killer (NK) cells are activated by rickettsial infection. Finally, both lymphokine (IL-2)-activated killer (LAK) and specific major histocompatibility complex (MHC)-restricted cytotoxic T cells able to recognize and kill rickettsia-infected cells have been demonstrated.

Evasive strategies by the organism

Despite the vigor and number of cellular immune reactions to rickettsial infection, persistent rickettsial infection and recrudescence has been demonstrated for *Rickettsia prowazekii*, *R. tsutsugamushi*, *Rochalimaea quintana*, and *Ehrlichia canis*. Of parti-

cular importance in human disease is the ability of strains of *Coxiella burnetii* with particular plasmid (or sometimes chromosomal) sequences to persist in the patient and later cause chronic hepatitis or endocarditis. The basic evasive strategy of the rickettsiae is their ability to invade host cells to escape the activated macrophages and antibody-dependent destruction mechanisms arrayed against them. Most rickettsiae appear able to induce their own phagocytosis in a variety of cells which are not professional phagocytes. Species of *Rickettsia* then escape from the phagosome directly into the cytoplasm and sometimes even invade the nucleus. In contrast *Ehrlichia* remain in the phagosome but prevent its fusion with lysosomes. Finally, *Coxiella* not only permits acidification of the phagosome by lysosome fusion but is actually activated metabolically by this step. How *Coxiella* persists in the liver and endocardium, despite antibiotic treatment, is not understood. Each of these genera appear to have developed specific transport mechanisms for regulating their metabolism extracellularly to maintain essential functions and only undergo replication once they are in their appropriate intracellular milieu. Indeed, in some cases these organisms barely damage their host cells while replicating. This equilibrium appears greatest in their arthropod host. The extent of imbalance between some rickettsiae and the vertebrate host (poor adaptation) contributes to the morbidity and lethality they induce. Although antigenic transformation as exhibited by *Borrelia* appears insignificant for rickettsiae, the binding of host cell components both intracellularly and extracellularly may be important in evading host recognition. Indeed, scrub typhus is particularly efficient in budding from the host cell in a plasma membrane blanket from which it can infect adjacent cells. *Rickettsia typhi* and spotted fever rickettsiae appear to rapidly spread from cell to cell with minimal damage on exit or entry. *Coxiella* appears to bind host cell proteins like non-immune antibody and ceruloplasmin that target it to specific host cells for phagocytosis. *Coxiella* also possesses a cell wall complex which can suppress host immune responses. Finally, strains of both interferon γ and α/β -resistant *R. prowazekii* have been discovered, suggesting that host cells may be unable to mount adequate attacks on intracellular rickettsiae. Indeed, cytotoxic T cells and LAK cells may merely act to disseminate the rickettsiae from heavily infected cells.

Vaccines

While protective immunity to rickettsiae may not always lead to complete clearance of the organism,

a large number of attenuated rickettsiae and killed subunit vaccines have been developed which can prevent lethal infection and reduce morbidity due to these agents. However, the commercial availability of these vaccines has been severely restricted by the expense and hazard of growing and purifying these agents and their antigens and the lack of understanding of the genetic basis of rickettsial attenuation. These vaccines also do not meet modern vaccine expectations in their reactogenicity, stability and standardization. Development of rickettsial vaccines is further complicated by the multiplicity of agents involved and the low degree of cross-protection between species and some serotypes. Recombinant DNA methods are rapidly permitting attacks on each of these problems. In a number of laboratories, both purified recombinant protein vaccines based on the immunodominant rickettsial antigens and live viral and bacterial vectors which express the recombinant rickettsial proteins are being investigated aggressively as candidate vaccines for the rickettsiae.

ROSETTING TECHNIQUES

Malcolm R MacKenzie, University of California School of Medicine, Section of Hematology and Oncology, California, USA

The interaction between an indicator particle and a surface molecule is among the most useful techniques in immunology. Indicator particles may exhibit natural receptors, or receptors may be attached by use of ligands. Erythrocytes of various species are used extensively by virtue of their availability, ease of detection and simplicity. Newer techniques have taken advantage of particles synthesized with hydrophilic materials with available hydroxyl and carboxyl groups to provide protein-binding sites for use in these assays. A rosette refers to the ability of sev-

eral cells, such as an erythrocyte, to react with and form a circle around another cell, much as an ornamental ring surrounds a centerpiece. Most workers require at least three particles adhering to the cell of interest as the definition of a rosette. The technique may be used to identify and/or to separate and purify a cell population. The relative simplicity of performance and equipment requirements make these techniques useful for field work. They only require a source of erythrocytes, minimal refrigeration capacity, a laboratory centrifuge and a microscope.

Erythrocyte (E) rosette

The most widely used rosetting technique in human immunology is the interaction between the sheep erythrocyte and human lymphocytes of the thymic or T cell lineage. This interaction, first appreciated by the laboratories of Brain, Coombs and Wybran, was a major step in the capacity to identify, separate and characterize the T and B cell lineages of lymphocytes in normal physiology and disease. The assay is performed by the incubation of a population of mononuclear cells obtained by a preliminary processing of blood, usually by differential density centrifugation of peripheral blood or of organ suspensions, with sufficient sheep erythrocytes to have a ratio of 50:1 or 100:1 erythrocytes to mononuclear cells. The suspension is incubated briefly at 37°C then centrifuged at 200 g and a further incubation for 1–2 hours or overnight at 4°C. The cells are gently suspended and counted in a hemocytometer.

The rosettes formed are more stable in a high protein solution such as 10% human AB serum or 25% bovine serum albumin. The prior treatment of the sheep erythrocytes with neuraminidase also increases the stability. Kaplan found that prior treatment of the sheep erythrocytes with neuraminidase also increases the stability. Kaplan found that prior treatment of the sheep erythrocytes with a sulfhydryl reagent such as 2-amino-ethyisothiuronium (AET) obviates the differences between batches of sheep erythrocytes and enhances the stability of the rosette. Recently Ocklind suggested the use of 1% w/v of polyethylene glycol 10 000 molecular weight in the medium allows for the detection of 97% of T cells. These modifications have proved very useful, particularly when the method is used to isolate T cells in preparative techniques.

The molecule on the surface of T cells responsible for this interaction is the 50 kDa glycoprotein CD2, present on more than 95% of thymocytes and all peripheral T cells. It binds to a protein present on sheep erythrocytes designated T11TS, which is the homolog of the human protein, lymphocyte function-associated antigen 3 (LFA-3). This latter protein is present on human erythrocytes and accounts for the observation that human erythrocytes can form rosettes with human thymocytes. The utility of the sheep erythrocyte over the human in this assay and its reaction with peripheral T cells is due to a three- to five-fold higher ligand density on its surface. The CD2 molecule is a T cell activation molecule involved in one alternate pathway. Thus T cells isolated by this technique may under certain circumstances be activated by the procedure. This phenomenon must be kept in mind when designing

experiments or making conclusions about the *in vivo* state of such populations.

In other species E rosette formation is less successful. Limited use of the technique occurs with sheep E and primate T cells. The cat T cell forms rosettes with guinea pig and gerbil erythrocytes.

Erythrocyte Antibody (EA) rosette

The identification of hematopoietic cells by their formation of rosettes with erythrocytes coated with antibody molecules is complex. Careful attention to the type of erythrocyte and of the antibody coating on that cell is required. Seven types of hematopoietic cells have receptors for immunoglobulin (Ig) on their cell membrane. An additional layer of complexity is that there are receptors for IgM, IgA, IgE and IgG and its subclasses. The difference between these receptors and their affinities is covered in the entry on Fc receptors. The most prominent Fc receptor-bearing cells are polymorphonuclear leukocytes and monocytes. In most immunologic studies of lymphocyte function the neutrophils are removed by density gradient centrifugation. They are readily identified by their characteristic morphologic appearance in smears or cytocentrifuge preparations. Monocytes are similarly identified as EA rosette-forming cells in such preparations. Monocytes are removed by glass or plastic adherence or passage through columns of Sephadex G-10. Platelets have Fc receptors and care must be taken to remove these cells as well from preparations. Eosinophils, basophils and mast cells are removed along with the neutrophils. B lymphocytes may be identified and isolated once contaminating cells are removed by their rosette formation with ox erythrocytes coated with anti-ox cell antibody. This method is inferior to their identification by anti-surface membrane immunoglobulin antibody techniques, but may be performed when fluorescence microscopy is not available. The results obtained should be correlated with the results of complement receptor assays (see below).

The T cell population can be subdivided into two populations by rosette formation with erythrocytes coated with IgM or erythrocytes coated with IgG. It is important in this assay to incubate freshly isolated T cells overnight in immunoglobulin free media to allow the *in vivo* passively absorbed IgM and IgG to be shed. Then rosette assays with appropriately coated erythrocytes can be performed. T cells with receptors for IgM were originally described as helper T cells, whereas cytotoxic T cells were said to have receptors for IgG. Subsequently it has been shown that these two classes of T cells cannot be distinguished on this basis. However, multiple cell types

Table 1 Rosette markers of human peripheral blood mononuclear cells

	<i>T cells</i>	<i>B Cells</i>	<i>Monocytes</i>
E Rosette	+	—	—
EA-Ox	—	+	+
EA-Human	—	(+)	+
EAC-CR1	—	+	+
EAC-CR2	—	+	—
EAC-CR3	—	—	+

can be identified by EA rosette formation but careful attention to details of preparation is essential.

Erythrocyte Antibody Complement (EAC) rosette

The use of erythrocytes coated with complement components, especially C3, to form rosettes is an extensively utilized technique. However, other particles such as zymosan or bacteria can also be used. There are a number of separate and distinct complement receptors on lymphocytes. Assays for CR1 receptor cells are performed using sheep erythrocytes sensitized with IgM antibody and purified complement components to build up a EAC1-4b or EAC1-3b. Alternative methods using heat inactivated serum to prepare appropriate reagents are available. Detection methods for CR2 use the EA cells and whole serum to prepare an EAC3d. Reagents for the detection of CR3 utilize the EAC3b cell subsequently treated with P1H and C3 inactivator. In such assays purified isolated mononuclear cells are incubated with the appropriate reagent, enumerated in a hemocytometer, and the percentage of positive rosettes determined. These rosette methods can also be used to isolate populations of cells for additional experiments. These methods are inexpensive and allow an excellent yield of cells. A summary of these tech-

niques and the mononuclear cell populations so identified is presented in Table 1.

S

SALMONELLA, INFECTION AND IMMUNITY

Carlos E Hormaeche, Department of Microbiology, University of Newcastle Upon Tyne,
The Medical School, Newcastle Upon Tyne, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Characteristics of the organism and its antigens

Salmonellae (family Enterobacteriaceae, genus *Salmonella*) are facultatively anaerobic, motile gram-negative rods. They are now classified into three main species (*S. typhi*, *S. cholerae-suis* and *S. enteritidis*) with over 2000 different serotypes considered different varieties of *S. enteritidis*. Pathogens of humans and animals, they can be found in the digestive tract, blood and internal organs, and can survive in the environment to cause water- or food-borne infections. Host-adapted salmonellae can cause severe invasive disease, e.g. *S. typhi* or the paratyphoid bacilli causing typhoid fever in humans, *S. gallinarum* or *S. pullorum* causing fowl typhoid. Others have a broader host range, causing invasive disease in one host species and more limited infections in others, e.g. *S. typhimurium* or *S. enteritidis*, which cause invasive disease in rodents and are common agents of food poisoning. These salmonellae of animal origin can also cause invasive disease in humans in the extremes of age or in situations of lowered host defences. Salmonella septicaemias are invasive infections with abscess formation, typically by *S. choleraesuis*. Asymptomatic carriers of *S. typhi* are the reservoir of human typhoid fever. Carriage of other serotypes in animals, including ovarian carriage in birds with infected eggs, causes contamination of foodstuffs and gastroenteritis.

Serological classification of salmonellae is based on the main determinants present on the somatic (O) and flagellar antigens. O antigens are present on the long side-chains of lipopolysaccharide (LPS or endotoxin). The lipid A of LPS is the main determinant of toxicity. 'Rough' mutants lacking the O side-chains are serum sensitive and avirulent. Some salmonellae (e.g. *S. typhi*, *S. dublin*, *S. paratyphi* C) express the Vi capsular antigen, a homopolymer of α -1,4-deoxy-2-N-acetylgalacturonic acid, which can mask the O antigen and is important in virulence and immunity. Enterobacterial common antigen (ECA)

may also be present. With few exceptions, salmonellae are motile with peritrichous flagella. Many serotypes show flagellar phase variation, reversibly expressing flagella with one or two different antigenic specificities. Important in classification, the relevance to pathogenicity of this highly conserved variability is unknown. Many salmonellae express fimbriae; other somatic components are also antigenic, and renewed attention is being given to the role of cell wall proteins in pathogenesis, immunity and diagnosis.

Evasive strategies by the organism

It is only in recent years that the molecular basis of virulence and the genetic determinants of pathogenicity which allow salmonellae to invade and multiply in the hostile environment of the host have begun to be elucidated. As *S. typhi* does not infect conventional laboratory rodents, much of the information is gained from animal models (mouse typhoid) and cell culture systems. Invasive salmonellae penetrate through the epithelial cells and M cells of the distal ileum and Peyer's patches; the brush border degenerates and the organisms pass through the cell enclosed in a membrane to exit through the basal pole to the submucosa. Flagella, motility, chemotaxis and smooth LPS contribute to invasion. Salmonella invasins and a cytotoxin have been described; invasion of and replication within epithelial cells are under separate genetic control. In gastroenteritis bacterial multiplication does not proceed beyond the intestine; some but not all strains will cause fluid accumulation in the rabbit ileal loop model. The precise mechanism of fluid loss remains unclear.

In invasive disease (e.g. enteric fevers) bacteria disseminate to the liver, spleen and bone marrow, grow within and kill hepatocytes. They also grow inside macrophages *in vitro* and can kill them, and the ability of salmonellae to grow inside cultured mouse macrophages correlates with mouse virulence. However, the ability of salmonellae to grow inside

macrophages in the tissues is debated, as macrophages in lesions have been seen to contain mainly dead salmonellae. Polymorphs are prominent in the early stages of infection and may contribute to the lysis of infected hepatocytes. In chickens purulent pericarditis caused by, for example, *S. enteritidis* is not uncommon. The precise mechanisms of survival within macrophages are still unclear; resistance to lysosomal enzymes and inhibition of phagolysosome fusion have been described, with the Vi antigen increasing the resistance of *S. typhi* to killing by leukocytes. Transposon-generated macrophage-sensitive mutants were found to be auxotrophic or sensitive to serum or oxidative stress. Mutations in genes which respond to environmental changes affect survival in macrophages; *ompR* regulates expression of outer membrane porins in response to osmolarity changes (*ompR* mutations are attenuating), while the *phoP phoQ* operon responds to phagolysosomal signals (low pH, cationic peptides), increasing resistance to phagocyte defensins. The large serotype specific ('cryptic') plasmid present in some but not all salmonellae (absent in *S. typhi*) affects serum resistance and persistence and growth in the tissues.

Immune responses of the host

Both innate and adaptive immune response mechanisms are crucial in survival following a primary infection with virulent organisms in the naive host. The ID₅₀ of *S. typhi* in humans is *ca.* 10⁵ organisms. Salmonellae initially grow exponentially in the reticuloendothelial system (RES). In lethal infections, growth continues unchecked until 'lethal numbers' of approximately 10⁸ organisms are reached; endotoxin poisoning is believed to contribute to death. Both strain virulence and host resistance determine the rate of increase of bacterial numbers in the RES; in mice, the *lty/lsh/bcg* gene on chromosome 1 regulates the growth rate of salmonellae in the tissues in the first days of the infection and determines the incubation period; the same gene modulates resistance to mycobacteria and *Leishmania*. In sublethal infections, exponential early growth is checked by a host response (the plateau phase) which is mediated by an influx of radiation-sensitive bone marrow-derived cells, tumor necrosis factor α (TNF α), interferon γ (IFN γ) and interleukin 12 (IL-12), but not T cells. LPS unresponsive mice, such as C3H/HeJ (*Lps*^d), are more susceptible.

After the plateau phase, bacteria are cleared from the tissues by an immune response phase (influenced by host genes within and outside the major histocompatibility complex, MHC) which can leave solid immunity to reinfection. CD4⁺ and CD8⁺ T cells,

TNF α , IFN γ and IL-12 are involved in bacterial clearance from the tissues, with TNF α involved in monocyte recruitment and granuloma formation, whereas T cells and IFN γ are needed for expression of increased antibacterial resistance. However, in contrast to immunity to mycobacteria and *Listeria*, immunity to salmonellae in mice also requires the participation of antibodies in addition to cell-mediated immunity (CMI), which is not common with intracellular bacteria. With the 'animal' salmonellae the antibody is probably directed against the LPS; in human typhoid antibodies to Vi are probably important. The targets of the cell-mediated response are, as yet, unclear. Antibodies to O and H antigens are diagnostic in typhoid fever, and carriers have elevated Vi antibodies.

Antibody alone or immunization with killed organisms, which do not elicit CMI, confer less protection than immunization with live organisms, which induce CMI as well as humoral immunity. Protection is best conferred by immunization with organisms which can persist and grow for a limited period in the tissues. Live organisms induce delayed-type hypersensitivity (DTH) to a crude salmonella elicitin, but the correlation of DTH with immunity is poor. The protective immunogen(s) may be the main LPS O antigen (or Vi in *S. typhi*), other protein antigens, or a combination of both. Mucosal immunoglobulin A (IgA)-mediated immunity confers a degree of protection. The precise mechanisms of immunity in human typhoid fever remain unclear, but the encouraging results obtained with live vaccines suggest that CMI is important, as well as Vi-specific antibodies. Cytotoxic T cells which lyse salmonella-infected target cells have been described in animals and humans.

Vaccines

Conventional parenteral salmonella vaccines consisting of killed organisms have been widely used; however, they confer incomplete protection and are excessively reactogenic. Human trials of oral vaccination with large doses of killed organisms did not show protection. A typhoid vaccine consisting of highly purified *S. typhi* Vi antigen is now available; it does not provoke the unacceptable side-reactions of killed whole-cell vaccines, and also confers significant but incomplete protection.

The superior efficacy of live vaccines in experimental models has led to the development of new candidate oral live attenuated salmonella vaccines for humans and animals. Mutations in the *galE* gene cause an LPS core defect with impaired synthesis of smooth LPS. The efficacy of *galE* mutants in mice

led to the development of *S. typhi* Ty21a, a nitroguanidine-induced Vi⁻ mutant which provided significant although incomplete protection. This is available as a human oral typhoid vaccine; it is very safe but also very attenuated; a Vi⁺ variant of strain Ty21a did not exhibit greater immunogenicity. More recently, an engineered *galE* Vi⁻ *S. typhi* vaccine candidate strain caused typhoid in volunteers, demonstrating that *galE* is not a fully attenuating mutation in *S. typhi*. It is now clear that chemical mutagenesis induced other unknown mutations responsible for the attenuation of Ty21a. Seroconversion rates in humans following oral immunization with Ty21a are not high. Vaccinees show positive proliferative responses in peripheral blood leukocytes stimulated with *S. typhi* antigens, suggesting induction of cellular immunity.

Other candidate live vaccines are also being developed. The use as vaccines of 'animal' salmonellae cured of the large virulence plasmid, which show reduced multiplication in the tissues, has been proposed. Mutants with lesions affecting adenylate cyclase and cAMP receptor protein (*cya crp* mutants) are attenuated and effective oral vaccines in mice. Aro salmonellae harboring lesions in genes of the aromatic pathway are attenuated, owing to their requirement for *p*-aminobenzoic acid which is unavailable in the mammalian host. Aro mutants grow slowly in the tissues, from which they are eventually cleared. Aro mutants of *S. typhimurium*, *S. dublin* and *S. enteritidis* are effective vaccines in mice, calves, sheep and chickens. Mutations in purine biosynthesis are also attenuating; *S. typhi* *aro pur* mutants are innocuous in humans, but the *pur* mutation appears to be excessively attenuating, making the vaccines poorly immunogenic. Mutations in *htrA*, a stress protein gene, are attenuating and provide good vaccines; human volunteer trials with an *S. typhi* *aroC aroD htrA* mutant are yielding promising results.

A further use of live attenuated salmonellae is their

potential as single-dose live oral multivaccine delivery systems for recombinant antigens from other pathogens. Salmonella vaccines can elicit humoral, secretory and cellular immunity to recombinant antigens. They have been used to express over 40 different antigens from viruses, bacteria and parasites, and with some antigens positive immune responses, toxin-neutralizing antibodies and protection from disease has been obtained, e.g. antibody to enterotoxins, fimbrial adhesins, and antigens from HbSAg, human immunodeficiency virus (HIV) and SIV, *Bordetella pertussis*, papilloma viruses and many others. Protection against *Plasmodium* spp., streptococci, tetanus and influenza infection in mice have been observed. Trivalent vaccines expressing recombinant antigens as genetic fusions to the immunogenic C fragment of tetanus toxin have conferred protection in mice against salmonellae, tetanus and schistosomiasis or herpes simplex virus. A recombinant Aro *S. typhi* expressing the *Plasmodium falciparum* circumsporozoite antigen elicited antibody and cytotoxic T cells in human volunteers.

SARCOIDOSIS

David R Moller, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Sarcoidosis is a disease of unknown etiology characterized by epithelioid granulomas and T cell infiltrations in multiple organ systems. The disease most commonly affects the lungs and intrathoracic lymph nodes. Eye and skin involvement is seen in approxi-

mately 20% of patients, and symptomatic involvement of other organ systems occurs less frequently. Sarcoidosis can be asymptomatic or present in an acute or subacute form. Spontaneous remissions occur in about 50% of cases; in other patients,

chronic, progressive disease ensues with an overall >5% mortality rate. Corticosteroids are the mainstay of treatment for threatened organ failure or chronic progressive disease. Sarcoidosis occurs worldwide, primarily in 20–40-year-old adults, with a frequency that varies among different populations and ethnic groups. Epidemiologic and family studies suggest that both environmental and genetic factors play a role in the etiology of sarcoidosis. Recent immunologic studies provide evidence for oligoclonal expansion of $\alpha\beta$ T cell subsets and predominant expression of type 1 cytokines (interferon γ (IFN γ), interleukin 2 (IL-2), IL-12) at sites of inflammation, suggesting that sarcoidosis is an antigen-driven, T_H1-mediated immune disorder. The fundamental question regarding the etiologic stimulus driving this inflammatory process remains to be elucidated.

Historical perspective

In 1899, Caesar Böeck described a patient with lymphadenopathy and multiple skin nodules with characteristic epithelioid granulomas on histologic examination; he proposed the term 'multiple benign sarkoids' for this condition. The view that sarcoidosis is a multisystem disease was first clearly expressed by Jörgen Schaumann in 1914. Thirty years later, Sven Löfgren observed that sarcoidosis frequently presents with asymptomatic bilateral hilar adenopathy or with erythema nodosum. For many years, sarcoidosis was conceptualized as a disease of suppressed immunity with peripheral lymphopenia and cutaneous anergy. Landmark studies of pulmonary sarcoidosis in the late 1970s led to a fundamental reappraisal of sarcoidosis as a disease of enhanced, cell-mediated immune activity associated with granulomatous inflammation.

Epidemiology

The prevalence of sarcoidosis ranges from 10 to 40 cases per 100 000 population in North America, southern Europe and Japan. Higher prevalence rates have been noted among Swedes in Sweden (64/100 000) and African-Americans in southeastern US. Erythema nodosum has a particularly high prevalence among Irish women in London and Puerto Rican women in New York City. Lupus pernio, a disfiguring facial skin condition associated with chronic sarcoidosis, is more frequent in patients of African descent. Worldwide, there is a slight female predominance.

Genetics

Familial clustering of sarcoidosis occurs in approximately 5–16% of patients. Within the same family, sibling pairs are most common, followed by mother-daughter pairs and father-son pairs. Monozygotic twins appear more likely to develop sarcoidosis than dizygotic twins, strongly suggesting a genetic component to the disease. The lack of a clear genetic pattern suggests that susceptibility to sarcoidosis is polygenic and associated with environmental factors. Worldwide, HLA studies have shown inconsistent results with associations reported for HLA-DR3 and bilateral hilar adenopathy or erythema nodosum in Swedish patients, B27 and uveitis, B13 and chronic disease, DR5 in Italian patients and DRw52 in Japanese patients.

Etiology

Given the clinical and histologic similarities to tuberculosis, investigators have searched for an infectious etiology of sarcoidosis since its original description, with inconclusive results. Since the 1960s there have been unconfirmed reports of cultivable mycobacterial or cell wall-deficient organisms in sarcoid tissue. Other investigators reported finding acid-fast staining material in pathologic specimens, but these findings are contrary to general experience. High titers of antibodies against many viral and bacterial antigens are found in sarcoidosis but probably reflect generalized B cell activation and not a causal relationship. Recently, polymerase chain reaction methods have been used to search for traces of microbial DNA in sarcoid tissue. Different studies have found mycobacterial DNA in 0–50% of biopsy specimens or bronchoalveolar lavage fluids, with false positive rates ranging from 0 to 9%. These divergent results have done little to clarify a possible causal link between sarcoidosis and mycobacterial disease.

The possibility of a noninfectious, environmental cause of sarcoidosis is suggested by the association of beryllium dust exposure with a chronic, interstitial granulomatous lung disease that is indistinguishable from sarcoidosis. Other investigators suggest that sarcoidosis is the result of autoimmunity (perhaps due to molecular mimicry of microbial antigens or to altered self antigens) or immune dysregulation. The presence of antinuclear antibodies, rheumatoid factor, hypergammaglobulinemia and immune complexes in sarcoidosis is cited as supporting evidence for these latter possibilities.

Kveim–Siltzbach test

In 1941, Ansgar Kveim, a dermatologist from Oslo, demonstrated that intradermal inoculation of a suspension of sarcoid tissue resulted in firm red papules containing sarcoid-like granulomas in patients with suspected sarcoidosis, but not in control individuals including patients with tuberculosis. In the following decades, Louis Siltzbach pioneered worldwide efforts that demonstrated a single, validated reagent gave positive reactions in 70–80% of patients early in their disease with a <1% false-positive rate. Similar

reactions can be elicited by dermal injection of autologous bronchoalveolar lavage cell suspensions.

The Kveim reaction takes 2–4 weeks to develop well-defined granulomas, similar to the Mitsuda reaction to lepromins in patients with tuberculous leprosy. Local CD4⁺ T cell and monocyte infiltration precedes the development of epithelioid granulomas. In the search for clues to the etiology of sarcoidosis, many attempts have been made to identify the granuloma-inducing factor contained in the Kveim–Siltzbach reagent. The component appears to be a heat-stable, cell wall-associated microparticulate, but precise characterization remains an elusive goal.

Table 1 Major immunologic features of tissue inflammation in sarcoidosis

Epithelioid granulomata

CD4⁺ T cell infiltration

- Activated phenotypes (IL-2R⁺, VLA-1⁺, DR⁺)
- Biased, oligoclonal αβ T cell expansions
- Enhanced T_H1 cytokine production (IFNγ, IL-2)

Monocyte/macrophage infiltration

- Activated phenotypes (increased surface HLA-DR, -DQ, -DP, -ICAM-1, -LFA-1)
- Enhanced reactive oxygen species, angiotensin-converting enzyme, lysozyme production
- Spontaneous cytokine production (IL-12, TNFα, IL-6, ?IL-1)
- Enhanced chemokine production (MIG, MIP-1α, MCP-1)
- Enhanced production of fibronectin, IGF-1
- Enhanced antigen presentation (alveolar macrophages)

Pathology

The histologic hallmark of sarcoidosis is the presence of discrete, noncaseating, epithelioid cell granulomas typically at different stages of development (Table 1, Figure 1). The dominant cell in the central core is the epithelioid cell, thought to be a differentiated form of a mononuclear phagocyte. CD4⁺ lymphocytes and mature macrophages are typically interspersed throughout the epithelioid core, whereas both CD4⁺ and CD8⁺ lymphocytes are seen in the periphery of the granuloma. Approximately 5–10% of T cells at sites of inflammation are IL-2R⁺ and 20–50% are HLA-DR⁺, indicative of their recent activation.

Figure 1 Principal events involved in granuloma formation in sarcoidosis. (A) In response to an unknown stimulus, activated macrophages and oligoclonal CD4⁺ T cells accumulate at sites of inflammation. (B) Epithelioid cells and giant cells, derived from differentiated macrophages, aggregate with fibroblasts, other CD4⁺ and CD8⁺ T cells and mononuclear phagocytes to form granulomas. These events are hypothesized to be driven by antigen-specific, T_H1-mediated immune responses that produce type 1 cytokines (IFNγ, IL-2, IL-12), TNFα and other proinflammatory chemokines and cytokines. (C) Granuloma formation may resolve spontaneously or persist, leading to chronic inflammation and fibrosis.

Giant cells, often containing cytoplasmic inclusions such as Schaumann bodies, are scattered throughout the inflammatory locus. In the lung, granulomas tend to form along bronchovascular regions, areas rich in lymphatic vessels. Granulomas and T cell infiltrations are also typically present in alveolar and bronchial walls.

Immunopathogenesis

The pathologic features of sarcoidosis are typical for 'immune-mediated' granulomatous diseases of known etiology such as mycobacterial or fungal infections and chronic beryllium disease. In these disorders, granulomatous inflammation is regulated by a complex interplay among T cells, mononuclear phagocytes, fibroblasts, dendritic cells and other accessory cells. In sarcoidosis, this inflammatory process results in pathologic changes in organ function by disrupting normal architecture, damaging local tissues and producing cytokines and chemical mediators with local and systemic effects. Current information on the immunopathogenesis of sarcoidosis has been derived in large part from studies of lung cells and fluid from the lower respiratory tract obtained by bronchoalveolar lavage.

T lymphocytes in sarcoidosis

Lung T cells recovered from the alveolar surface are predominantly of the CD4⁺ phenotype, typically with a CD4:CD8 ratio of 3–10:1 compared with a ratio of 2:1 in healthy individuals (Table 1). Sarcoid and normal lung T cells are almost all memory T cells expressing CD45RO⁺/CD29⁺ surface markers. Greater numbers of lung T cells express activation markers such as IL-2R, VLA-1 (CD49a) or HLA-DR molecules than circulating T cells. Sarcoid lung T cells demonstrate reduced surface density of the CD3/T cell receptor complex, a hallmark of antigen-stimulated T cells. Consistent with recent activation, greater numbers of lung T cells express the cell cycle-related nuclear antigen Ki67 and a small proportion of lung T cells are spontaneously proliferating. Lung T cells in sarcoidosis spontaneously produce the type 1 cytokines IFN γ and IL-2 *in vitro*.

In contrast to the lung, patients with sarcoidosis often demonstrate CD4⁺ T cell lymphopenia in peripheral blood. Increased numbers of circulating T cells are IL-2R⁺, suggesting that these cells are trafficking from inflamed tissues.

T cell receptor gene expression

Investigators have analyzed T cell receptor gene expression in sarcoidosis in order to define disease-

specific T cells and their reactivity. Results of these studies demonstrate the presence of expanded numbers of V β ⁻ or V α ⁺ T cell subsets (e.g. V β 8⁻, V β 19⁻ or V β 5⁺ T cells) in the lung, blood or skin (sites of Kveim-Siltzbach reactions) of subgroups of patients. Sequence analyses demonstrate that expanded $\alpha\beta$ T cell subsets are oligoclonal and sometimes contain shared amino acid motifs in the CDR3 region of their V β genes, consistent with local antigen-driven T cell responses. Expanded numbers of V α 2.3⁺ lung T cells are found in Swedish patients with DR3/DQ2 haplotypes, perhaps reflecting T cell responses to a specific peptide-MHC complex. Despite intense efforts, the reactivities of these expanded T cell clones have yet to be identified.

Studies of $\gamma\delta$ ⁺ T cells in sarcoidosis have led to divergent results. In some reports, as many as 30% of patients have greater proportions of circulating $\gamma\delta$ T cells, predominantly of the V γ 9⁺V δ 2⁻ subset. Other studies have found that the increase in $\gamma\delta$ T cells is secondary to a reduction in circulating $\alpha\beta$ T cells or have not found any difference from control populations. Since $\gamma\delta$ T cells are rarely found around granulomas in lymph nodes or skin, a role for $\gamma\delta$ T cells in the pathogenesis of sarcoidosis remains uncertain.

Mononuclear phagocytes in sarcoidosis

Sarcoid alveolar macrophages appear activated, producing increased amounts of lysozyme, angiotensin-converting enzyme and reactive oxygen species (Table 1). Reports of enhanced lung macrophage expression of the IFN γ -inducible chemokine MIG (monokine-induced by IFN γ), provide evidence of cellular activation by IFN γ . Sarcoid alveolar macrophages contain a twofold increased density of surface class II MHC (DR,DQ,DP) molecules and the adhesion molecules LFA-1 and ICAM-1. These characteristics probably contribute to the enhanced ability of sarcoid alveolar macrophages to present antigen to autologous T cells compared with normal alveolar macrophages.

Sarcoid alveolar macrophages spontaneously produce IL-12, tumor necrosis factor α (TNF α), IL-6, and possibly IL-1, cytokines known to regulate granuloma formation. These cells also release increased amounts of fibronectin and insulin growth factor 1 (IGF-1), molecules important in fibroblast recruitment and replication. In contrast, sarcoid alveolar macrophages produce lesser amounts of the counterinflammatory prostaglandin E₂, than normal alveolar macrophages. In a subgroup of patients, enhanced *in vitro* production of transforming growth factor β (TGF β) by lung macrophages has been as-

sociated with remission of active disease, suggesting this cytokine is critical to downregulating the inflammatory process.

Multiple chemokines including MCP-1, RANTES, MIP-1 α and IL-8 are found in bronchoalveolar lavage or tissue specimens in sarcoidosis. These chemokines probably assist in the recruitment of monocytes, macrophages, memory T cells and granulocytes to inflammatory loci in sarcoidosis. Natural killer (NK) cells, B cells, eosinophils and mast cells are also occasionally seen around granulomas; their contributions to the inflammatory response are uncertain.

Cytokine interactions in sarcoidosis

Substantial evidence indicates that granulomatous inflammation in sarcoidosis is characterized by a predominant type 1 cytokine response. Bronchoalveolar lavage studies demonstrate increased mRNA and protein levels of IFN γ , IL-2 and IL-12, low or undetectable levels of IL-4 and IL-5, and normal or low levels of IL-10 in pulmonary sarcoidosis. The known dependence of many granulomatous disorders on type 1 cytokines suggest they function in a similar manner in sarcoidosis. One hypothesis suggests that successful removal of the inciting agent by this T_H1-dependent response allows for TGF β inhibition of IL-12 and IFN γ production and resolution of the disease. If the immune response is ineffective in removing the inciting stimulus or T cell autoimmune responses develop, dysregulated cytokine production driven by a positive feedback loop between IFN γ and IL-12 results in maintenance of the granulomatous inflammation. A fibrotic outcome from accumulated tissue injury may theoretically be prevented by suppressing the inflammatory response early in the course of the disease. Consistent with this hypoth-

esis, drugs capable of suppressing IFN γ and IL-12 production (e.g. corticosteroids, pentoxifylline) are often beneficial in the treatment of sarcoidosis.

SCHISTOSOMIASIS

Michael J Doenhoff and **Anthony E Butterworth**, School of Biological Sciences, University of Wales, Bangor, Gwynedd, UK

Schistosomiasis is the generic term given to diseases caused by digenetic trematodes, or blood flukes, of the genus *Schistosoma*. The three main species of schistosome that are pathogenic for humans, *S. mansoni*, *S. haematobium* and *S. japonicum*, are estimated to affect some 200 million people throughout the tropics and cause extensive chronic morbidity and some mortality, especially among children and young adults. *Schistosoma haematobium* causes urinary schistosomiasis in Africa and the Middle

East, *S. mansoni* causes intestinal schistosomiasis in South America, the Caribbean, Africa and the Middle East, and *S. japonicum* causes intestinal schistosomiasis in the Far East, especially China and the Philippines. Two other species of schistosome, *S. intercalatum* and *S. mekongi*, are also significant human pathogens, but have relatively restricted geographical distribution, and the important parasites of African cattle and sheep, *S. bovis* and *S. matthei*, occur in this genus.

Characteristics of the organism and its antigens

Figure 1 is a representation of the schistosome life cycle. A phase of sexual maturation and mating in the definitive mammalian host alternates with a phase of asexual replication in an intermediate molluscan host, i.e. freshwater snails of the genera *Biomphalaria*, *Bulinus* and *Oncomelania* for *S. mansoni*, *S. haematobium* and *S. japonicum*, respectively.

The free-living cercaria is released from infected snails and swims actively in fresh water for several hours. Upon contact with the skin of an appropriate mammalian host it penetrates directly through the skin, sheds its tail and outer glycocalyx coat and transforms into the young schistosome or schistosomulum. After a 2 day sojourn in the skin of experimentally infected animals the schistosomulum enters the bloodstream. The larvae can be found in large

numbers in the lungs of experimental hosts between 4 and 7 days after skin penetration, but it is believed that during this time they are circulating throughout the body, lodging only temporarily in highly vascularized tissues such as the lungs. From 7 to 10 days after infection the larvae are found in increasing numbers in the hepatic portal system. Maturation and pairing of the sexually differentiated worms occurs, and the paired worms take up their final position in the small mesenteric veins (*S. mansoni* and *S. japonicum*) or the veins of the vesical plexus (*S. haematobium*).

The mean lifespan of the adult worm is estimated to be 2–8 years, depending on species, but there is evidence of *S. mansoni* worms being able to survive 2–3 decades. Egg-laying starts about 6 weeks after infection, the females releasing between 300 eggs (*S. mansoni*) and 3000 eggs (*S. japonicum*) a day. A proportion of the eggs released by *S. mansoni* and *S.*

Figure 1 The schistosome life cycle.

japonicum worms are carried by hepatic portal blood flow to lodge in the liver, or they can be trapped locally in the intestinal walls, from which some pass into the gut lumen to be excreted. *S. haematobium* eggs are trapped in tissues of the urinogenital system, from which some leave the body in urine. The eggs hatch upon contact with fresh water, releasing the ciliated miracidium, a second free-living stage which is infective for the snail intermediate host. An asexual replicative phase in the snail leads to the production, after 4–6 weeks, of large numbers of cercariae.

A common feature of virtually all helminth parasites is that they do not replicate in their definitive hosts. In schistosomiasis, morbidity is largely attributable to the retention of eggs in the tissues, and the severity of disease is dependent on the number of eggs that are retained. This in turn depends on the number of worms acquired by the host (the intensity of infection) and their lifespan. Infection loads build up during childhood and intensities of naturally acquired infections are characteristically overdispersed, with a small proportion of individuals harboring most of the worms. These are the individuals who are most likely to develop severe disease. Although schistosome worms have a long lifespan the parasites acquired during childhood spontaneously die after several years. In addition, adult humans fail to become heavily reinfected, because of either lack of exposure or acquired immunity, or both. Intensities of infection in endemic areas therefore characteristically show a convex distribution with age, with a peak during the second decade of life.

It is accepted that eradication is an unachievable objective in the short to medium term, and the aim of control, whether by chemotherapy or eventually by vaccination, is now rather to reduce intensities of infection to levels sufficiently low that severe morbidity is not observed.

The several stages of the parasite that occur in the mammalian host are morphologically distinct and express both common and stage-specific antigens and epitopes. The young schistosomulum, about 100–150 μm long, has a syncytial tegument, containing spines bounded by an outer membrane composed of a double lipid bilayer. The tegument surrounds layers of circular and longitudinal muscle. Differentiated regions, in particular an oral and a ventral sucker, can be distinguished, but there is no functional gut, and nutrient and metabolite exchange takes place across the tegumental membrane. Development of a functional intestine and of specialized reproductive organs occurs during maturation into the adult worm: the sexes are morphologically distinct and permanently paired, with the flattened male (about

1 cm long) enclosing the longer and thinner round female in a gynaecophoric canal or schist. The egg comprises the larval miracidium enclosed by a rigid shell that bears, according to the species, a lateral spine (*S. mansoni*), a terminal spine (*S. haematobium*), or virtually no spine (*S. japonicum*) (see Figure 1). Micropores in the eggshell permit the passage of macromolecular antigens from the inside of the egg into the surrounding tissues.

Immune responses of the host

Repeated exposure to schistosome larval antigens, including those of nonhuman species, can result in hypersensitivity and cercarial dermatitis or 'swimmer's itch'. Initial exposure to a heavy primary infection of *S. mansoni* or *S. japonicum* can result some weeks later in an acute febrile syndrome, Katayama fever, which some have considered analogous to serum sickness or immune complex disease.

Immune reactions to the later stages of infection have different consequences for the host and are associated primarily with morbidity or in mediating resistance against infection.

Egg-induced immunopathology

Most of the pathological consequences of schistosome infection are attributable to prolonged deposition of eggs in the tissues, with the ensuing granulomatous reactions that the eggs induce leading to fibrosis. This in turn may lead to portal hypertension or urinogenital dysfunction, depending on the parasite species. The disease symptoms of schistosomiasis are therefore attributable to immunopathology.

The egg granuloma (Figure 2) is elicited in response to stage-specific egg antigens, though pre-

Figure 2 The schistosome egg granuloma. Section through an inflammatory lesion surrounding a *Schistosoma mansoni* egg in the liver of an infected mouse. Schistosome eggs are approximately 150 μm long, and in early infection the volume of a granuloma can be 100 times that of the egg.

sensitization can be achieved with unisexual male worm alone infections. The granuloma is a T cell-dependent, delayed-type hypersensitivity reaction comparable to that seen in other chronic granulomatous conditions, except that eosinophils as well as lymphocytes and macrophages are abundant in the lesion. The etiology of the subsequent fibrosis is also assumed to be an egg antigen-induced, T cell-dependent event, attributable to stimulation of fibroblasts by T cell-derived mediators. In mice, the granulomata that are induced around freshly deposited eggs during chronic infection are smaller and lead to less fibrosis than those that develop during acute infection. Such reactions are said to be 'modulated' and the capacity to mount a modulated reaction can be reproduced *in vitro* and adoptively transferred to acutely infected animals with CD8⁺ lymphocytes. There is evidence that modulation also occurs in chronically infected humans, in whom a variety of potential immunoregulatory mechanisms have been demonstrated, including serum factors, adherent and nonadherent suppressor cells, and T cells with idiotypic specificity for anti-egg antibodies.

Host reactions to egg antigens may play a protective as well as a deleterious role. Mice depleted of T cells show an enhanced mortality during *S. mansoni* infections, associated with hepatic parenchymal damage. This has been attributed to the action of an egg-derived toxin, the pathogenic effects of which can be prevented by passive transfer of immune serum.

In mice, excretion of *S. mansoni* eggs via the feces depends on an intact immune system, with both antibodies specific for egg antigens and immune lymphocytes having been implicated in this process. It has been postulated that the principal biological role of the egg granuloma is to facilitate egg excretion, and there is recent evidence that *S. mansoni*-infected humans with concurrent HIV infection have reduced schistosome egg excretion rates. Tumor necrosis factor α (TNF α) has also been identified as an important mediator in both the egg excretion process and female worm fecundity, as well as in host morbidity.

Anti-infection immunity

In contrast to the pathological effects of the egg granuloma, reactions to the schistosomulum are largely host-protective. Early studies by Smithers and colleagues showed that in rhesus monkeys adult worms of a primary infection continued to survive while the host was demonstrably resistant to reinfection by a secondary challenge of fresh cercariae, a phenomenon referred to as 'concomitant immunity'. Subsequent work in the mouse has shown that the

resistance induced by chronic patent infections may, however, be in part attributable to a nonspecific trapping or elimination of schistosomula following the formation of egg granulomas, i.e. as a result of disruption of the vascular migration routes normally used by incoming larvae.

Attempts to induce protective immunity with crude antigenic extracts of schistosomula, adult worms or eggs, or antigens purified therefrom have given variable results depending on the antigen(s), host animal species, type of adjuvant, etc., that were used. Partial, but specific protection against cercarial challenge can, however, be induced routinely in mice and other experimental hosts by immunization with irradiated cercariae which fail to mature into egg-laying adults. Relatively nonpermissive hosts such as the rat, as well as developing a specific resistance to cercarial challenge following immunization with irradiated larvae, tend also to become more immune after primary infection with unattenuated larvae or immunization with isolated antigens.

Although immune responses are elicited by both the adult and egg stages, the principal target of destructive immune attack is the migrating schistosomulum, and mechanisms of expression of antischistosomula immunity differ in host species. In most murine models, elimination of schistosomula occurs during or after the lung stage of migration, and is largely attributable to a T cell response to released schistosomulum antigens leading to macrophage activation and nonspecific killing of the parasite as a result of entrapment in inflammatory cellular foci or nitric oxide protection. In some circumstances, however, mice can also be protected against challenge by the passive transfer of monoclonal antibodies or of serum from donors that have been multiply vaccinated with irradiation-attenuated larvae. In the rat, death of schistosomula may occur either in the skin or after migration through the lungs, and may be attributable to antibody-dependent cellular cytotoxicity (ADCC) reactions against schistosomulum surface antigens. These reactions can involve eosinophils as well as macrophages or platelets, and immunoglobulin E (IgE) as well as IgG2a antibodies, suggesting a functional role for the long-recognized association between helminth infections, eosinophilia and IgE-mediated immediate hypersensitivity reactions.

In humans, the convex distribution of age-specific intensities of infection suggests the slow development of a concomitant immunity, and recent studies have demonstrated an age-dependent acquired resistance to reinfection after chemotherapy that is distinguishable from age-dependent changes in exposure to infection. In *S. haematobium* infections the expres-

sion of this resistance is correlated with peripheral blood eosinophilia, and human eosinophils are particularly potent mediators of ADCC reactions against schistosomula *in vitro* (Figure 3). This effect is enhanced by activation of the eosinophils *in vivo* or *in vitro*. Recent studies on both *S. mansoni* and *S. haematobium* infections in humans have demonstrated an association between the expression of infection-protective immunity and the development in older individuals of IgE antibodies against adult worm antigens. However, resistance in humans develops only in late childhood, and this may be attributable to the presence in younger children of 'blocking' antibodies of an inappropriate isotype and with specificity directed against carbohydrate epitopes on larvae.

Antigen carbohydrate epitopes are present in abundance on schistosome polysaccharides, glycoproteins and glycolipids, such residues being generally shared between the different parasite stages, and also between different schistosome species. Carbohydrates account for over 90% of the antigens expressed at the surface of the young schistosomulum, and antibodies, particularly IgM, IgG2 and IgG4, elicited early in infection in response to egg polysaccharide antigens may cross-react with the schistosomulum: this cross-reactivity may modulate or block the expression of potentially protective anti-schistosomular (ADCC) reactions. In contrast, peptide antigens tend to be both species- and stage-specific, although there is some sharing of these antigens by the schistosomulum and adult worm. Of the multiplicity of different proteins and glycoproteins that have been identified in the schistosomulum and adult worm, some have been implicated in the expression of protective immunity (see under Vaccination).

Cytokines and the T_H1/T_H2 cell axis

The identities of the populations and subpopulations of cells involved at various stages of schistosome infection, and of the cytokines they produce and respond to, are currently the subject of intensive investigation. Adult worms activate mainly T_H1-type responses, while eggs induce T_H2 responses. Protective responses in mice vaccinated with irradiated larvae appear to be driven principally by T_H1 cells, and can be enhanced by administration of interleukin 12 (IL-12).

TNF α mediates in egg granuloma formation in early patent infections and granulomatous activity is inhibited by treatment of normal mice with IL-4-specific antibody or exogenous administration of IL-12. In contrast to many other delayed-type hypersensitivity reactions the early egg granuloma is thus T_H2-dependent, which would account for the presence of large numbers of eosinophils in granulomas. Anti-IL-5 treatment results in the absence of eosinophils in egg-induced lesions which are otherwise of normal size. Hepatic fibrosis (collagen deposition) also appears to be T_H2 cell-mediated in mice.

The downmodulation of granulomatous activity that occurs as infections become chronic is mediated by T_H1 cells, as well as by CD8⁺ T cells.

Evasion of the host response

While in some combinations of host and parasite species there is evidence for an immunologically mediated suppression of egg output by adult females, the adult worm is generally not susceptible to immune attack, and can continue to survive for many years even in hosts that are immune to reinfection.

Figure 3 Antibody-dependent cellular cytotoxicity (ADCC) immune reactivity against a schistosomulum. The larval schistosome was incubated in culture medium together with a purified population of human eosinophils and human infection serum. After adhering to the parasite surface the eosinophils release the toxic constituents of their granules, resulting in damage and death to the former.

tion. Early work suggested that the loss of susceptibility to immune attack is attributable to the passive uptake onto the worm's surface of host-derived macromolecules that mask the expression of parasite surface antigens. Host constituents which have been shown to be present on or in adult worms include erythrocyte antigens, products of the MHC gene complex, immunoglobulins and plasma protease inhibitors. In addition the developing worm may simply lose antigenic macromolecules from the outer of the two lipid bilayers of the tegument, with adults thus having immunologically inert outer surfaces. Results showing that the schistosomicidal activities of drugs such as praziquantel are partially immune-dependent are consistent with this, in so far as the drugs erode the outer surface of the adult worms, thus exposing antigens which in normal worms are concealed from immune attack. Another explanation for immune evasion, currently less in favor, is that the parasite expresses epitopes which are shared with its host (the 'antigen mimicry' hypothesis). The developing schistosomulum may also partly evade immune damage, although less successfully than the adult, by releasing mediators that interfere with mast cell and lymphocyte function, proteolytic enzymes that cleave bound immunoglobulins, or lysophospholipids that kill effector cells of ADCC reactions.

Immunodiagnosis

Diagnosis of schistosomiasis is still done mostly by detection of the characteristically shaped eggs in human excreta. Indirect diagnosis using antibody detection assays, particularly ELISA are, however, becoming increasingly routine in the clinic, with antibodies against schistosome egg antigens showing somewhat more specificity and sensitivity than those against adult worm or larval antigens. The presence of at least two schistosome-derived carbohydrate-rich antigens in the blood of infected patients is enabling more direct immunodiagnostic tests to be developed using 'sandwich' ELISA.

Vaccination

No vaccine is yet available for protection against schistosomiasis in humans, though cattle have been protected against field challenge with *S. bovis* by immunization with irradiated larvae. The demonstration that experimental hosts can be partially protected against the human schistosomes by immunization with irradiated larvae, killed organisms or individual antigens suggests that vaccination in humans should be feasible.

Monoclonal antibodies with specificity for either carbohydrate or polypeptide epitopes confer protection after passive transfer in mice and rats. Carbohydrate antigens are not amenable to molecular cloning, but vaccination of rats with an anti-idiotypic monoclonal antibody that mediates ADCC reactions against the schistosomulum surface has been reported. This monoclonal antibody recognizes a carbohydrate epitope that is shared between schistosomula, eggs, and various molluscan macromolecules including keyhole limpet hemocyanin.

Various candidate polypeptide vaccine antigens have been prepared, following either affinity purification of the native molecule with monoclonal antibodies or monospecific sera, or molecular cloning and expression of relevant genes in *E. coli* or other hosts. Indeed, the application of recombinant DNA techniques now allows the production of parasite polypeptide antigens in sufficient amounts for large-scale use, and the World Health Organization has recently conducted preliminary independent laboratory trials on the immunoprophylactic potential of six recombinant *S. mansoni* proteins: 97 kDa paramyosin, a 62 kDa irradiation-associated vaccine antigen IrV-5, 28 kDa glutathione S-transferase, 28 kDa triose-phosphate isomerase, a 23 kDa membrane-bound antigen and 14 kDa fatty acid-binding protein.

Complete protection against challenge has not so far been demonstrated in any experimental host, either with attenuated organisms or with crude, purified or cloned antigens. However, in schistosomiasis a vaccine need not necessarily be completely effective in order to be of value. Since the adult worms do not proliferate within the human host, even a partial limitation on the establishment of adult worms will reduce the *intensity* of infection and may therefore prevent the development of severe morbidity.

SDS-POLYACRYLAMIDE GEL ELECTROPHORESIS (SDS-PAGE)

J Paul Banga, Department of Medicine, King's College School of Medicine, London, UK

The ability to separate a polypeptide of interest and to have an indication of its molecular size is a crucial element in any study involving mixtures of proteins. A variety of biochemical techniques are available to fractionate and analyze protein mixtures. These include electrophoretic, chromatographic and ultracentrifugation methods. The most relatively simple and powerful technique involves sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE). In this method, separation of proteins occurs on the basis of their molecular size where the SDS-protein complexes are sieved through a polyacrylamide gel matrix. The combination of SDS and sieving properties in the molecular sized pores of the gel matrix, leads to an exceedingly high resolution of separation which is unattainable with any other separation method based upon protein size.

In SDS-PAGE, the protein(s) react with the anionic detergent SDS:

The binding of SDS destroys the tertiary structure of the protein, leading to partial unfolding of the polypeptide chain. This gives rise to a denatured protein whose biological function, with a few notable exceptions, is usually lost. SDS binds to both the hydrophobic and hydrophilic areas of the polypeptide chain to give a negatively charged, 'cigar'-shaped molecule, that is studded along its entire surface with negatively charged sulfonate ions. The protein, with bound SDS, thus has a net negative charge which overrides the intrinsic charge in the protein molecule contributed by the individual amino acids of the primary sequence. Generally, with a few exceptions, the amount of SDS bound per gram protein occurs at a constant SDS:protein ratio of approximately 1.4 g SDS g⁻¹ protein. This ratio is achieved under reducing conditions (when the inter- and intramolecular disulfide bonds are cleaved and the free thiol groups

blocked) and under these circumstances, the amount of SDS bound is proportional to the size of the protein giving a constant charge to mass ratio. Carbohydrate-containing proteins usually bind less SDS than other comparatively sized proteins.

Once SDS-protein complexes have been obtained in a protein mixture, they have to be separated into different polypeptide components. This is achieved by using a supporting medium called polyacrylamide and applying an electric field to the negatively charged complexes.

Polyacrylamide is a synthetic polymer formed by polymerization of acrylamide monomer with bifunctional cross-linking agents – the polymerization is usually aided by a catalyst. The final polymerized polyacrylamide matrix comprises a three-dimensional network of pores whose size is regulated by the percentage degree of acrylamide monomer and cross-linker concentration in the polymerizing mixture. The molecular size of the pores in the polyacrylamide gel is comparable to the size of protein molecules. Thus during electrophoresis, the proteins are sieved through the pores of the gel with large proteins having a slower migration than the smaller proteins. The choice of acrylamide concentration is important for a good separation and generally for proteins between the molecular weights of 10 and 200 kDa, an acrylamide gel concentration of 8–12% is sufficient. A single concentration of acrylamide in the gel for separating proteins will usually suffice, although the resolution of the separation can be increased even further by incorporating a gradient of acrylamide in the gel. The presence of an acrylamide gradient in the gel (usually 5–15% gradient) leads to a gradual reduction in the pore size accompanied by a greater sieving effect during electrophoresis and hence sharper protein bands.

Various forms of SDS-PAGE protocols have been described with electrophoresis in tube or slab gels with a variety of different buffer systems. The most common with the highest resolution is the buffer sys-

Figure 1 SDS-PAGE to show affinity purification of a recombinant protein from bacterial extracts. The gel is a 10% polyacrylamide gel and stained for protein with Coomassie brilliant blue. The arrows indicate molecular weight derived from electrophoresing a known mixture of proteins – from top to bottom, 205, 116, 97, 66, 45, 36, 29, 24 and 20.1 kDa. Lane 1 shows the presence of over 50 protein staining bands in the bacterial extract, with a strong band of glutathione-S-transferase at approximately 26 kDa (arrowhead). Lane 2 shows the same bacterial extract after passing through a column of glutathione agarose, where the 26 kDa protein is considerably reduced following the affinity chromatography step. Lane 3 shows the purified glutathione-S-transferase which was bound to the affinity column and specifically eluted with reduced glutathione. It is clear from this electrophoretic analysis that the purity of the recovered enzyme is >95%.

tem described by Laemmli and colleagues and commonly referred to as the Laemmli SDS-polyacrylamide gel system. The Laemmli gels use a discontinuous pH buffer system which allows the proteins (which are in a large volume when the sample is loaded on the

gel) to concentrate into a narrow, sharp band in the stacking gel during electrophoresis. Briefly, the principle of this system is based upon the use of two different buffers containing chloride ions (in the gel) and glycine ions (in the buffer reservoir). At the pH of the stacking gel (pH 6.8), the SDS-protein complexes have an intermediate mobility between the leading chloride and trailing glycine ions such that during electrophoresis the proteins are swept into sharp, narrow zones at the trailing glycine ions accelerate to keep up with the leading chloride ions. There is no separation of protein as they stack and concentrate into narrow zones in the stacking gel. Separation occurs when these stacked proteins enter the separating gel, which is at a different pH (pH 8.8) to give the chloride and glycine ions a comparable mobility.

SDS-PAGE has played a central role in biochemical fractionation procedures. Its role in assessing the purity of antigen or immunoglobulin preparations together with defining the molecular weights of target antigens by immunoprecipitation or immunoblotting (western blotting) techniques has given it an important role in immunochemistry. This is illustrated in Figure 1 which shows various fractions during the affinity purification of recombinant glutathione-S-transferase to yield a virtually pure preparation of the enzyme (Figure 1, lane 3). Additionally, combined with other fractionational procedures such as isoelectric focusing (two-dimensional electrophoresis), SDS-PAGE combines high resolution and simplicity not achieved with other electrophoretic methods.

SECOND SIGNALS FOR LYMPHOCYTE ACTIVATION

Maria-Luisa Alegre and **Craig B Thompson**, Howard Hughes Medical Institute, University of Chicago, Chicago, Illinois, USA

Lymphocyte activation requires the recognition of antigen by a lymphocyte receptor of unique specificity. Antigen is recognized in soluble form by the B cell surface immunoglobulin receptor (BCR), or complexed to a major histocompatibility complex (MHC) molecule on an antigen-presenting cell (APC) by the α/β heterodimer of the T cell receptor (TCR) complex. In each case the antigen receptor chains are coupled to a transmembrane signaling complex (Ig- α and Ig- β in B cells, CD3 in T cells) responsible for triggering a cascade of intracellular biochemical events that initiate the process of lymphocyte activation. However, under most circumstances, lymphocytes that receive only this signal do not become fully activated, but rather are turned off and become unresponsive to subsequent receptor stimulations, or undergo apoptotic cell death. In order to generate a productive immune response, lymphocytes must normally receive a second signal that increases lymphocyte proliferation, promotes cell survival and/or prevents lymphocyte receptor unresponsiveness. The hypothesis of a required second signal for lymphocyte activation was first proposed for B lymphocytes by Bretcher and Cohn in 1970. Second signals for lymphocyte activation can now be divided into two

categories: first, those that potentiate the signal transduced by TCR ligation and trigger enhanced proliferation; second, those that not only augment antigen-driven lymphocyte proliferation but also prevent the induction of lymphocyte unresponsiveness, and/or of programmed cell death (Figure 1). The latter are termed costimulatory signals, and activate intracellular pathways distinct from those triggered by the antigen-receptor complex. Some ligands can serve both functions. Second signals can be provided by different surface molecules depending on the type of lymphocyte considered as well as its stage of differentiation.

Second signals for T lymphocyte activation

Adhesion molecules

Certain adhesion molecules have been shown to enhance TCR-mediated T cell proliferation. It has been difficult to determine whether the increased proliferative response results from greater strength of the signal mediated by the TCR because of increased

Figure 1 Two signals are required to induce full activation of T cells. T Lymphocytes receive signal 1 from specific interaction of their TCR with the peptide-MHC complex on an APC. This signal is increased by the simultaneous ligation of adhesion molecules such as LFA-1. Signal 2 results from the binding of a costimulator receptor such as CD28 with its ligand. Signaling through the TCR in the absence of a costimulatory signal results in hyporesponsiveness of the T cell upon restimulation.

cell-cell adhesion, or from direct transduction of a similar signal by the intracellular portion of the adhesion molecule. It has been proposed that adhesion molecules from the integrin family may prevent lymphocyte apoptosis through their binding to extracellular matrix components.

LFA-1 LFA-1 is a member of the integrin family of adhesion molecules, and is expressed constitutively on naive T cells, as well as on activated T cells and most other leukocytes. It is a heterodimeric structure composed of an $\alpha 1$ chain (CD11a) and a $\beta 2$ chain (CD18). Its described ligands, intercellular adhesion molecule 1 (ICAM-1) (CD54), ICAM-2 and ICAM-3 are expressed on a variety of cell types, including B cells, macrophages and endothelial cells. LFA-1 binding is thought both to increase adhesion between T cells and APCs and to potentiate the TCR signal in naive T lymphocytes. Binding of LFA-1 to ICAM-1 has been shown to augment TCR-induced interleukin 2 (IL-2) production and proliferation of naive T cells. In addition, simultaneous ligation of the TCR and LFA-1 augments activation of phospholipase $C\gamma 1$ (PLC $\gamma 1$) and Ca^{2+} flux over that induced by TCR ligation alone. However, disruption of LFA-1 interaction with its ligand by antibodies does not result in T cell unresponsiveness upon restimulation. Mice deficient in the expression of ICAM-1 are resistant to lethal doses of *Staphylococcus aureus* endotoxin B (SEB) as a result of reduced cytokine production in response to the toxin. T cells from these mice display diminished responses to alloantigen and to substances mediating contact hypersensitivity reactions. Mice deficient in CD18 (which is the common β chain shared by LFA-1, Mac-1 and p150/95) have delayed cardiac allograft rejections and impaired delayed-type hypersensitivity.

VLA-4 VLA-4 is also a member of the integrin family ($\alpha 4\beta 1$). VLA-4 can bind to vascular cellular adhesion molecule 1 (VCAM-1). VLA-4 ligation has been shown to augment TCR-mediated T cell proliferation, presumably in a similar manner to ligation of LFA-1, by increasing the strength of the signal delivered by the TCR. Gene disruptions of the α chain of VLA-4 or of VCAM-1 have lethal consequences, because of the involvement of these molecules in placental and umbilical cord generation.

CD2 The CD2 receptor on T cells binds to LFA-3 (CD58) or CD48 expressed on a wide variety of cells. Antibodies to CD2 have been shown to induce T cell proliferation, but their function is dependent on TCR expression. CD2 ligation results in augmented tyro-

sine phosphorylation of PLC $\gamma 1$ and Ca^{2+} mobilization, suggesting that interaction of CD2 with LFA-3 also acts by increasing specific signaling through the TCR. However, mice made deficient in CD2 by gene targeting lack obvious T cell defects, indicating that the function of CD2 may be redundant *in vivo*, or its function may be replaced by a different molecule when development takes place in the absence of CD2.

CD43 Recent data have attributed activating properties to human and murine CD43 (leukosialin), a molecule expressed on T cells, B cells, thymocytes, monocytes and fibroblasts, and capable of binding ICAM-1. Antibodies to CD43 increase TCR-mediated proliferation. CD43 is constitutively phosphorylated in T lymphocytes and monocytes, and becomes hyperphosphorylated upon activation. A possible association of CD43 with protein kinase C (PKC) has been suggested. However, the exact role of CD43 in T cell activation remains to be established.

B7 receptors

CD28 The best characterized costimulatory receptor is probably CD28, a homodimeric glycoprotein composed of two 45 kDa subunits and a member of the immunoglobulin gene superfamily. CD28 is constitutively expressed on virtually all murine T cells, 95% of human CD4⁺ cells, 50% of human CD8⁺ lymphocytes, as well as on developing thymocytes and plasma cells. Its ligands are members of the B7 family. B7-1 is expressed on activated B cells and monocytes, as well as on dendritic cells and Langerhans cells. B7-2 is detected on resting monocytes and dendritic cells, and on activated natural killer (NK) cells, T cells and B cells. Signaling T cells through CD28 with CD28-specific monoclonal antibodies (mAbs) in the presence of suboptimal TCR stimulation has been shown to enhance dramatically T lymphocyte proliferation, as well as to increase production of IL-2, tumor necrosis factor α (TNF α), lymphotoxin, interferon γ (IFN γ) and granulocyte-macrophage colony-stimulating factor (GM-CSF). This augmentation of cytokine production may occur predominantly via stabilization of cytokine mRNA. Furthermore, prevention of the CD28/B7 interaction during TCR stimulation using blocking antibodies of CTLA-4Ig, a soluble fusion protein that binds with higher affinity to both B7-1 and B7-2 than does CD28, results in the induction of T cell unresponsiveness in T_H1 lymphocytes and IL-2-producing CD8⁺ T cells.

CD28-deficient mice have impaired T cell proliferation and IL-2 production in response to TCR stimu-

lation, as well as absent germinal center formation and reduced immunoglobulin class switching. CD28-deficient mice are resistant also to lethal injections of *Staphylococcus aureus*, due to reduced production of TNF α and IFN γ in response to the toxin injection. In contrast, these mice display normal cytotoxic responses.

CD28 signaling has been suggested to be necessary for differentiation of naive T cell towards a T_H2-like phenotype. In fact, repeated stimulation with B7-2 but not B7-1 has been reported to preferentially generate cells that produce IL-4. In addition, costimulation through CD28 has been shown to prolong T cell survival. Part of this effect is mediated by the ability of CD28 costimulation to upregulate Bcl-x_L, a member of the Bcl-2 family of antiapoptosis genes. As expected, T lymphocytes from CD28-deficient mice express lower levels of Bcl-x_L protein upon activation than do T cells from wild-type animals.

Cross-linking of CD28 with CD28-specific mAbs has been shown to augment the elevation in [Ca²⁺]_i induced by TCR ligation. However, in contrast to signals mediated by the TCR, the increased IL-2 production induced by CD28 cross-linking is resistant to the inhibitory effects of cyclosporine, indicating partially non-overlapping signaling pathways for these two surface molecules. The cytoplasmic tail of CD28 contains a phosphatidylinositol 3'-kinase (PI3K)-binding site, and stimulation via CD28 has been reported to activate PI3K. Transfection studies have demonstrated that p56^{lck} and p59^{fyn} can phosphorylate CD28 at Tyr191, which correlates with the recruitment of PI3K and the adapter protein GRB-2.

However, several studies have demonstrated that PI3K activity is not necessary for the effects of CD28 on IL-2 production. It has been suggested that signaling CD28 with CD28-specific mAbs can be different from that observed with normal B7 ligands. Ligation of CD28 with anti-CD28 in Jurkat cells results in tyrosine phosphorylation of p95^{vav} and a 36 kDa protein that associates with a complex of GRB-2 and the guanine nucleotide exchange factor SOS, and results in activation of p21^{ras}. In contrast, B7-1^{-/-} stimulator cells induce tyrosine phosphorylation of Vav but not p36, and do not trigger activation of p21^{ras}. CD28 signaling also activates the protein tyrosine kinase ITK. However, mice made deficient in ITK by gene targeting do not have impaired CD28 signaling. CD28 has been shown also to cooperate with CD3 to activate the mitogen-activated protein (MAP) kinases JNK1 and JNK2, enzymes involved in enhancing the transcriptional activity of AP-1, which is a factor directly involved in the transcription of the IL-2 gene. In addition, CD28 engagement has been shown to activate an acidic sphingomyelinase, resulting in the proteolytic degradation of I κ B. This event is necessary for nuclear translocation of NF κ B and has been detected both in Jurkat cells and in primary human T cells. Several mAbs against human CD28 have been reported to induce the nuclear translocation of the different components of NF κ B, namely c-Rel, NF κ B1 and RelA, that participate in IL-2 gene transcription (Figure 2).

CTLA-4 CTLA-4 is not constitutively expressed on T lymphocytes, but is induced following T cell

Figure 2 CD28 signaling. Schematic representation of some of the enzymatic and transcription factor activities induced by CD28 ligation.

activation, with peak levels being reached after 48–72 h. CTLA-4 is a second receptor for B7 family members, that shares 30% homology with CD28, but that binds both B7-1 and B7-2 with higher affinity. A third ligand for CTLA-4 and presumably CD28 has been implicated recently in mouse, the binding of which also promotes costimulation of T lymphocytes. Several reports suggest that CTLA-4 acts as a negative regulator of T cell activation rather than as a positive costimulatory molecule. Indeed, cross-linking of CTLA-4 molecules on the cell surface results in decreased T cell proliferation and IL-2 production. Conversely, blockade of CTLA-4 interactions using anti-CTLA-4 mAbs increases T cell responses *in vitro*, and leads to the rejection of implanted tumors in murine models *in vivo*. Furthermore, in previously activated human T cells, cross-linking of CTLA-4 has been reported to induce apoptosis, perhaps upon binding to a ligand different from B7-1 and B7-2. Consistent with these data, CTLA-4-deficient mice generated by homologous recombination develop a fatal lymphoproliferative syndrome and autoimmune disease, manifested by myocarditis, pancreatitis and high levels of circulating immunoglobulins. Both CD28 and IL-2 signaling can independently upregulate CTLA-4 expression. Therefore, the most potent signals for T cell activation appear to be the most powerful inducers of CTLA-4 expression. In addition, upregulation of CTLA-4 requires entry into the cell cycle, as agents capable of arresting T cells in G₁/S phase also inhibit CTLA-4 expression. These data suggest a negative feedback role for CTLA-4 that could control cell division after proliferation has occurred. Surprisingly, much more CTLA-4 is found intracellularly than on the cell surface at all time points. It appears that CTLA-4 is efficiently transported to the cell surface, but rapidly endocytosed, suggesting that CTLA-4 molecules cycle to and from the cell surface, with only a minimal fraction of the pool expressed transiently on the cell surface at any one time.

Little is known about the signals transduced upon CTLA-4 ligation. Like CD28, the cytoplasmic tail of CTLA-4 contains a PI3K-like binding motif, and it has been shown that CTLA-4 can associate with PI3K. Recently, T cells from CTLA-4-deficient mice have been reported to have an increased pattern of tyrosine phosphorylation, and the cytoplasmic portion of CTLA-4 has been found to interact with the protein tyrosine phosphatase SHP-2 (PTP1D).

Tumor necrosis factor (TNF) and TNFR family members

All known ligands of this family (CD40L, CD30L, TNF α , lymphotoxin β (TNF β), CD70, FasL and 4-

1BBL) as well as their receptors (CD40, CD30, TNFR1, TNFR2, CD27, Fas, 4-1BB and O $\times$ 40) can be expressed by T cells. CD40, CD30, CD27, TNF α , lymphotoxin and 4-1BB are also found on B cells, and TNF α , CD30L, and 4-1BB are also detected on activated macrophages. Expression of CD40L and O $\times$ 40 appear to be restricted to CD4⁺ T cells. Human peripheral blood T cells as well as CD4⁺ T cell clones show enhanced proliferation when stimulated simultaneously through the TCR and any of the TNF-like and TNFR-like proteins. These molecules can also trigger T cell death, and their ability to induce apoptosis or proliferation depends on the cell type, the stage of differentiation, the transformation status, and the presence of other stimuli. Because T cells express both TNF-like and TNFR-like molecules, T lymphocytes could potentially costimulate themselves or commit themselves to programmed cell death. The intracellular domains of CD40, TNFR2, and CD30 have been shown to interact with members of the TNFR-associated factor (TRAF) family. The TRAF proteins are now known to induce survival signals, as well as to activate the transcription factor NF κ B. In contrast, Fas and TNFR1 have been shown to associate with proteins containing a 65 amino acid domain termed a death domain. These receptors appear able to assemble a signal transduction complex that initiates apoptosis through the activation of proteases in the IL-1-converting enzyme (ICE) family.

CD40L CD40L (gp39) is a 33 kDa protein almost exclusively expressed by activated CD4⁺ T cells, although some expression has been described on CD8⁺ T cells, basophils and mast cells. Therefore, CD40–CD40L interaction can induce proliferation of CD4⁺ T cells upon TCR activation. CD28 stimulation induces upregulation of CD40L. Recent data indicate that CD40L/CD40 may also be implicated in negative selection of thymocytes. Mice made deficient in the CD40L gene by homologous recombination appear to have normal T cell responses to mitogens, but reduced antigen recall responses in terms of T cell proliferation.

CD30 CD30 was first described as a marker for Hodgkin lymphoma cells, but is also expressed by a subset of normal T lymphocytes. CD30 has been implicated as a costimulatory molecule on activated but not resting T cells. It has also been suggested to promote the differentiation of T cells into T_H2 effector cells, and is thought to play a role in the transcriptional reactivation of latent human immunodeficiency virus (HIV). Mice made deficient in CD30 by gene targeting show a defect in negative selection.

Cytokine receptors

IL-2R IL-2R is a trimeric receptor composed of an α chain, a β chain shared by IL-2R and IL-15R, and a γ chain, that is also shared by IL-4R, IL-7R, IL-9R and IL-15R. IL-2 is a growth factor and a survival factor for most T cells. Furthermore, the induction of TCR unresponsiveness by TCR stimulation in the absence of CD28 ligation can be prevented, in most cases, by the addition of exogenous IL-2. Proliferation of T cells from CD28-deficient mice in response to CD3-specific mAbs can be restored by the addition of exogenous IL-2. Similarly, high doses of IL-2 bypass the requirement for CD28 costimulation, as exogenous IL-2 can overcome blockade by CTLA-4Ig. On the other hand, IL-2 can sensitize T cells to activation-induced cell death. Consistent with this result, mice made deficient for IL-2 or IL-2R α by gene disruption develop a lymphoproliferative disorder and autoimmune disease.

IL-2 signaling requires the heterodimerization of the β and γ cytoplasmic domains. Neither the β chain or the γ chain have known intrinsic catalytic activity. Therefore, signaling operates via the recruitment of proteins containing SH2 domains. JAK3 has been shown to interact with the γ chain, whereas the β chain can associate with Syk, PI3K, SHC and JAK1. Recruitment of JAK1 and JAK3 is followed by activation of STAT3 and STAT5. IL-4R and IL-7R, which share a common γ chain with the IL-2R, have also been reported to be important in regulating lymphokine survival during the immune response.

IL-1R IL-1R functions as a costimulatory receptor for most murine T_H2 but not T_H1 clones, and allows T_H2 clones to respond to the IL-4 that they produce. Blocking IL-1 during TCR stimulation of T_H2 clones may result in TCR hyporesponsiveness upon restimulation, as determined by a decreased ability to provide B cell help. Proliferation of those cells remains intact, indicating that not all functions are desensitized under those conditions.

Heat stable antigen (HSA) receptor

HSA (CD24) is expressed on dendritic cells and B cells and binds to an unknown ligand on T lymphocytes. Some antibodies to HSA can induce T cell unresponsiveness upon restimulation. In addition, the combination of antibodies to HSA and CTLA-4Ig has been reported to completely block T cell proliferation induced by activated B lymphocytes, suggesting additive effects provided by B7 and HSA receptors. The effect of HSA receptor stimulation on T cell survival has not been investigated thus far. The level of expression of HSA does not correlate with

its costimulatory function, as expression is higher on resting B cells that are poor providers of costimulatory activity, than on activated B lymphocytes. This could result from a conformational change of HSA upon B cell activation, and differentially glycosylated forms have been described. Alternatively, an inhibitory molecule might be produced by naive but not activated B cells.

Second signals for B lymphocyte activation

Soluble antigens are recognized by surface immunoglobulins on B lymphocytes, processed into peptides, internalized and presented to CD4⁺ T cells in the context of MHC class II. Engagement of the BCR transmits a signal (signal 1) that induces a number of changes on the surface of B cells, including upregulation of B7-2, thus promoting T cell activation if antigen-specific T cells are encountered. This signal also appears to direct B lymphocytes to the outer region of the periarteriolar lymphoid sheath in the white pulp of the spleen, a region rich in T cells. During T/B cell contact, activated T lymphocytes provide second signals to B cells in the form of soluble cytokines, as well as membrane-bound ligands and adhesion molecules. This serves to enhance B cell activation, proliferation, differentiation, and immunoglobulin isotype switching. In return, engagement of MHC class II induces upregulation of B7-1 and other molecules capable of delivering second signals to T cells. Several surface molecules have been implicated in augmenting B cell signaling, the most important one being CD40, that plays in B cells a similar role to CD28 in T cells. In addition, monoclonal antibodies to LFA-1, ICAM-2, CD2, CD4, CD19, CD38, CD58 and MHC class II have all been reported to partially inhibit T-dependent B cell activation to different degrees.

In some situations, mouse and human B cells can be protected from apoptosis by CD38-specific mAbs. Following successful T/B lymphocyte interaction, oligoclonal proliferative foci can be detected that reach maximum size after 3–4 days, and then dissipate. Many B cells in these foci secrete IgM antibodies and undergo isotype switching, others migrate to the primary follicles and initiate the formation of germinal centers. CD40, B7-2 and lymphotoxin have all been shown to be required for germinal center formation, as mice made deficient for any of these molecules or their ligands by gene targeting are devoid of germinal centers.

TNF and TNFR family members

CD40 is a 45–50 kDa molecule and is a member of the TNFR family. It is expressed on the surface of B cells, macrophages, follicular dendritic cells and some T cells. The importance of CD40 in B cells has been exemplified by a naturally occurring disease in humans. The hyper-IgM syndrome is an immunodeficiency due to a mutation in the gene encoding CD40L, that either prevents expression of CD40L, or renders it incapable of binding to CD40. This results in the absence of serum IgG, IgA and IgE, the absence of germinal centers, and the inability to mount secondary antibody responses to thymic-dependent antigens. Similar phenotypes are found in mice made deficient for CD40 or CD40L by homologous recombination. CD40 has different functions in B cells, depending on the cell type considered. Resting B cells enter the cell cycle upon CD40 ligation. In contrast, CD40 signaling has been reported to trigger proliferation in some chronic leukemic B cells, programmed cell death in some B lymphoma cell lines, and prevention of apoptosis in germinal center B cells. In fact, CD40 ligation has been shown to induce upregulation of Bcl- x_L in B cells, similarly to engagement of CD28 in T cells. In addition, several studies have documented a role for CD40 in the induction of B cell memory. Finally, CD40L can induce upregulation of B7-1 and B7-2 on resting B cells and thus indirectly regulates T cell activation.

The cytoplasmic chain of CD40 does not possess intrinsic enzymatic activity. Rather, CD40 triggering is thought to induce an association with TRAF proteins such as TRAF-3 as well as lead to recruitment and activation of tyrosine kinases. Stimulation of transformed B cell lines with antibodies to CD40 induces tyrosine phosphorylation of several substrates, including Lyn and Syk. It also triggers turnover of inositol phosphates and activation of different serine/threonine kinases. Possible substrates of these protein tyrosine kinases are PLC γ 2 and PI3K, as these molecules have been shown also to undergo activation upon CD40 ligation with antibodies in the Daudi B cell line. In murine resting B cells, cross-linking of CD40 induces activation of ERK and JNK in a PKC-independent manner. This contrasts with the PKC-dependent activation of these enzymes observed after BCR stimulation. The two pathways seem to converge at the level of MEK in mediating ERK activation (Figure 3). However, in human tonsillar B cells, CD40 ligation has been found to activate JNK but not ERK. The discrepancy in these results may result from species differences, or antibody epitope variations.

CD40 binding to CD40L, in combination with

surface Ig cross-linking, has been reported to result in activation of NF κ B through its association with TRAF proteins. In addition, CD40 signal transduction can induce *c-jun* and *c-fos* although the mechanism for this activation has not yet been defined. In addition, CD40 ligation has been shown to result in decreased tyrosine phosphorylation of several cellular proteins, suggesting that CD40 also activates phosphatases. Increased cAMP and ornithine carboxylase activity have also been described following CD40 ligation. Signaling through CD40 may be different depending on the stage of differentiation or activation of B cells. It seems that in germinal center B cells, the CD40 pathway is coupled to protein tyrosine kinases but not to PI turnover. Tyrosine phosphorylation appears to be necessary for the antiapoptotic effect of CD40 in these cells. In addition to CD40L, other ligands in the TNF family, such as TNF α , have been shown also to enhance B cell proliferation after T cell contact.

Cytokine receptors

The response to CD40 ligation is enhanced by lymphokines such as IL-4. Exposure of B cells to IL-4 and IL-5 in the mouse or IL-4/IL-13, IL-2 and IL-10 in the human induces differentiation, antibody secretion and immunoglobulin isotype switching. Although surface immunoglobulin engagement by soluble antigen (signal 1) is necessary to attract B lymphocytes to T cell-rich zones, studies *in vitro* have shown that B cell proliferation and antibody production can be achieved in the presence of activated T lymphocytes and of the relevant cytokines. Through the cytokines that they produce, T cells help

Figure 3 CD40 signaling. Schematic representation of some of the intracellular events triggered by CD40 ligation.

to determine the isotype switch that occurs following B cell activation. Thus, T_H1 clones have been shown to promote immunoglobulin switching to the IgG2a isotype. T_H2 clones induce IgG1 and IgE secretion. IFN γ inhibits the secretion of IgG1 and promotes that of IgG2a. IL-4 is required for IgE production and has also been found to induce expression of B7-1 and B7-2 on resting murine B cells.

The cytoplasmic domain of the IFN γ R has been shown to associate with JAK1 and JAK2 and to trigger activation of STAT1. Mice made deficient in STAT1 lack IFN γ signaling. The IL-4R interacts with JAK1 and JAK3, inducing activation of STAT6. STAT6-deficient mice display a similar phenotype to IL-4-deficient mice, showing diminished production of IgE and IgG1 antibodies.

Conclusion

Major advances have been made in the understanding of lymphocyte activation. Participation of costimulator molecules is an essential component of the initiation of productive lymphocyte activation. When lymphocytes are stimulated in the absence of second signals, an unresponsive state results. This knowledge has enabled immunologists to design therapeutic strategies aimed at blocking or triggering second signals, thus allowing for antigen-specific suppression or augmentation of immune responses, respectively. Indeed, treatment with CLTA-4Ig and/or CD40Ig in several animal models (including nonhuman primates) of transplantation has proven very efficacious at immunosuppression, and, in some cases, is capable of inducing donor-specific tolerance. Administration of CLTA-4Ig or CD40Ig can also prevent or treat some autoimmune diseases. Conversely, activation of the CD28 pathway of signaling has been shown to promote tumor rejection in other

experimental models. Application of these new therapeutic strategies to the treatment of human diseases holds considerable promise for the future.

SECRETORY COMPONENT (THE POLYMERIC Ig RECEPTOR)

Per Brandtzaeg, Finn-Eirik Johansen, Peter Krajči and Inger B Natvig, Laboratory of Immunohistochemistry and Immunopathology (LIIPAT), University of Oslo, The National Hospital, Rikshospitalet, Oslo, Norway

The existence of an adaptive mucosal immune system was proposed in 1919 by Besredka when he demonstrated that rabbits, after oral immunization with killed *Shigella*, were protected against fatal dysentery irrespective of the serum antibody titer. In 1922 Davies was able to detect antibodies against the dysentery bacillus in stools from infected patients several days before such activity was present in serum. The interest in local immunity was significantly revived after 1965 when it was reported by Tomasi's group and also other laboratories that the predominating immunoglobulin (Ig) in external body fluids was IgA; this secretory IgA (S-IgA) was shown to have unique immunochemical and physicochemical properties because of its polymeric nature and association with an epithelial glycoprotein called 'secretory piece' or 'secretory component' (SC). At the same time Crabbé and coworkers demonstrated a class distribution of intestinal Ig-producing plasma cells remarkably different from that in peripheral lymphoid tissues; mucosal IgA immunocytes were strikingly predominant – being more than 20 times as numerous as IgG-producing cells. This finding has been repeatedly verified for most categories of normal exocrine tissues. Moreover, in the early 1970s Brandtzaeg and coworkers obtained evidence suggesting that the mucosal IgA immunocytes produce dimers or larger polymers (collectively called pIgA) rather than monomers.

The latter workers also pointed out that local production alone does not explain the preferential appearance of pIgA in exocrine fluids. They showed that serum IgG is abundantly represented in interstitial tissue fluid but is not internalized by secretory epithelia, whereas pentameric IgM (pIgM) is trans-epithelially translocated to the lumen in a preferential manner like pIgA. A common receptor-mediated external transport mechanism for S-IgA and secretory IgM (S-IgM) was therefore proposed by Brandtzaeg in 1973–74. The SC was suggested to be the transmembrane receptor responsible for the epithelial binding and uptake of the pIg ligands. The J chain was taken to be a key factor in the initial noncovalent binding process. This polypeptide was in 1971 shown by Mestecky and coworkers to be a common disulfide-linked component of pIgA and

pIgM; it is known to be selectively incorporated into these polymers within the Ig-producing plasma cells. Secretory immunity thus depends on a fascinating cooperation between the mucosal B cell system and the secretory epithelia.

Molecular biology and function of secretory component

The human SC gene locus (PIGR) has been assigned to the long arm of chromosome 1 (region q31–q42). This region contains other genes of immunological interest and is involved in a significant number of recombination events. We have detected restriction fragment length polymorphism (RFLP) for the SC gene; Pvu II revealed a two-allele RFLP with an autosomal codominant inheritance pattern.

Human SC occurs in three molecular forms: as a basolaterally expressed transmembrane protein (~100 kDa) functioning as pIg receptor (pIgR); as a stabilizing integrated component (~80 kDa) in S-IgA and S-IgM (bound SC); and as an excess of free SC (~80 kDa) in most exocrine fluids (Figure 1). Cell biology studies first substantiated in the rabbit that SC is produced as a transmembrane protein 25–30 kDa larger than the secreted form.

Transmembrane SC (pIgR) is composed of five homologous extracellular domains, a transmembrane anchor, and a cytoplasmic tail (Figure 2). Proteolytic cleavage near the apical cell membrane releases SC (bound or free) into exocrine secretions. Free SC appears to exhibit eosinophil-activating properties and may block adhesion of *Escherichia coli*. Such additional functions suggest that SC has originated phylogenetically from the innate defense system.

The five repeating domains of pIgR are stabilized by intrachain disulfide bridges and show considerable amino acid homology with several members of the Ig supergene family, particularly with Ig V domains. The full-length receptor characterization obtained by cloning of cDNA from different species has allowed identification of conserved regions and experimental definition of the functionally most important sequences. The cDNA for human pIgR first isolated in our laboratory, encodes a transmem-

Figure 1 Schematic representation of various steps involved in the generation of human secretory IgA (top right) and secretory IgM (bottom right) via plgR-mediated epithelial transport of J chain-containing polymeric IgA (IgA-J) and pentameric IgM (IgM-J) secreted by local plasma cells (left). Transmembrane SC is synthesized in the rough endoplasmic reticulum (RER) of secretory epithelial cells and matures by terminal glycosylation (—●) in the Golgi complex. After being sorted through the trans-Golgi network (TGN), it is phosphorylated (○) and expressed as plgR at the basolateral plasma membrane. Endocytosis of ligand-complexed and unoccupied plgR is followed by transcytosis to apical endosomes and finally by cleavage and release of secretory Ig molecules with bound SC as well as excess of free SC at the luminal cell face. However, some basolateral recycling may first take place for unoccupied plgR. During the external translocation, covalent stabilization of the IgA–SC complexes regularly occurs (two disulfide bridges indicated in secretory IgA), whereas free SC in the secretion apparently serves to stabilize the noncovalent IgM–SC complexes (dynamic equilibrium indicated for secretory IgM).

Figure 2 Schematic depiction of the mature human transmembrane SC or plgR. The position of cysteines participating in disulfide bonds stabilizing the extracellular Ig-like domains 1–5 (D1–D5) are indicated. Arrows mark the initial Ig-binding site in D1, the site for secondary covalent plgA bonding in D5, and the cleavage site near the epithelial cell membrane. Glycosylation sites (—●) and disulfide bonds (—S—S—) are also depicted. Putative determinants in the cytoplasmic tail critical for proper cellular routing are delineated on the basis of findings reported for the rabbit plgR, including the phosphorylated serine residue (P) S655 (counterpart to rabbit S664) and the two tyrosine-based endocytosis motifs. The kink-inducing proline in the membrane-spanning segment suggests signal-transducing capacity of the receptor.

brane protein of 746 amino acids (Figure 2) and a signal peptide of 18 residues. The average overall amino acid homology between human pIgR and the rabbit, rat, mouse and bovine counterparts is 73%. However, functionally important sequences such as the putative initial Ig contact site in domain 1 (see below), the transmembrane segment, and the basolateral targeting sequence in the cytoplasmic tail (see below), show average homologies of 93%, 87% and 92%, respectively.

Northern blot analysis has revealed that pIgR mRNA is 3.5–3.9 kb in all investigated species. Curiously, rabbit pIgR mRNA contains a second smaller form (~3.1 kb) generated by an alternative splice that gives rise to a functional receptor protein lacking domain 2 and domain 3. In humans, pIgR mRNA is expressed most strongly in the gut but can also be detected in other exocrine tissues. The weak expression revealed in the human liver probably reflects the activity of biliary duct epithelium. By contrast, rodents express almost as high levels of pIgR mRNA in the liver as in the intestinal mucosa because their hepatocytes produce SC (see below).

Intracellular sorting of the pIgR

After synthesis and core glycosylation in the rough endoplasmic reticulum of the epithelial cell, the pIgR further matures in the Golgi apparatus; it is then sorted in the trans-Golgi network for delivery to the basolateral plasma membrane (Figure 1). Both ligand-complexed and unoccupied pIgR is internalized by endocytosis in coated pits and sorted for transcytosis in the basolateral endosomal compartment; binding of pIg to the receptor is in fact not mandatory for its transport to the luminal cell surface. Here bound and free SC molecules are released by cleavage from the transmembrane anchor by a leupeptine-sensitive protease, while the remaining segment is degraded. Transmembrane SC has therefore been called a 'sacrificial receptor'.

The complex intracellular routing of the pIgR through the epithelial cell has made it a model protein for the characterization of intracellular sorting signals. Several studies by Mostov and coworkers based on mutants of rabbit pIgR have characterized the function of its cytoplasmic tail (103 residues in human) as an effector segment for routing through the epithelial cell; it apparently carries all the information needed to provide proper delivery at the different cellular locations, including an autonomous basolateral targeting signal, two tyrosine-based endocytosis motifs, and one major phosphorylation site (Figure 2). Phosphorylation of this serine (Ser664) in rabbit pIgR (equivalent to Ser655 in

human) stimulates transcytosis, which for pIgA-receptor complexes in addition is upregulated by ligand binding, probably through second messenger systems. The high conservation of the α helical membrane spanning domain, including a kink-inducing proline, further suggests that the pIgR is capable of mediating signal transduction.

Interactions between pIg and SC/pIgR

Various research groups have determined the affinity (K_a) of pIg for free SC in solution to be about 10^8 M^{-1} . This value is similar to that for a variety of antigen-antibody reactions. Also pIgR-expressing epithelial cells bind pIg with high affinity. Such non-covalent interactions of pIgA and pIgM with SC/pIgR depend on their incorporation of J chain. Evidence supporting this notion has recently been obtained both in transgenic plants and in J chain knockout mice.

There are much stronger noncovalent interactions between pIgM and free SC than between pIgA and free SC, the K_a being several times higher for the former ligand. The two subclasses of human IgA (IgA1 and IgA2) are apparently similar in this respect. It remains to be clarified whether a 'bonus' effect of a higher molar J chain content in pIgM than in pIgA explains the different properties of their SC-binding sites. Nevertheless, the *in vivo* efficiency of external translocation appears to be much better for pIgA than for pIgM (see below).

The I region of SC ('I' stands for 'inaccessible' antigenic determinant in bound SC) appears to be primarily responsible for the noncovalent binding of pIg molecules; this region corresponds to the N-terminal domain 1. The highly conserved sequence in this region (amino acids 15–37) probably reflects its functional importance as an initial Ig contact area; binding studies with synthetic peptides have demonstrated that this sequence alone shows 'promiscuous' relatively low affinity not only for pIg molecules but also for monomeric IgA and IgG. This binding site forms a loop similar to the first complementarity determining region (CDR1) of Ig V $_{\kappa}$ domains. Complexing with pIgA further appears to depend on the CDR2 and CDR3 loops, followed by noncovalent interactions extending beyond domain 1. Although the C $_{\alpha}$ 2 and particularly the C $_{\alpha}$ 3 domain of pIgA are involved in these interactions, the exact part of the pIg molecules that initially contacts the pIgR remains undefined. The subsequent covalent stabilization, which appears to occur selectively for S-IgA, depends on disulfide exchange reactions between one C $_{\alpha}$ 2 domain and domain 5 of pIgR (Figures 1 and 2),

although other possibilities have not been completely excluded.

Purified J chain shows only marginal affinity for free SC. However, one computer-assisted model of this peptide in humans and mice has suggested that, despite a low degree of primary structure homology with Ig domains, the J chain may nevertheless show an Ig domain-like folding of its secondary structure. It seems likely that appropriate binding of pIgR to the Fc portion of the pIg molecules is determined by complementary interdomain interactions both with the J chain and the C region domains of the α or μ chains. The role of J chain in the binding process may thus be to stabilize the noncovalent pIgR-pIg complexes as a requirement for their endocytic internalization by secretory epithelial cells.

Efficiency of pIg transport through secretory epithelia

Immunohistochemical studies have shown that SC is expressed mainly by serous types of epithelial cells in exocrine tissues. In the human liver, SC is restricted to the bile duct epithelium whereas abundant SC expression is shown by hepatocytes in the rat and some other animals. This species difference has been supported by Northern blot analysis of pIgR mRNA (see above) and harmonizes with the fact that ~90% IgA in duodenal fluid is derived from bile in the rat but <15% in humans.

Exocrine tissues constitute quantitatively the most important effector sites of specific humoral immunity with the gut as the major contributor. It has been estimated that at least 80% of all Ig-producing cells in humans and mice are located in the intestinal mucosa. Nevertheless, there is normally very little spillover of locally produced IgA from the human gut lamina propria to lymph and venous blood. The capacity of the pIgR-mediated external transport through human intestinal crypt epithelium is hence remarkable; more pIgA is translocated to the gut lumen by this mechanism every day (40 mg kg^{-1} body weight) than the total daily production of IgG (which is about 30 mg kg^{-1}). An *in vitro* model system established in our laboratory to characterize this process has shown that the epithelial transport of pIgA and pIgM mediated by the human pIgR is equally efficient. However, *in vivo* external translocation of pIgA is on a molar basis favored 6–12 fold over that of pIgM because the latter ligand is severely impeded when diffusing through the lamina propria and basement membrane. Nevertheless, S-IgM is an important compensatory antibody class in external secretions of newborns and patients with selective IgA deficiency.

Regulation of secretory immunity

The biological significance of the striking J chain expression shown by Ig-producing cells in exocrine tissues is that pIgA and pIgM are generated locally and thus become readily available for pIgR-mediated external transport. This important goal, in terms of clonal B cell differentiation, may be sufficient justification for the J chain to be expressed also by a variable fraction of B cells terminating in exocrine tissues with IgD or IgG production; these immunocytes may be considered as 'spin-offs' from recently stimulated memory B cells that through clonal isotype switching are on their way to IgA expression. The J chain appears to be a marker of fairly recently differentiated B cell memory clones, and no other function has been identified for this peptide than incorporation into the quaternary structure of pIgA and pIgM, thereby contributing to their SC pIgR binding site (see above). This incorporation takes place intracellularly as shown by the preferential binding of free SC to the cytoplasm of mucosal IgA and IgM immunocytes in affinity tests performed on tissue sections (color plate).

The precursors for Ig-producing cells in exocrine tissues are apparently in the main derived via lymph and peripheral blood from organized lymphoepithelial structures where the primary mucosal B cell responses are induced. The most important inductive site seems to be the gut-associated lymphoid tissue (GALT), particularly the Peyer's patches; but bronchus-associated lymphoid tissue (BALT) and probably the tonsils also contribute, especially to plasma cell populations in the upper alimentary and respiratory tracts.

It has been known for more than two decades that Peyer's patches are enriched in IgA-producing cell precursors. Some immunoregulatory mechanism(s) must exist in GALT and similar mucosa-associated lymphoid tissue (MALT) that facilitates expansion of early memory clones with activated J chain gene while allowing very little terminal B cell differentiation *in situ*. The final maturation to pIg-producing plasma cells will therefore mainly take place after precursor distribution to exocrine effector sites. Although uptake of antigens by lymphoepithelial MALT structures, and the involvement of antigen-presenting cells, T cells and various cytokines have been subjected to extensive studies, it remains obscure how B cells of the mucosal immune system normally are tuned for activation of the J chain gene and preferential pIgA responses.

Studies in our laboratory as well as by other groups have shown that SC/pIgR expression by secretory epithelium may be modulated by cytokines

Figure 3 Paired immunofluorescence staining for IgA and SC in tissue section from human nasal mucosa; the same field is shown after incubation with 'red' anti-IgA + 'green' anti-SC, (a) (red filtration) and (b) (double exposure). IgA alone is present in immunocytes and throughout the stroma; SC alone is present in the Golgi zones (arrows) adjacent to nuclei of glandular acinar cells; both IgA and SC (mixed color) are present basolaterally on acinar cells and apically in their cytoplasm. Original magnification $\times 180$. (See also color Plate 5A.)

Figure 4 Paired immunofluorescence staining for IgA and total SC, or for unoccupied and bound SC, in tissue sections of human colonic mucosa. (a) left part (red filtration) and right part (double exposure), comparable fields in adjacent sections of gland incubated with 'red' anti-SC and with 'red' anti-IgA + 'green' anti-SC, respectively. Prominent SC-containing granules are present in the Golgi zones, whereas the rest of the cytoplasm and the basolateral aspects of columnar epithelial cells are positive for both SC and IgA (mixed color). Goblet cells are devoid of both markers. (b) (red filtration), (c) (left part, double exposure), and (d) (green filtration), same field in a section of gland incubated with 'red' anti-I determinant (specific for unoccupied SC) + 'green' anti-A determinant (accessible on free as well as bound SC). The two antigenic determinants show distinct differential distribution with a relative dominance of I in the Golgi zones, and of A in the remaining cytoplasm and weakly also basolaterally. Right part of (c) (double exposure) shows a comparable field after prolonged exposure time for red (anti-I) emission. Note that neither of the two anti-SC reagents produced fluorescence of elements in the lamina propria. Original magnification $\times 180$. (See also color Plate 5B.)

such as interferon γ (IFN γ), interleukin 4 (IL-4) and tumor necrosis factor α (TNF α). Experiments with the HT-29 adenocarcinoma cell line have suggested that IFN γ , IL-4 and TNF α all induce transcriptional upregulation of pIgR, and IL-4 may additionally stabilize the specific message. We and others have recently cloned and characterized the promoter

region of the SC/pIgR gene. DNA elements that bind transcription factors belonging to the basic helix-loop-helix leucine-zipper family or the interferon regulatory factor family appear important for constitutive or IFN γ -enhanced transcription, respectively.

There thus appears to exist a positive immunoregulatory link between the function of the pIgR and

Figure 5 (a) Paired immunofluorescence staining to demonstrate *in vitro* SC affinity to IgA immunocytes in section of human colonic mucosa preincubated with free SC followed by 'red' anti-SC + 'green' anti-IgA. Note in double exposure (center) that most IgA cells show varying degree of mixed color as evidence for binding of SC to cytoplasmic pIgA, whereas a few cells (probably pure monomer producers) lack SC-binding capacity and are therefore only green. The purely red cells in the double exposure are SC-binding IgM immunocytes. The columnar epithelial cells of the glands at top and bottom contain innate SC and transport pIgA; they therefore show mixed cytoplasmic color with the exception of the Golgi zones which contain SC but no IgA. Magnification $\times 110$. (b) Similar SC-affinity test on section of human salivary gland. Double exposure (center) shows various tints of yellow in IgA immunocytes located between acini (A) and duct (D); in several immunocytes the yellow color is restricted to areas close to the nucleus (arrow), suggesting accumulation of pIgA. One immunocyte (at the bottom) is purely green, suggesting production of only monomeric IgA. Acini and duct are faintly double-stained for innate SC and translocated pIgA. Magnification $\times 430$. (See also color Plate 5C.)

the magnitude of the local immune response. Our immunohistochemical observations on Sjögren's syndrome and chronic gastritis harmonize with this notion; signs of increased SC expression and enhanced uptake of IgA are seen in glandular structures surrounded by dense infiltrates of mononuclear cells. Similar epithelial features are seen in celiac disease; and enhanced external transport probably explains that there is little increase of the serum IgA level compared with the remarkably expanded jejunal IgA cell population. Nevertheless, the pIgR-mediated epithelial transport capacity may be insufficient in certain patients with an unusual intestinal IgA cell expansion, resulting in excessive amounts of pIgA in serum.

SELECTINS (CD62-E/L/P)

Masayuki Miyasaka, Department of Bioregulation, Osaka University Medical School, Osaka, Japan

Selectins are a family of three Ca^{2+} -dependent transmembrane lectins i.e. L-selectin (CD62L), E-selectin (CD62E), P-selectin (CD62P) that initiate the tethering of leukocytes to activated endothelium under shear forces. They have a characteristic structural motif consisting of an N-terminal lectin domain, a domain with homology to epidermal growth factor (EGF), and a variable number of complement regulatory protein repeat sequences (Figure 1). L-Selectin is constitutively expressed on the majority of leukocytes, while E-selectin is often expressed by activated endothelium. P-Selectin is normally stored in α granules in platelets and the Weibel–Palade body in endothelial cells, and transported to the cell surface upon activation where it is expressed transiently. All selectins bind specific sialylated, fucosylated carbohydrates such as sialyl Lewis^x (sLe^x; Neu5Ac α 2–3Gal β 1–4(Fuc α 1–3)GlcNAc). Presentation of these carbohydrates in a clustered form on the protein backbone appears to confer high affinity to the sel-

ectin ligands. As shown in Figure 2, the glycoprotein ligands for L-selectin, GlyCAM-1 and CD34 are expressed on high endothelial venules (HEVs) in peripheral lymph nodes. Another L-selectin ligand, MAdCAM-1, is expressed specifically on HEVs in Peyer's patches and mesenteric lymph nodes. Both E-selectin glycoprotein ligand, ESL-1, and P-selectin glycoprotein ligand, PSGL-1, are expressed in neutrophils.

L-Selectin (CD62L)

L-Selectin (previously referred to as LECAM-1, LAM-1, Mel-14 antigen or Leu8 antigen) is expressed constitutively on leukocytes. It was

Figure 1 The selectins. The selectin family members have a unique domain structure consisting of the c-type lectin domain (LEC), epidermal growth factor-like domain (EGF) and complement regulatory protein domain with multiple short consensus repeats (SCR).

Figure 2 Selectins and their glycoprotein ligands. The lectin domains of the selectins (LEC) bind to clustered carbohydrate epitopes present on the protein backbone of sialomucins. L-Selectin recognizes at least three distinct sialomucins, GlyCAM-1, CD34 expressed on high endothelial venules of peripheral lymph nodes and also MAdCAM-1 expressed on high endothelial venules of mesenteric lymph nodes and Peyer's patches. Two endothelial selectins, E- and P-selectin recognize ESL-1 and PSGL-1, respectively, both of which are expressed on neutrophils. With GlyCAM-1, CD34, MAdCAM-1 and PSGL-1, O-linked sugars are recognized by selectins, whereas with ESL-1, N-linked sugars are recognized by E-selectin.

initially characterized by monoclonal antibody (mAb) Mel-14 as the murine homing receptor mediating lymphocyte binding to HEVs in peripheral lymph nodes. However, recent studies indicate that L-selectin is expressed on nonlymphoid leukocytes and is involved in the leukocyte traffic to inflamed tissues.

cDNA encoding L-selectin has been cloned in mice, humans, rats and cattle. L-Selectin has a characteristic lectin domain, an EGF domain, and two consensus repeats of the complement-regulatory protein domains. Human L-selectin has a core protein of 37 kDa with seven potential N-glycosylation sites, but no O-linked glycan appears to be present. Post-translational glycosylation yields L-selectin of different molecular sizes that are differentially expressed in various leukocyte subsets; 75 kDa in lymphocytes, 95–105 kDa in neutrophils and 110 kDa in monocytes. The L-selectin gene is located on human chromosome 1 and on murine chromosome 1 in close association with E- and P-selectin genes in both species. The proximity of these genes and similarity in the sequence of selectin genes (40–60% at the nucleotide level) suggest that they originated from a common primordial ancestor.

A unique feature of L-selectin is that it is rapidly shed from the cell surface upon activation. It is cleaved at the membrane-proximal site as a result of proteolysis, and increased levels of soluble L-selectin are present in the plasma of patients with sepsis, leukemia and the acquired immune deficiency syndrome (AIDS). Although the biochemical nature of this proteolytic enzyme, 'secretase' or 'shedase', remains to be fully elucidated, a novel type of zinc-dependent metalloprotease, similar to the one involved in the processing of membrane-bound tumor necrosis factor α (TNF α), appears to play a key role in proteolysis. Inhibition of the activity of this enzyme leads to reduced neutrophil rolling velocity under hydrodynamic flow conditions, resulting in increased accumulation of neutrophils. This suggests that the shedding process of L-selectin occurs very rapidly during rolling interactions and may be necessary for subsequent leukocyte adhesion and transmigration.

L-Selectin recognizes sialylated Lewis^x and sialylated Lewis^a (sLe^a; Neu5Ac α 2–3Gal β 1–3(Fuc α 1–4)GlcNAc), as do other selectins. Similar to P-selectin, L-selectin also binds to sulfatides and sulfated polysaccharides such as fucoidan and heparin. A group of O-glycosylated mucins decorated with sialic acid, termed sialomucins, represents the protein ligands for L-selectin. They are GlyCAM-1, CD34 and MAdCAM-1. GlyCAM-1, which bears sLe^x-type carbohydrates, is a secretory molecule expressed specifically on HEVs of peripheral lymph nodes and

probably acts as a regulator for L-selectin-mediated cell adhesion. CD34 is a transmembrane glycoprotein expressed extensively on blood vessels and hematopoietic stem cells, neither of which bind L-selectin under normal circumstances. Appropriate glycosylation appears to confer the ability to bind to L-selectin, and a specifically glycosylated form of CD34 expressed on HEVs serves as a ligand for L-selectin. However, mice deficient of CD34 by gene targeting possess almost normal lymph node architecture, and hence, CD34 is apparently not the sole ligand responsible for L-selectin-mediated lymphocyte trafficking into peripheral lymph nodes. MAdCAM-1 is expressed on HEVs of Peyer's patches and venules in intestinal lamina propria, and has been shown to bind L-selectin and $\alpha_4\beta_7$ -integrin. Recognition of vascular MAdCAM-1 by lymphocyte $\alpha_4\beta_7$ -integrin plays a crucial role in lymphocyte trafficking into intestinal lymphoid tissues. The physiological significance of L-selectin binding to MAdCAM-1 is unclear at present.

P-Selectin (CD62P)

P-Selectin (previously referred to as PADGEM or GMP-140) is normally stored in the Weibel–Palade bodies in endothelial cells and in α granules inside the platelets. It is rapidly mobilized to the cell surface upon appropriate activation, such as exposure to histamine, oxygen radicals, interleukin 1 (IL-1) and TNF α . P-Selectin has a domain organization common to all selectins, and nine consensus repeats in the complement regulatory protein domain in humans, six and eight repeats in cattle and mice, respectively. Alternative splicing of mRNA can yield two isoforms in humans; one variant lacks the seventh consensus repeat, whereas the other lacks the transmembrane region. Soluble P-selectin is detected in normal human plasma in concentrations of approximately 100 ng ml⁻¹, and structural analysis indicates that the plasma P-selectin is derived from alternative splicing of mRNA and limited proteolysis of the intact transmembrane form. In certain pathological conditions, such as the adult respiratory distress syndrome (ARDS), the plasma concentration of P-selectin may increase to 1.0 μ g ml⁻¹, a level that may be sufficient to modulate P-selectin-mediated cell adhesion *in vivo*. Data obtained from gene-targeted mice and mAb blocking studies indicate that endothelial P-selectin mediates the initial capture of leukocytes from the flowing blood, while the synergistic action of leukocyte L-selectin and endothelial P- or E-selectin is required for optimal leukocyte rolling (Figure 3).

Similar to other selectins, the lectin domain of P-

Figure 3 Synergy in selectin function in leukocyte rolling along the endothelium. Leukocyte L-selectin or endothelial P-selectin mediates the initial capture of leukocytes from the flowing blood as well as tethering of leukocytes to the endothelial cells. Subsequently, leukocyte rolling is mediated optimally by synergistic action of L-, E- and P-selectin. Leukocyte rolling is facilitated by leukocyte integrins and endothelial ICAM under low shear forces, leading to a firm adhesion of leukocytes to endothelial cells, a process also mediated by integrins, ICAM and VCAM (Modified from Ley and Tedder (1995)).

selectin plays a crucial role in the recognition of sLe^x- or sLe^a-type carbohydrate chains present on membrane glycoprotein counter-receptors. The appropriate presentation of the carbohydrate by glycoprotein scaffolds apparently allows high-affinity binding of the selectins. Several glycoproteins have been reported to be ligands for P-selectin. PSGL-1 is a transmembrane sialomucin of 110 kDa expressed on various types of leukocytes including T and B lymphocytes as homodimers. However, the majority of PSGL-1-positive peripheral blood lymphocytes do not display significant P-selectin binding. Only stimulated T cells show significant binding to P-selectin, and PSGL-1 is the predominant counter-receptor for P-selectin on this cell type. On the other hand, myeloid cells constitutively express an active form of PSGL-1. Thus, activation-dependent and/or cell-lineage specific post-translational events appear to contribute to the expression of functional PSGL-1. *In vitro* studies indicate that L-selectin may also act as a P-selectin ligand by presenting specific carbohydrate side-chains, although its significance *in vivo* remains unknown. Another P-selectin ligand on neutrophils was reported recently in the mouse. It is a 80 kDa glycoprotein (160 kDa; nonreduced), and its binding to P-selectin is sensitive to EDTA and O-sialoglycoprotease. P-Selectin also recognizes 3-sulfated galactosyl ceramides, sulfatides, which are expressed on the surface of granulocytes and certain tumor cells, and this may influence pathological interactions between tumor cells and activated endothelium or platelets.

E-Selectin (CD62E)

E-Selectin (CD62E or previously referred to as ELAM-1) is an inducible endothelial cell surface molecule of 115 kDa. Its expression on endothelial cells is transcriptionally upregulated by various pro-inflammatory substances such as IL-1, TNF α and lipopolysaccharide (LPS). Cytomegalovirus infection also induces E-selectin expression. The expression peaks 4–6 h after stimulation, and is rapidly down-regulated by internalization, returning to basal levels after 48 h, although sustained levels of expression may occur in the presence of interferon γ (IFN γ). E-Selectin has the C-type lectin domain, EGF-like domain and the complement regulatory protein homology domain consisting of six consensus repeats. E-Selectin mediates leukocyte rolling on the endothelium, and thus is involved in the recruitment of neutrophils, monocytes and T cells to inflammatory foci. However, blocking of E-selectin alone appears to have a limited effect on inflammatory responses *in vivo*. Results from gene-targeted mice deficient for expression of individual selectin also indicate that E-selectin alone is unable to recruit these inflammatory cells *in vivo*. Migration of neutrophils into the peritoneal cavity still occurs in E-selectin-deficient mice, but can be almost completely abrogated by pretreatment with mAb against P-selectin. Similarly, although E-selectin-specific mAb shows little effect in blocking leukocyte rolling in normal mice, it has a significant blocking effect in P-selectin-deficient mice. These results indicate that E- and P-selectin are partially redundant as mediators of leukocyte rolling *in vivo* (Figure 3).

Certain types of sialylated sugars, such as sLe^a and sLe^x have been identified as ligands that bind to the N-terminus lectin domain of E-selectin. CLA (cutaneous lymphocyte antigen) recognized by mAb HECA-452 is a fucosylated, sialylated structure closely related to sLe^x that can bind to E-selectin, and is expressed in a subset of skin-seeking memory-type lymphocytes. Expression of CLA in certain skin-infiltrating lymphocytes and the preferential expression of E-selectin in infiltrating foci suggest that CLA functions as a skin-homing receptor for lymphocytes. Several glycoproteins bearing sLe^a or related structures have been reported to bind E-selectin, although its significance *in vivo* remains unknown. These include L-selectin, CD66 and CD11/CD18. T Cells expressing $\gamma\delta$ -type T cell receptors (TCR) express a 250 kDa glycoprotein ligand in cattle. Furthermore, a 150 kDa glycoprotein ESL-1 (130 kDa nonreduced) was identified as a high-affinity ligand for E-selectin on murine neutrophils and human leukemia cell line HL60. This ligand appar-

ently lacks O-linked sugars, and utilizes N-linked sugars to bind E-selectin.

SEPTIC SHOCK

Peter Brouckaert, Molecular Pathophysiology and Experimental Therapy Unit, Department of Molecular Biology, Flanders Interuniversity Institute for Biotechnology, Gent, Belgium

Sepsis is a systemic inflammatory response syndrome resulting from and complicating an infection. The clinical expression is extremely variable, but temperature dysregulation, tachypnea, tachycardia and leukocyte redistribution are common features. When the situation deteriorates, severe sepsis and septic shock may develop, with circulatory insufficiency, inadequate organ perfusion, capillary leak, an imbalance between oxygen demand and supply, and metabolic dysregulation. This may be further complicated by diffuse intravascular coagulation and multiple organ dysfunction syndrome.

The incidence of sepsis is increasing, presumably due to the improved possibilities of medical technology, which allows the survival of patients with important dysfunctions. Although this syndrome and related entities have attracted the attention of numerous (pre)clinical researchers, both from academies and industrial companies, the resulting gain in our understanding of sepsis has so far not been translated into an improved efficacy of treatment. The prognosis of patients with severe sepsis, septic shock and multiple organ dysfunction syndrome remains poor.

The question whether the data collected from (pre)clinical research during the last decades have brought more insight into the relevant pathways leading to lethality is appropriate. The complex pathophysiology of this entity, in which almost all organs and all physiological systems may become

involved in a redundant, concerted and interacting way, perhaps leads to a self-sustaining chaotic situation, in which our mechanistic approaches are inadequate. Furthermore, the highly variable clinical expression of these syndromes has led some authors to propose that these syndromes only exist in the mind of clinicians and researchers, and are in fact a variety of disparate pathological processes. Or, in other words, every patient with sepsis has his or her own subtype of the syndrome with a unique pathophysiology. The latter is not only determined by the original provoking challenge, but maybe more importantly by underlying, concomitant disorders and the reactivity of the individual patient. This not only makes it difficult to design an adequate treatment, but also hampers the development of relevant animal models and the design of clinical trials. Perhaps the most devastating concept which inhibited progress was the acceptance of the existence of 'black knights', central mediators of sepsis that would be responsible for the major deleterious, and only for deleterious, events. During the last years, the insight has grown that these presumed central mediators, such as tumor necrosis factor and nitric oxide, are in fact also indispensable to survive major challenges. It is only when the reaction of the body becomes malignant, i.e. uncontrolled, self-sustaining and chaotic, that the deleterious effects become predominant.

Table 1 Definitions

Infection = microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by those organisms

Bacteremia = the presence of viable bacteria in the blood

Systemic inflammatory response syndrome (SIRS) = the systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following conditions: 1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; 2) heart rate >90 beats per minute; 3) respiratory rate >20 breaths per minute or $\text{Paco}_2 <32$ mmHg; and 4) white blood cell count $>12\,000$ per cu mm, <4000 cu mm, or $>10\%$ immature (band) forms

Sepsis = the systemic response to infection, manifested by two or more of the following conditions as a result of infection: 1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; 2) heart rate >90 beats per minute; 3) respiratory rate >20 breaths per minute or $\text{Paco}_2 <32$ mmHg; and white blood cell count $>12\,000$ per cu mm, <4000 cu mm, or $>10\%$ immature (band) forms

Severe sepsis = sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to lactic acidosis, oliguria, or an acute alteration in mental status

Septic shock = sepsis-induced with hypotension despite adequate fluid resuscitation along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are receiving inotropic or vasopressor agents may not be hypotensive at the time that perfusion abnormalities are measured

Sepsis-induced hypotension = a systolic blood pressure <90 mmHg or a reduction of ≥ 40 mmHg from baseline in the absence of other causes for hypotension

Multiple organ dysfunction syndrome (MODS) = presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention

Reproduced with permission from Bone *et al* (1992).

It may be expected that this cluster of syndromes will remain a major challenge for the biomedical community. The results from such a major effort most likely will also find applications in less dramatic inflammatory responses.

Definitions

Being a syndrome ('a set of signs and symptoms') with an important interindividual variation, the decision as to who should be identified as a 'septic patient' relies on the presence of a sufficient number of preset symptoms, which may be attributed a weight factor. Especially since no single sign or symptom is explicitly required, it is not difficult to conceive that the great differences observed in epidemiology, outcome, efficacy of interventions and presence of mediators between the distinct clinical studies might be more a result from different definitions than from anything else.

Recently, an American College of Chest Physicians/Society of Care Medicine (ACCP/SCCM) consensus conference has proposed a new set of definitions of sepsis and related disorders that is becoming more and more accepted by the scientific community. 'Sepsis' is defined as a systemic inflammatory response to an infection. When sepsis is associated with organ dysfunction, hypoperfusion or hypotension, it is termed 'severe sepsis'. When the hypotension induced by sepsis persists despite adequate fluid resuscitation, in the presence of perfusion abnormalities, the term 'septic shock' is adequate. The recommendations of this conference

and the interrelationship of the distinct entities are shown in Table 1 and Figure 1, respectively.

Since sepsis and related disorders may present themselves in an important variation of severity, a severity-of-illness scoring system is an essential part of the description of patient populations. APACHE (Acute Physiology and Chronic Health Evaluation) scores are the most widely used severity scores, but a number of other scores exist.

Epidemiology and prognosis

Although there is, depending on the definitions used, quite some variation in the published numbers, there is a general agreement of increasing incidence. A reasonable estimate of sepsis complicating infections with gram-negative organisms is 500 000 cases/year in the USA. A recent trend is an increasing incidence of sepsis resulting from infections with gram-positive organisms. The majority of cases occur in patients who have already been admitted to hospital. Mortality rates range from 10 to 90%, septic shock having a higher mortality rate than uncomplicated sepsis. The presence of underlying organ dysfunction also contributes to a poor prognosis.

Pathophysiology

Table 2 is an incomplete listing of the various physiological systems involved in the pathophysiology of sepsis. A theory has evolved comprising successive waves of mediators and events which might result in lethality. In a first stage, bacterial products

induce cytokine mediators. These in turn would activate endothelial cells and white blood cells, in this way inducing neutrophil/endothelial cell adhesion and the release of a second wave of mediators, including nitric oxide, elastase and products of the coagulation pathway. This second stage would then result in microcirculatory inflammation, capillary leak and circulatory insufficiency. The end-result is tissue hypoxia and multiple organ dysfunction. The latter events could result in a new trigger, either by inducing bacterial translocation in the gut or in other ways, and so be responsible for the vicious self-feeding character of the disease. On the other hand, negative feedback is induced: cytokine inhibitors, anti-inflammatory cytokines and acute-phase proteins. The balance between the proinflammatory events and the negative feedback would then determine whether sepsis will be transient or is going to develop into an uncontrolled disaster.

As a result of this theory, 'magic bullets' have been sought which might stop the deleterious activity of presumed 'central mediators' presented as 'black knights'. It was hoped that such an approach would allow the addition of an anti-inflammatory component to the supportive and source-controlling components of the therapy. Clinical trials could not confirm this approach. In the mean time, it has been recognized that at least two of the presumed 'black knights', nitric oxide and tumor necrosis factor, in fact are Janus-faced and also have indispensable protective properties. Perhaps this concept should be extrapolated to the septic reaction as a whole.

What prospects do we have? There is a general feeling that one should go back to basics, accept the complexity and the redundancy of the system, and become aware that the pure hierarchical mechanistic way of thinking is inadequate to approach this chaotic system. More insight should be gained into the factors that are responsible for the switch from a transient sepsis to an irreversible self-sustained syndrome. Alternatively, one could focus on the intracellular signal transduction pathways, rather than on intercellular mediators.

SEROTONIN

Frank A Redegeld, Department of Pharmacology and Pathophysiology, Utrecht Institute of Pharmaceutical Sciences, Utrecht University, Utrecht, The Netherlands

Henk Van Loveren, Laboratory of Pathology and Immunobiology, National Institute of Public Health and the Environment, Bilthoven, The Netherlands

In addition to its role in neurological processes, the biogenic amine 5-hydroxytryptamine (5-HT) or serotonin (Figure 1) can be active as a vasoactive amine causing vascular permeability, smooth muscle contraction, and also playing an important role in the regulation of immunological responses. The following entry will summarize the most relevant information on storage and release of this catecholamine

Figure 1 Structure of 5-hydroxytryptamine (serotonin).

by cells that belong to the immune system, or are associated with that system, and on the activity of serotonin in the context of the immune system.

Serotonin is released by rodent but not human mast cells, and also by basophils, platelets, and certain T cell populations with serotonin-positive granules. Upon activation, mast cells release a variety of mediators, including serotonin. Release occurs by a noncytolytic process that under most circumstances can be described as granule exocytosis. A large series of agents (secretagogues) are able to induce this release. The most well-studied example of mast cell release is induced by protein allergens in immunoglobulin E (IgE)-sensitized mast cells participating in

hypersensitivity reactions of the immediate, or anaphylactic type. Upon atopic sensitization, allergens induce specific antibodies of the IgE class (so-called anaphylactic, or reaginic, or cytotoxic IgE antibodies). Mast cells possess surface membrane receptors that specifically bind the Fc part of the IgE antibody with high affinity. Bridging of these Fc receptors by cross-linking of the bound IgE by the bi- or multivalent allergen, or anti-IgE, or otherwise, results in a transmembrane signal that causes activation of membrane-associated enzymes, leading ultimately to degranulation and release of mediators, among which is serotonin.

Apart from the classical IgE-mediated release of mast cell products, activation and mediator release can be initiated by a number of other potent secretagogues. Among those are products generated during inflammatory reactions such as the anaphylatoxins C3a and C5a which are produced during complement activation, and leukocyte-derived factors, i.e. products released from neutrophils, eosinophils, macrophages and lymphocytes, some of which are IgE-binding factors. Complement receptors have been demonstrated on mast cells. Other, non-immunological, secretagogues include several neuropeptides such as substance P, somatostatin, neurotensin and nerve growth factor, which is interesting in view of the fact that there is a close anatomical relationship between mast cells and nerve fibers. Further stimuli are opioids, smooth muscle relaxants and other drugs, highly charged basic polypeptides, the calcium ionophore A23187, compound 48/80, dextran and enzymes like chymotrypsin and phospholipase. Also physical factors like ultrasound, heat, cold, pressure and physiological conditions such as hypoxia, osmotic alterations and stress are considered stimuli for mast cell activation.

The ultrastructure of anaphylactic degranulation of mast cells in various species has been described in detail both *in vivo* and *in vitro*. Briefly, degranulation proceeds by swelling of the granules, converting the electron-dense granule contents into a more particulate appearance, and fusion of perigranular membranes with each other and with the plasma membrane. Thus, extensive channels, labyrinths or vacuoles opening to the exterior are formed, from which the granular contents are extruded into the environment. Degranulation requires calcium uptake and consumption of metabolic energy, i.e. it is a non-cytolytic process. After degranulation, mast cells still possess a full complement of cytoplasmic organelles, recover and regranulate.

In basophils and also in mast cells, a process of exocytosis that differs from the process described above has been described called 'piecemeal' degranu-

lation. Here, partial release of granular contents occurs by a vesicular transport mechanism involving budding of loaded vesicles from the granule membrane, transit through the cytoplasm, and fusion of these transport vesicles with the plasma membrane. This mechanism is thought to cause mild or gradual and time-spaced degranulation from basophils and differential release of serotonin from mast cells in mice. Differential release of serotonin can occur if mast cells are pretreated with certain drugs (such as the tricyclic antidepressant amitriptyline) and may occur *in vivo* in delayed-type hypersensitivity (DTH) responses.

Serotonin and delayed-type hypersensitivity

Thus far, substantial evidence has been obtained indicating that some type of antigen-specific T cell factor is capable of activating mast cells to release mediators, especially vasoactive amines in the early and late phases of DTH responses. The molecular nature of such factors remains to be fully defined. Activation of the mast cell may, conceivably, be achieved through specific receptors for the T cell factors. The events that take place during DTH responses can be summarized as follows. Early after immunization, antigen-specific T cell factors are produced and released by T cells in the lymphoid organs. These factors are transported in the circulation and leave the circulation to sensitize the peripheral extravascular tissues, i.e. bind to the mast cells that possess putative specialized receptors for these factors. Upon local antigen challenge the sensitized mast cells, and perhaps other serotonin-containing cells, release serotonin. This acts on serotonin receptors of postcapillary venules causing activation and the formation of gaps between endothelial cells, which results in increased vascular permeability. This allows circulating T cells, some of which are antigen specific, to leave the circulation and enter the site of the reaction where interaction with antigen takes place, probably in the context of major histocompatibility complex (MHC) class II antigens on local antigen-presenting cells such as Langerhans cells. Activation of these T cells by antigen-MHC complexes, and also by serotonin through 5-HT₂ receptors on their membranes, leads to local production of non antigen-specific lymphokines, which ultimately attract circulating bone marrow-derived leukocytes, such as monocytes, to also enter through the gaps between endothelial cells and constitute the classical perivascular infiltrate of DTH reactions.

There are several lines of evidence that favor a role of serotonin released from mast cells or platelets in

DTH-associated cellular immune responses in the mouse. First, these responses are elicited preferentially at those cutaneous sites that are enriched in mast cells, such as ears and footpads. In contact-sensitivity to trinitrochlorobenzene, as well as in hematorporphyrin derivative-induced phototoxicity, evidence of release of mediators by mast cells was obtained; in these studies histologic signs of hypogranulation of mast cells were noted. Secondly, pretreatment of cutaneous sites with serotonin causes tachyphylaxis, i.e. specific desensitization of vascular serotonin receptors on the endothelial cells, and this inhibits subsequent elicitation of DTH by local antigen challenge. Thirdly, treatment with the cromoglycate-like drug proxicromil, which prevents release of mediators including serotonin, or treatment with serotonin antagonists, like methysergide or ketanserin, suppresses contact sensitivity and also T cell-mediated inflammatory responses due to infection with *Trichinella spiralis*. Fourthly, studies employing the drug reserpine, which depletes serotonin from mast cells, platelets and neurons, showed suppression of DTH responses, contact photosensitivity, T cell-dependent immune responses to tumor cells, and the development of allergic encephalomyelitis. Finally, defective DTH responses have been observed in two strains of mast cell-deficient mice. This pertains to contact sensitivity to picryl chloride, delayed-type hypersensitivity to sheep red blood cells and to allogeneic tumor cells, and in mice sensitized to 3,3',4',5-tetrachlorosalicylanilide.

A potential role for mast cells and serotonin in contact sensitivity has been challenged. In contrast to defective DTH responses in mast cell-deficient mice, normal and even greater than normal responses were noted in other studies. Local reconstitution of mast cell-deficient ears with mast cells did not increase the responsiveness of such ears with respect to contact sensitivity. It can be concluded from these conflicting results that DTH can be elicited in mast cell-deficient mice, but that it is sometimes diminished. Crucial in this respect is how serotonin-dependent DTH responses are elicited in mast cell-deficient mice. The skin of these mice is not serotonin deficient. The source of serotonin is undoubtedly platelets, which could thus play a role in DTH. Therefore, recent findings concerning the role of platelets in IgE-dependent hypersensitivity responses could be extended to indicate an important role for platelets in DTH responses. It is noteworthy that active systemic anaphylactic responses were shown to occur in mast cell-deficient mice. Since such immediate-type IgE-dependent hypersensitivity reactions are shown to involve mast cells, these data can lead to two types of conclusions: 1) It may be that the relative low number

of mast cells (less than 1% of mast cells of normal litter mates) provides sufficient amounts of mediators, including serotonin, for systemic anaphylactic reactions and also can support DTH responses. Thus, mast cell-deficient mice may be a poor model to study the role of mast cells in such responses. 2) It is possible that other nonmast cell sources of serotonin are available for the elicitation of responses. In the skin this could be the rich supply of serotonin in platelets in the vessels and in systemic anaphylaxis this could be the extensive enterochromaffin tissue of the gut.

Serotonin and macrophages

At sites of inflammation, macrophages are exposed to mediators released by activated lymphocytes and aggregated platelets. The lymphokine interferon- γ (IFN γ) is a well-known activator of macrophages and induces, for example, increased expression of MHC class II on the plasma membrane of macrophages, rendering these cells capable of participating as antigen-presenting cells. Serotonin, which is likely to be present at sites of inflammation, is capable of suppressing the induction of the IFN γ -induced class II expression on macrophages. This inhibition is specific and is blocked by 5-HT $_2$ receptor antagonists.

Phagocytosis by macrophages is differentially modulated by serotonin. At low concentrations of IFN γ , serotonin augments phagocytosis, whereas at high concentrations of IFN γ , serotonin suppresses phagocytosis. These effects were blocked by the 5-HT antagonists spiperone, ketanserin, LY53857, mCCP and PAPP. Thus 5-HT could either counteract or augment the stimulatory effects of cytokines, depending on the overall balance of 5-HT and IFN γ , or other inflammatory mediators.

Serotonin and natural killer cells

Natural killer (NK) cell-mediated cytotoxicity against tumor target cells is enhanced by the addition of 5-HT to the incubation mixtures. The stimulation by 5-HT is dependent on the presence of monocytes and is presumably due to the abrogation of the monocyte-induced inhibition of NK activity. These effects are mediated through the 5-HT $_1$ receptor, although they were only evident at relatively high concentrations of 5-HT, suggesting that 5-HT may only have a role as an immunomodulator in local host defense against neoplastic cells and microorganisms.

Serotonin and lymphocytes

Serotonin has dual effects on lymphocyte function and proliferation. Addition of relatively high concentrations of 5-HT to phytohemagglutinin-stimulated lymphocytes suppresses *in vitro* proliferation. This effect could not be reversed by addition of interleukin 2 (IL-2) to the culture and was most likely due to inhibition of the activation of lymphocytes, since proliferation of other cells was not affected. In other studies stimulatory effects of serotonin on T cell activity were reported. Depletion of endogenous sources of serotonin reduced the capacity of splenic T cells to proliferate and to express IL-2 receptor in response to concanavalin A stimulation. Similarly, 5-HT₂ receptor antagonists had the same suppressive effect on the activation of normal spleen cells. Activated differentiated T cells express a 5-HT_{1a} receptor with an inhibitory regulatory effect on adenylate cyclase activity. Thus, 5-HT may have a T cell regulatory role at sites of inflammation by interfering with the suppressive effects of compounds that elevate cAMP (e.g. prostaglandins, β -receptor agonists, etc.). Serotonin may also act on other 5-HT receptors, such as 5-HT₁ and 5-HT₃, resulting in modulation of voltage-gated conductance in lymphocytes. Potassium channels are thought to play an important role in a variety of lymphocyte effector functions, including secretion of lymphokines and mitogenesis.

Serotonin and secretion of lymphocyte chemoattractant factors

At sites of inflammation, the accumulation of T lymphocytes is regulated by the sequential effects of multiple cytokine networks, resulting in the increased expression of adhesion molecules, production of chemoattractants and growth factors to induce cell migration and proliferation, respectively. Recently, a possible role for serotonin has become evident in these processes. Stimulation of aortic endothelial cells by serotonin results in the production of a novel 13–15 kDa T lymphocyte-specific chemotactic cytokine, endothelial cell-derived lymphocyte chemoattractant activity (ED-LCA), which is distinct from other endothelial derived cytokines (e.g. IL-1, IL-6 and IL-8). ED-LCA is not stored in an active form in endothelial cells; its secretion occurs within 60 min after stimulation with serotonin. No secretion of ED-LCA was found after stimulation with histamine or angiotensin II. ED-LCA acts as a chemoattractant for both CD4⁺ and CD8⁺ T cells. In addition, ED-LCA also primes T lymphocytes to respond to IL-2 by virtue of upregulation of IL-2 receptor expression. Another lymphocyte chemoattractant factor (LCF or

IL-16) is produced after stimulation of CD8⁺ T lymphocytes with serotonin or histamine. IL-16 is preformed and stored in biologically active form and release from CD8⁺ cells is essentially complete at 4 h after stimulation with serotonin. This release is mediated through 5-HT₂ receptors. IL-16, identified as a protein with a molecular weight of 56 kDa, has selective chemoattractive activity for CD4⁺ T lymphocytes and may play an important role in the recruitment of CD4⁺ T lymphocytes into sites of inflammation. Interestingly, it has been demonstrated that IL-16 is released in bronchoalveolar fluid following subsegmental allergen challenge of atopic asthmatics but not in normal individuals.

SERUM SICKNESS

Ekaterini Paizis and Brendan F Murphy, Department of Nephrology, St Vincent's Hospital, Victoria, Australia

Serum sickness is a type III hypersensitivity reaction that develops after exposure to xenogeneic proteins. It was first described by Von Piquet and Schick in 1905, who noted the development of rash, fever, lymphadenopathy and arthralgia in some recipients of xenogeneic sera – horse serum for diphtheria. The pathogenesis of this serum sickness was attributed to the host's immunological reaction to injected antigens and has been described as a generalized Arthus reaction.

Serum sickness was proclaimed as an important experimental model of human immunological disease. In the 1950s several elegant animal studies using radiolabeled serum proteins conclusively demonstrated the association of the pathological lesions of serum sickness with the detection of circulating immune complexes. Circulating and tissue-bound immune complexes form at the time of immune elimination: for a number of factors determine whether circulating immune complexes are deposited in tissues rather than cleared by the reticuloendothelial system. These factors include vascular permeability, local hemodynamic flow, size of complexes and affinity of the antibody. Once deposition takes place, there is activation of the complement cascade and

release of chemotactic factors with resultant leukocyte infiltration which results in a characteristic inflammatory response in the target organ.

Experimental models of serum sickness

Acute serum sickness

This is the classical serum sickness model and is also known as acute immune complex disease. It is normally induced by a single intravenous injection of xenogeneic protein – most commonly bovine serum albumin (BSA) (250 mg kg⁻¹) into rabbits. Antibody is formed and binds to circulating antigen to form immune complexes. These complexes are observed in the sera and from day 10 there is no detectable antigen in the circulation. The events occurring in the 2 weeks following radiolabeled antigen administration are depicted in **Figure 1**.

Characteristic histopathological lesions are described in acute serum sickness; vasculitis with prominent neutrophil infiltration is seen in large and medium-sized vessels and endocarditis is observed in the cardiac valves. The type of lesions observed in the glomeruli of the kidney are dependent on the size of the immune complexes. In conditions of antigen

Figure 1 A graph showing events occurring in the 2 weeks following radiolabeled antigen administration.

excess, complexes are small and deposit in the subepithelial space; when complexes are large they deposit in a subendothelial location. There is an associated monocyte macrophage infiltration which is unique to the renal lesion. Proteinuria normally accompanies the glomerular lesion.

The mediation of injury in serum sickness appears to involve several mechanisms. Vasoactive amine-induced increase in vascular permeability appears to be of initial importance as is the infiltration of neutrophils in the vascular lesions. Macrophage depletion and interruption of the terminal complement components are capable of preventing nephritis. Cytokines, in particular tumor necrosis factor α (TNF α) and interleukin 1 (IL-1), have been shown to play a role in the activation of endothelial and mesangial cells and in leukocyte recruitment.

Chronic serum sickness

This model was developed as the prototype of human immune complex glomerulonephritis; it does not feature the vascular lesions of acute serum sickness. Repeated antigen injection (again normally in rabbits) creates a state of antigen excess and maintains immune complexes in the circulation. The main site of immune complex deposition is the kidney; joints, arteries and skin are rarely involved. The type of glomerulonephritis that develops is dependent on the antigen dose, antibody affinity and the resultant size of immune complexes. In states of antigen excess and low antibody affinity, complexes are small and the renal lesion is characteristic of membranous glomerulonephritis or severe endocapillary proliferative nephritis. With intermediate and high-affinity antibodies the complexes are large and insoluble and deposit in the mesangium with some juxtaglomerular subendothelial deposition. The glomerulonephritis associated with this is a mild mesangial proliferative nephritis.

If the antigen is chemically modified to impart a cationic charge, glomerular immune complex deposition and rapid onset of glomerulonephritis occurs without relative equivalence of antigen and antibody. *In situ* immune complex formation in the glomerulus is likely to be important here. Interestingly, heparin has been shown to enhance the removal of immune complexes, an action not mediated by its anticoagulant properties, but most likely related to its charge.

Serum sickness in humans

With the decline in use of heterologous serum products since the beginning of this century, there has been a marked reduction in the incidence of serum sickness in humans. Current heterologous proteins still in use are antithymocyte globulin and antivenom which carry with them a dose-dependent risk of serum sickness. Reactions resembling serum sickness have been associated with various nonprotein drugs, in particular cefaclor, β -lactam antibiotics, streptokinase and β blockers. This serum sickness-like illness has been postulated to be due to drug-related hapten antibodies, but this has never been proven. Other plausible alternatives are direct toxicity to the vessel wall, development of autoantibodies to endothelial cells and cell-mediated cytotoxicity. Most cases of drug-induced serum sickness are not associated with hypocomplementemia, which is a feature of classic serum sickness.

The typical clinical presentation of serum sickness in humans is seen 8–14 days after antigen exposure unless sensitization has occurred. The commonest clinical presentation is the development of fever, lymphadenopathy and morbilliform rash which normally starts in the extremities. Urticaria may occur, but is less common. Fifty per cent of cases have associated visceral involvement of which arthralgia and arthritis are the most common. Significant systemic vasculitis and glomerulonephritis are uncommon although transient abnormalities are often noted on urinalysis. Classically there is depletion of complement; investigations reveal low C3 and C4 levels.

Treatment involves withdrawal of the suspected antigen, symptomatic relief with antihistamines, analgesics and steroids if indicated. Effective treatments in animal studies include antioxidants, cyclosporine and plasmapheresis; these have not been subject to clinical trials in humans.

SEVERE COMBINED IMMUNODEFICIENCY

Shigeaki Nonoyama and **Jun-ichi Yata**, Department of Pediatrics, School of Medicine, Tokyo Medical and Dental University, Tokyo, Japan

Severe combined immunodeficiency (SCID) is the most devastating form of the human primary immunodeficiencies, characterized by the absence of both cellular and humoral immunity. Although the phenotype is similar, genetical heterogeneity has been observed in the group of patients and several genes causing SCID have recently been identified.

The mode of inheritance may be X-linked recessive (X-SCID) or autosomal recessive (AR-SCID). X-SCID is caused by mutations of the IL-2R γ chain (common γ chain, γ c). AR-SCID are reported to be caused by mutations of various genes, including JAK3, RAG-1/RAG-2, adenosine deaminase (ADA) and purine nucleotide phosphorylase (PNP). In addition, HLA class II deficiency caused by the defects of *trans*-acting regulatory molecules for the expression of class II, and T cell receptor–CD3 signaling deficiency caused by defective CD3 γ , CD3 ϵ , and ZAP-70, are also included in the category of AR-SCID. The approximate percentages of SCID categories classified on the basis of genetic etiology are shown in Figure 1.

In this article, we give an overview of the general symptoms and treatment of human SCID, and describe the various SCID entities on the basis of the responsible genes. In addition, we will briefly discuss mice with the SCID phenotype, including spontaneously derived SCID mice, RAG-1/RAG-2 targeted mice, JAK3 targeted mice, and common γ chain targeted mice.

Clinical phenotype of human SCID

As expected from the severe defects affecting both cellular and humoral immunity, SCID patients commonly have persistent and recurrent infections. Patients with SCID often present with oral candidiasis, diarrhea, otitis, sepsis, cutaneous infections and

pneumonia. Failure to thrive is observed secondary to chronic infection, malabsorption and diarrhea. Patients often suffer from infections by opportunistic microorganisms including *Pneumocystis carinii*, *Cryptosporidia* and *Candida albicans*. Herpes virus, adenovirus and cytomegalovirus often cause lethal systemic infections. Live vaccines such as BCG, oral polio vaccine, and varicella vaccine are contradicted in patients with SCID. Since SCID patients lack the ability to reject foreign tissue, chronic GVHD (graft-versus-host disease) caused by maternal T cells that cross the placenta may occur in affected infants. Similarly, nonirradiated blood transfusions can cause GVHD.

Figure 1 Classification of human SCID.

X-SCID

The gene that causes X-SCID has been mapped to Xq13 by linkage studies. The cloning of IL-2R γ chain (common γ chain, γ c) and the localization of this gene to Xq13 led to the hypothesis, subsequently confirmed, that mutation of γ c causes X-SCID. γ c is a subunit of the IL-2 receptor which consists of an α , β and γ chain, and is shared by IL-4R, IL-7R, IL-9R and IL-15R (Figure 2). Thus, γ c chain plays an important role in the signal transduction of multiple cytokine receptors. Subsequent studies of the γ c gene confirmed that all patients with X-SCID have mutations within the γ c gene. Approximately 100 unique mutations of γ c have been reported and registered in the worldwide database. They include missense and nonsense mutations, deletions, insertions and splice site mutations and affect all domains of γ c. The missense mutations of the extracellular domain of γ c result in impaired binding of IL-2. Mutations affecting the four cysteine residues that are conserved in the cytokine receptor family and the mutations affecting the WSXWS motif disrupt the configuration of the γ c chain. Missense mutations at the transmembrane domain cause unstable expression of the γ c chain either by the replacement of hydrophobic amino acids or the disruption of anchoring residues. Mutations within the intracellular domain affect the signal transduction pathway of IL-2R. Deletion of 62 amino acid residues at the C-terminal region of γ c caused a severe phenotype of X-SCID. A missense mutation at amino acid residue 271 (L271Q) interferes with the association of γ c and JAK3 (Figure 3).

Although T cells and natural killer (NK) cells are absent in X-SCID patients, B cell numbers in the peripheral blood are normal or elevated. The phenotypes of B cells are relatively immature and the diversity of Ig rearrangement is limited. This could be caused by the lack of appropriate T cell help or by the fact that γ c is shared by IL-2R, IL-4R, IL-7R, IL-9R and IL-15R, resulting in a lack of B cell activation by cytokines. B cell function after allogeneic bone marrow transplant (BMT) of patients not undergoing conditioning is known to be impaired when

major histocompatibility complex (MHC)-matched normal donor-derived T cells but not B cells were engrafted. Immunoglobulin (Ig) rearrangements of recipient-derived B cells are often limited.

γ c-deficient mice made by gene targeting show defective lymphocyte development. However, in contrast to human X-SCID, the number of mature B cells is decreased and CD4⁺CD8⁻ and CD4⁺CD8⁺ thymocytes are present, although the absolute numbers are low. The discrepancy between the phenotype of γ c-deficient mice and that of human X-SCID indicates that the requirement of cytokines during lymphocyte development is different between human and mouse. The difference can be explained in part by the observation that IL-7 is indispensable for murine but not human B cell development. IL-7 receptor knockout mice show severe reduction of both T cells and B cells. The exact role of cytokines for human lymphocyte development has not been determined. *In vitro* culture systems that allow the maturation of functional B cells and T cells from human lymphoid stem cells will facilitate our understanding of defective lymphoid development in X-SCID.

JAK3 deficiency

JAK3 is a member of the Janus family kinases (JAK), which include JAK1, JAK2, JAK3 and Tyk2. These kinases are known to play important roles in the signal transduction via cytokine receptors, and transmit signals by binding to STAT (signal transducers and activators of transduction) family proteins. Of the JAK family kinases, JAK3 is the only kinase whose expression is limited to hematopoietic cells and is associated with γ c. In addition, mutations of γ c in the position that associates with JAK3 have been identified in patients with X-SCID. These observations suggested the possibility that AR-SCID might be caused by a defect of JAK3. This hypothesis was confirmed when female SCID patients were found to have mutations in both JAK3 alleles. The phenotypes of immunodeficiency observed in these patients are similar to those observed in X-SCID. B cells are present in normal or elevated numbers, while T cells

Figure 2 Structure of cytokine receptors sharing the common γ chain (γ c).

Figure 3 Structure of the IL-2 receptor and the binding site of JAK3.

and NK cells are absent. JAK3-deficient B cells are functionally defective. STAT6 could not be activated by IL-4 in JAK3-deficient B cells, suggesting the indispensable role of JAK3 in signal transduction from the IL-4 receptor to STAT6. These findings are consistent with the hypothesis that the signal transduction pathway from γ c to JAK3 is linear and that there is a direct association of these two molecules (Figure 3).

JAK3-deficient mice made by gene targeting have demonstrated abnormalities of lymphoid development identical to those described in γ c-deficient mice.

RAG-1/RAG-2 deficiency

RAG-1/RAG-2 is a recombinase activating protein that plays an important role in the initiation of V(D)J gene rearrangement of both the T cell receptor (TCR) and B cell receptor (BCR). Mice deficient in RAG-1 or RAG-2 made by gene targeting were found to show complete absence of both mature T cells and B cells. In human AR-SCID, RAG-1 and/or RAG-2 mutations were identified. The characteristic of this

form of SCID is absence of B cells, which is similar to RAG-1/RAG-2 knockout mice. The recombination frequency found in patients with RAG-1/RAG-2 mutations was decreased if determined in human 293 fibroblasts by the extrachromosomal V(D)J assay.

ADA deficiency and PNP deficiency

Adenosine deaminase (ADA) is an amino hydrolase that deaminates adenosine to inosine. Absence of ADA results in the accumulation of toxic metabolites including deoxy-ATP interfering with DNA synthesis, causing lymphopenia and SCID. ADA deficiency has been observed in approximately 15% of patients with AR-SCID. Although most patients with ADA deficiency demonstrate severe reduction of T cells, B cells and NK cells, T cells are more sensitive to the toxic metabolites than other lymphocyte subpopulations.

Purine nucleoside phosphorylase (PNP) is an enzyme that converts inosine to hypoxanthine. PNP deficiency results in the accumulation of toxic meta-

bolites including deoxy-GTP. Generally, the effect of PNP deficiency on lymphocyte number and function is less severe than that seen in ADA deficiency.

ZAP-70 deficiency, CD3 γ deficiency and CD3 ϵ deficiency

ZAP-70 (zeta-associated protein 70) is a non-src family protein kinase which associates with phosphorylated CD3 ζ chain, and plays an important role in TCR-CD3 complex signaling (Figure 4). In patients with ZAP-70 deficiency, CD8 $^{+}$ T cells are almost completely absent while CD4 $^{+}$ T cells and B cells are present. Thymocytes expressing both CD4 and CD8 (double positive) are present while CD4 $^{+}$ CD8 $^{-}$ thymocytes are absent, indicating that ZAP-70 is indispensable for the development of CD8 single-positive cells. Lack of ZAP-70 may be partly compensated by the presence of syk, allowing the development of CD4 $^{+}$ T cells but not CD8 $^{+}$ T cells. However, CD4 $^{+}$ T cells fail to respond to anti-CD3, mitogens or allogeneic cells *in vitro*, indicating defective signal transduction. NK cell activity is normal.

Mice with defective ZAP-70 lack both CD4 $^{+}$ and CD8 $^{+}$ T cells in peripheral lymphoid organs. This observation suggests that the requirement of ZAP-70 and syk for T cell development is different between mice and human.

A few patients with CD3 ϵ deficiency and CD3 γ

deficiency were reported, demonstrating the importance of these components of CD3 for TCR signal transduction (Figure 4). This is further supported by the observation that T cells from these patients proliferate poorly to anti-CD3 stimulation.

MHC class II deficiency

MHC class II deficiency is a rare primary immunodeficiency disorder characterized by defective expression of MHC class II antigens. Patients with MHC class II deficiency have a severe defect of cellular and humoral immune responses. CD4 $^{+}$ T cells are often decreased, while CD8 $^{+}$ T cells and B cells are present in normal numbers. In spite of the presence of B cells, serum immunoglobulin concentrations of one or more isotypes are decreased in the patients. The hypogammaglobulinemia observed in MHC class II deficiency seems to be caused by the lack of appropriate T cell help and/or by the defective activation of B cells, since class II molecules play important roles in antigen presentation to T cells and transduce activation signals into B cells. Specific antibody responses are severely impaired.

This deficiency is caused by abnormal *trans*-acting proteins that regulate the transcription of the MHC class II gene. At least four complementation groups (A, B, C and D) have been identified by cell fusion experiments. The genetic complementation approach

Figure 4 Association between the TCR-CD3 complex and ZAP-70.

has led to the cloning of MHC class II transactivator (CIITA), X box binding factor regulatory factor X (RFX5), and RFXAP genes. Group A is caused by mutations of the CIITA gene, group C is caused by mutations of RFX5 and group D is caused by mutations of RFXAP. The gene responsible for group B has not yet been identified. Some patients with MHC class II deficiency also have decreased expression of MHC class I for unknown reasons.

SCID mice

Mice with SCID mutation lack the appropriate rearrangements of TCR and Ig, which results in the absence of mature T and B cells. SCID mice also show abnormal sensitivity to ionizing radiation, which causes DNA double-strand breaks. A recent report suggests that murine SCID cells lack a DNA-dependent protein kinase (DNA-PK_{cs}), which is involved in the repair of DNA double-strand breaks during V(D)J rearrangement. Defective DNA-PK_{cs} has not been demonstrated in human SCID.

Treatment of patients with SCID

Patients with SCID have a poor prognosis and in most cases do not survive more than a few months without appropriate treatment. Supportive treatment with intravenous immunoglobulin infusions at regular intervals, and prophylaxis for *Pneumocystis carinii* is indicated. Bacterial or fungal infections are treated with intravenous infusions of antibiotics or antifungal agents. Epstein-Barr virus, herpes virus and cytomegalovirus infection may result in systemic and lethal disorders and should be treated with antiviral reagents. Prophylactic infusions of immunoglobulin with high titer for cytomegalovirus has been advocated. For ADA deficiency, enzyme replacement with polyethylene glycol-modified ADA (PEG-ADA) resulted in limited but significant improvement of the immunodeficiency.

To reconstitute the impaired immune system in SCID, bone marrow transplantation is the treatment of choice. If successfully engrafted, BMT is a curative treatment, although incomplete reconstitution of the immune system and post-transplant lymphoproliferative disorders caused by Epstein-Barr virus are major problems that need to be solved. To improve engraftment, various conditioning regimens including chemotherapy, total body irradiation, and anti-lymphocyte globulin (ALG) have been tried. HLA-haploidentical marrow from a parent can be used for BMT, although T cell depletion is necessary to prevent GVHD. Recently, a successful *in utero* transplantation of parental CD34⁺ hematopoietic progenitor cells into an X-SCID fetus has been reported.

Gene therapy has been attempted in patients with ADA deficiency. Two patients repeatedly received infusions of autologous T cells transduced with the ADA gene inserted in a retroviral vector. Circulating T cells producing ADA were detected, and a possible improvement of the immune responses were observed, including increased numbers of T cells, appearance of T cell cytotoxicity, positive delayed-type hypersensitivity skin tests, and proliferative responses to antigen by specific T cells. The fact that these patients also received PEG-ADA makes the interpretation of these findings difficult. Although many technological breakthroughs are needed, gene therapy has the potential to become a curative therapy for some primary immunodeficiencies whose genetic bases have been identified.

Concluding remark

Although the clinical symptoms of SCID patients are largely similar, they represent genetically heterogeneous disorders. SCID patients can be phenotypically classified into B⁻SCID and B⁺SCID. Approximately half of patients with B SCID are caused by RAG-1/RAG-2 deficiency, the genetic basis of the other half is unknown. Seventy per cent of all SCID cases are B⁻, and several genes that cause B⁺SCID have been identified. Selective lack of CD8⁺ T cells is associated with ZAP-70 deficiency. The presence or absence of NK cells also varies among the different types of SCID. Thus, a phenotype/genotype correlation exists in SCID. The functional analysis of proteins encoded by the affected genes will further clarify the pathogenesis of SCID.

SEX HORMONES AND IMMUNITY

Howard S Fox, Department of Neuropharmacology, The Scripps Research Institute, La Jolla, California, USA

In addition to their profound effects on sexual differentiation and reproduction, sex steroids also influence the immune system's function. The effects of these hormones on the immune system initially attracted the attention of investigators working on autoimmunity, as a sexual dimorphism exists in human autoimmune diseases – that is, one gender is often more susceptible than the other. Although the precise mechanisms through which sex steroids interact with the immune system remain unknown, we do know that these hormones can act directly on certain of the system's cells, or indirectly either through cells controlling the immune system's growth and development or through organs eventually destroyed by autoimmune diseases. Understanding such mechanisms will allow new insight into autoimmune diseases and also into the normal development and function of the immune system and its responses to challenge.

Autoimmunity

In certain individuals, the immune system fails to recognize one's healthy tissue as self, and a humoral and/or cellular immune response develops, leading to the afflictions collectively known as autoimmune diseases. Historically, women have suffered from a greater (up to ninefold) prevalence of many autoimmune diseases. Such female-predominant diseases include systemic lupus erythematosus (SLE), rheuma-

toid arthritis, primary biliary cirrhosis and Graves' disease. This gender preference makes sex steroids an obvious starting point for investigations into the issue. Yet, despite clear-cut results in a number of laboratories, our knowledge of how sex steroids influence the development of autoimmune disease remains largely conjectural.

There are two well-studied, sexually dimorphic autoimmune diseases in laboratory mice modeling SLE and diabetes. In both, the manipulation of sex steroids profoundly influences the course of disease. The first example involves offspring (F1 hybrids) of NZB and NZW strain mice. Although almost all females from this NZB/NZW breeding die of a lupus-like disease within the first year of life, tenfold fewer males die of disease. However castration of NZB/NZW males causes them to suffer a similarly high death rate, and treatment with the male hormone androgen (testosterone or dihydrotestosterone) protects female mice from early fatality. In this experimental model of human lupus, the thymus is an important participant in androgen-induced protection. The second example is the NOD mouse strain, which suffers a high incidence of insulin-dependent diabetes mellitus. By 6 months of age, approximately 80% of NOD strain females are diabetic, whereas only 20% of the males have obvious disease. After castration, these male mice undergo a significant increase in the incidence of diabetes, an effect heightened by removal of the thymus. As in

the NZB/NZW hybrid mice, NOD females given androgen do not get the disease. However, when the androgen-treated females are injected with spleen cells from diabetic animals, diabetes develops. Therefore, the hormone is likely acting on immune cells, not the pancreas – the organ attacked by this disease.

Immune interactions

Studies such as these indicate that sex steroids can influence an abnormally functioning immune system or contribute to the cause of its abnormalities. Yet, the effect of these steroids on the normal immune system is less clear. Still, a few hints have come from studies of humans as well as experimental animals. For example, female mice can produce substantially more antibody in response to particular antigens than their male counterparts; however, humans inoculated with vaccines have virtually identical antibody responses, whether female or male. Also, in mice, cell-mediated responses to certain antigens were notably stronger in females than in males. When researchers mimicked the conditions of pregnancy by combined estrogen and progesterone treatment in mice, the result was a lowered production of B cells by the bone marrow. Additionally, antigen presentation in the uterus and spleen of female rats is highest at proestrus, when estrogen levels peak, and estrogen treatment of oophorectomized rats increases antigen presentation by uterine epithelial cells. Additional studies on the female reproductive tract in mice have shown that during the luteal phase, when there are high levels of progesterone, the number of dendritic cells increases in the vaginal epithelium.

Sex steroids can also profoundly affect the thymus. Studies of rodents and other animals indicate that administration of the hormones androgen or estrogen result in thymic involution, whereas castration leads to thymic enlargement in comparison to gonadally-intact animals. During pregnancy, marked thymic involution occurs, with recovery to normal size and shape after delivery, perhaps caused by markedly elevated levels of progesterone, although other factors could be responsible.

Compared to rodents, primates have fewer reported gender- and hormone-related differences. However, two differences are notable in the human immune system: women have higher levels of plasma immunoglobulin M (IgM) than men and also an elevated CD4:CD8 T cell ratio in the peripheral blood, due to an increase in the absolute number of CD4⁺ lymphocytes. Interestingly, in a nonhuman primate (rhesus macaque) model of acquired immune deficiency syndrome (AIDS), progesterone treatment

increased the number of animals infected by vaginally inoculated simian immunodeficiency virus (SIV) (the monkey homolog of human immunodeficiency virus, HIV), and the female animals so treated developed a more rapid disease course. Although the increased percentage of infected animals may be due to a progesterone-induced thinning of the vaginal epithelium and/or effects on dendritic cells, which play an important role in HIV infection, the nature of the accelerated disease course is unknown.

Targets of action

The potential targets of sex steroids are numerous. The studies cited above point to potential effects on sites where the precursors of immunity originate and differentiate (bone marrow, thymus), as well as on organized lymphoid tissue, circulating immune cells or organ-resident cells. To clarify where the sex steroid hormones have possible direct or indirect effects, lymphoid organs and cells of the immune system have been examined for the presence of specific receptors for sex steroids. However, pursuing this objective has been problematic, in general, because sex steroid receptors are relatively scarce on lymphoid cells compared to more traditional targets of sex steroid activity, such as the reproductive tract or breast. Still, the thymus clearly contains receptors for androgen, progesterone and estrogen. Although the cellular location of these estrogen receptors remains unclear, androgen receptors are present in immature thymocytes, and progesterone receptors are expressed in epithelial cells; it is possible that additional thymic cell types also express these receptors. In the major categories of mature immune cells, it appears that CD8⁺ T cells can express estrogen receptors and that macrophages express receptors for estrogen and also androgen. Two additional sites, endothelial cells and bone marrow stromal cells, also express estrogen receptors, and interactions with these cell types affect the immune system.

Cytokines

Given the prime importance of cytokines in the development, regulation and effector functions of immune reactions, numerous investigators have examined how sex steroids control cytokine genes. Additional impetus to perform such studies stems from experiments revealing gender differences in cytokine production by mice given experimental immune challenges. In one such study, 3 weeks after BCG sensitization, mice were challenged with purified protein derivative (PPD) – constituting a strong antigenic challenge. Four hours later, the resulting

immune response to this challenge was that serum from female mice contained 2.5–4-fold more interferon γ (IFN γ), an immunostimulatory cytokine produced mainly by T cells, than did sera from male mice. A second experimental protocol examined cytokine production four hours after lipopolysaccharide (LPS) administration, which induces a septic shock-like syndrome and proinflammatory cytokine expression. Plasma from female mice contained 4–5-fold more interleukin 1 (IL-1), and 2.5-fold more IL-6, than did plasma from male mice, although equivalent amounts of tumor necrosis factor α (TNF α) were produced. Since LPS is thought to first induce TNF α in macrophages, which then helps stimulate production of IL-1 and IL-6 production in macrophages, this equivalence of TNF α levels indicates that the effect may occur in a common pathway for IL-1 and IL-6 production, such as receptor signaling by TNF α , gene transcription, protein processing or protein release. Finally, androgen treatment of castrated mice leads to increased transforming growth factor β (TGF β) production in the thymus, potentially contributing to androgen-induced thymic involution.

In addition to establishing these gender-based differences in living animals, the role of sex steroids has

been examined directly *in vitro*, using cells from the immune system and elsewhere. When lymph node cells from mice were stimulated by anti-CD3 antibody then treated with androgen, the result was decreases in IFN γ , IL-4 and IL-5 production. However, in a separate study, androgens induced IL-5 expression in lymphoid cells. Elsewhere, estrogen enhanced IFN γ production by stimulated mouse spleen cells. Estrogen also enhanced IFN γ and IL-10 production by clones of CD4 $^{+}$ human T cells, and IL-1 production by macrophages. IL-6 production by bone marrow stromal cells was inhibited by estrogen, an effect with important implications for osteoporosis, considering the stimulatory effect of IL-6 on osteoclasts (macrophage-like cells that resorb bone) and the decreased estrogen content of postmenopausal women. A second sex steroid-regulated cytokine is also likely to be important in osteoporosis, as in osteoblasts (bone-forming cells), estrogen stimulates TGF β production, and TGF β can induce apoptosis (programmed cell death) of osteoclasts. Molecular studies of estrogen's ability to regulate cytokine gene expression have revealed this hormone's stimulatory influence on the IFN γ and TGF β promoter, and inhibitory effect on the IL-6 promoter.

Figure 1 Immune organs/cells known to be affected by sex steroids. These hormones can act during the development of immune cells, as well as directly on mature effector cells.

Table 1 Some of the effects of sex and/or sex steroids on immune system properties or molecules

Parameter	Sex/sex steroid effect
CD4 $^{+}$ T cells	Higher in women
IgM levels	Higher in women
B cell production	Decreased by estrogen plus progesterone
Autoimmune diseases	Higher in women Ameliorated by androgen in mice
SIV infection	Enhanced by progesterone in monkeys
Thymic size	Decreased by estrogen or androgen
IL-1	Higher in female mice Increased by estrogen in macrophages
IL-6	Higher in female mice Decreased by estrogen in bone marrow stromal cells
IL-10	Increased by estrogen in T cell clones
IFN γ	Higher in female mice Increased by estrogen in T cell clones Increased by estrogen in spleen cells
TGF β	Decreased by androgens in T cells Increased by androgen in thymus Increased by estrogen in osteoblasts

Perspectives

Clearly, sex steroid hormones are capable of affecting the development and function of a variety of immune cells (Figure 1 and Table 1). With our increasing knowledge of immune system development and function, testing of hypotheses regarding the mechanisms of sex steroid actions should be increasingly fruitful. Understanding the etiology of these differences may help in the development of therapies for a variety of conditions where the immune system's actions are critical, such as in transplantation and autoimmune and infectious diseases.

SHIGELLA, INFECTION AND IMMUNITY

David WK Acheson and **Gerald T Keusch**, Division of Geographic Medicine and Infectious Diseases, Tupper Research Institute, New England Medical Center, Boston, Massachusetts, USA

Characteristics of the organism and its antigens

Shigella species are gram-negative bacteria of the family Enterobacteriaceae. They cause watery or bloody diarrhea, or the dysentery syndrome and occasionally lead to systemic complications, such as

the hemolytic-uremic syndrome, leukemoid reactions, and autoimmune phenomena such as reactive arthritis. *Shigella* are pathogens only for humans and primates with a low ID₅₀ of a few hundred to a few thousand organisms. Ubiquitous in distribution, they principally cause illness in children, especially where the infection is endemic, suggesting immunity is

acquired. Less commonly, shigellosis occurs in non-immune adults. Severe persistent bacteremic disease has been documented in immunocompromised patients with the acquired immune deficiency syndrome (AIDS).

Shigella invade the colonic mucosa, a step essential for virulence, and divide and spread from cell to cell within the intestinal epithelial cell layer. This process requires both chromosomal and plasmid genes, many of which have now been determined. Cytokines are produced, neutrophils recruited and there is an intense inflammatory response. The most characteristic lesions involve inflammation and ulceration of the colonic mucosa, resulting in the clinical presentation of dysentery, characterized by both blood and pus in the stools of infected patients.

There are four species of *Shigella*: *S. dysenteriae* (group A, 10 types), *S. flexneri* (group B, 6 serotypes and 14 subtypes), *S. boydii* (group C, 18 serotypes), and *S. sonnei* (group D, 1 serotype and 20 colicin types). *Shigella* are nonmotile and generally nonencapsulated. Like other Enterobacteriaceae, they display O (somatic) and K (capsular) antigens. Accurate serotyping of *Shigella* isolates using specific anti-O antigen antibody is best done after heating test organisms to denature K antigens which can obscure the seroreactivity of O antigens. Many immunologically defined *Shigella* O antigens are shared with serotypes of *Escherichia coli* or other gram-negative bacilli. Specific antibody responses occur to *S. dysenteriae* 1 (the only member of the genus to produce Shiga toxins), *S. flexneri* 6, and *S. sonnei*; group responses to *S. flexneri* 1–5 also develop.

Immune responses of the host

Despite the major advances in relation to the pathogenesis of *Shigella* infection in recent years there is still a relative paucity of knowledge of the host protective immune responses. Despite the fact that the bacteria appear to be taken up by M cells, the nature and the role of the ensuing immune responses in controlling the infection or in preventing subsequent infections by the same organism are poorly understood. It is reasonable to assume that the immunoglobulin A (IgA) secretory immune response should be protective in shigellosis, although it has been difficult to convincingly demonstrate this in humans. The only well-established principal is that exposure to one serotype generally induces type-specific immunity, such that reinfection occurs only with different *Shigella* species or serotypes. This is presumed to be associated with immune responses to the oligosaccharide structure of the lipopolysaccharide (LPS), and is the basis for a resurgence in interest in LPS

determinants for immunization, even by the parenteral route. The fact that *Shigella* are taken up by M cells may be a mixed blessing in terms of the immune response. While the M cells deliver antigens to underlying lymphoid tissues (Peyer's patches) in the gut, pathogenic *Shigella* also replicate in M cells and may destroy the cells involved in antigen presentation. Invasion of neighboring cells by *Shigella* clearly occurs before an immune response can develop, thereby allowing systemic exposure to *Shigella* antigens and toxins early in the course of the disease.

In the past, parenteral immunization with killed *Shigella* bacterial vaccines or extracts have demonstrated that serum IgG has no protective effect. In contrast, experimental oral vaccination of humans with attenuated *Shigella* produces high degrees of type-specific protection, suggesting that mucosal immunity is key. Indeed, specific intestinal IgA levels increase during *Shigella* infection. In *S. sonnei*-challenged volunteers, IgA-secreting lymphocytes are present in the circulation 8–10 days after infection, probably *en route* to other mucosal sites, such as the mammary glands. Prior infection with *Shigella* results in specific IgA secretion in breast milk, thereby offering some protection to breastfed infants.

Antibody responses to the somatic antigens of *Shigella* develop early in infection and follow the typical course for antibodies to LPS. The initial IgM response peaks within weeks and wanes after 1–2 years. Assays have been developed using specific antigens for the detection of antibodies against O antigen. While such assays are of use in epidemiological studies they are of little value as diagnostic tests. *S. dysenteriae* type 1 LPS has unique O-repeat units shared only with *E. coli* expressing O-1 or O-120 antigens. Since neither *E. coli* O-1 nor O-120 is common among bacterial pathogens, testing for antibody to *S. dysenteriae* 1 LPS is quite specific. *S. flexneri* types 1a–5b contain a tetrasaccharide repeat and extensive cross-reaction occurs amongst them. Despite this, antibodies to *S. flexneri* are so unusual in developed countries that even such a nonspecific immune response can be a useful tool to detect current infection. In contrast, the LPS from *S. flexneri* type 6 is distinctive. The *S. sonnei* antigen is an unusual disaccharide, also allowing specific serodiagnosis.

Shiga toxin, a multimeric protein composed of a single enzymatically active A subunit and five B subunits responsible for toxin binding, is produced only by *S. dysenteriae* type 1 strains and is considered to be an important virulence factor in the pathogenesis of the hemolytic-uremic syndrome, a devastating complication of infection. IgM antibody to Shiga

toxin has been documented both in field and experimental settings. The relative lack of an IgG response is consistent with the observation that toxin binds to CD77⁺ IgG- and IgA-producing B lymphocytes, and not T lymphocytes, and inhibits immunoglobulin synthesis in these cells. Another endogenous B lymphocyte surface protein, CD19, is reported to have sequence homology with Shiga toxin and the cocapping of CD19 and CD77 that occurs in the presence of CD19-specific antibodies is prevented by the prior binding of Shiga toxin B subunit to CD77. The effect of this would be to inhibit B cell activation. There is also some *in vitro* evidence to suggest that the Shiga toxin B subunit induces apoptotic changes in the high CD77-expressing Burkitt lymphoma cells, which could also account for the lack of an IgG and IgA immune response to the toxins. In animal models, however, it is possible to raise serum IgG to Shiga toxin, and such animals are protected against *in vivo* challenge with toxin. The humoral response to LPS or plasmid-encoded protein antigens have been principally implicated in the protection against *Shigella*. Recent work has, however, suggested that T cells become activated *in vivo* following infection with *Shigella*, and that there may indeed be a correlation between the degree of T cell activation and disease severity. This is supported by other recent studies suggesting that the T cell receptor V β repertoire may be skewed in *Shigella* infection toward certain V β types in CD4⁺ and CD8⁺ T cells. Such events would be compatible with an oligoclonal activation of certain T cell subsets, which would be related to the presence of either immunodominant peptides or superantigen-like molecules. Intestinal lymphocytes from Peyer's patches are able to kill *Shigella* when armed with IgA, but not with IgG. Peripheral blood lymphocytes are cytotoxic to *S. flexneri*-infected HeLa cells *in vitro*, especially when stimulated with interleukin 2 or interferon γ .

Local cytokine production may also be important in shigellosis, which is a reflection of the intense inflammatory response in the intestinal mucosa in this disease. Elevated cytokine levels have been detected in stool and plasma of infected patients, particularly interleukin 1 (IL-1), IL-6, tumor necrosis factor α (TNF α) and interferon γ (IFN γ) producing cells in those with severe inflammation. Thus both T_H1 and T_H2 response cytokines are modulated in shigellosis and there may be both a humoral and a cytotoxic defense mechanism involved which could be activated during and after infection. Systemic cytokines may also play a major role in the pathogenesis of the thrombotic microangiopathy which occurs during the hemolytic-uremic syndrome (HUS). Certain cytokines (IL-1 β and TNF α) are

known to increase expression of the Shiga toxin receptor on certain human endothelial cells. The importance of this is that endothelial cells are considered to be the major target of the toxin in HUS. Despite the role of Shiga toxin in HUS, high serum antitoxin titers do not protect against intestinal disease in monkeys challenged with live *S. dysenteriae*. However, antibodies to the toxins do protect animals following parenteral challenge with Shiga toxin.

Postinfectious reactive arthritis has been theorized to be caused by cross-reactivity between bacterial envelope proteins and class I HLA antigens. Reactive arthritis is particularly associated with infection due to *S. flexneri*, which express antigens similar to synovial membrane antigens. The fact that reactive arthritis also occurs following infection with several other enteric bacterial pathogens such as *Yersinia*, *Salmonella* and *Campylobacter* suggests that there may also be some nonspecific component of reactive arthritis pathogenesis associated with mucosal inflammation common to all.

Vaccines

In view of the clinical severity of shigellosis and the ever-changing status of antibiotic resistance there has been a significant effort to develop effective vaccines. The original *Shigella* vaccines were heat- or acetone-killed whole-cell preparations for parenteral administration, designed to induce circulating antibody. These failed to provide significant protection when administered either enterally or parenterally. Attention then focused on secretory immunoglobulin A and mucosal lymphocytes. A major role of secretory IgA bathing a mucosal surface is to prevent attachment of microorganisms to the mucosa, and secondarily to neutralize microbial products such as toxins. It is not certain that either mechanism is relevant to shigellosis, since secretory IgA collected from the gut of rabbits immunized with an invasive *E. coli*-*shigella* hybrid vaccine strain failed to inhibit the invasion of cultured mammalian cells by *S. flexneri* 2a. Current efforts have been focused on the construction of *S. flexneri* live attenuated strains. This has generally taken one of three routes: 1) *Shigella* strains attenuated by a chromosomal mutation, 2) *Shigella* strains attenuated by mutations in plasmid virulence genes, or 3) hybrid *Shigella* or *E. coli* strains expressing cloned *Shigella* virulence determinants. Despite these various approaches none have been very successful as human vaccines either because of instability, failure of protection or reactogenicity. One principal emerging from the various vaccine studies however, is that the ideal vaccine will probably have to be invasive. The noninvasive

candidates generally elicit an inadequate immune sponse.

Several groups have continued to explore the use of killed vaccine preparations. Such preparations include the conjugation of O-specific side-chains of *Shigella* LPS with carrier proteins. The idea is that this would generate such a high serum IgG titer that enough IgG antibody would leak into the lumen to kill organisms at, and within, the mucosa, and that circulating antibody will be bactericidal for organisms gaining entrance to the circulation.

SJÖGREN'S SYNDROME

PJW Venables and **RN Maini**, The Mathilda and Terence Kennedy Institute of Rheumatology, Kennedy Building, London, UK

Clinical descriptions of patients with dry eyes and a dry mouth associated with swellings of lacrimal and salivary glands began to appear in the medical literature towards the end of the nineteenth century. In all probability a heterogeneous group of disorders such as sarcoidosis and lymphoma was included in these early descriptions, but in 1888 Mikulicz gave a histo-

pathological account of the glands from a patient with the characteristic histological picture of Sjögren's syndrome (SS). In 1933, Sjögren, a Swedish ophthalmologist, published a thesis on patients with dry eyes, dry mouth and a deforming arthritis, mostly without swollen lacrimal or salivary glands. Correlations between dry eyes, a dry mouth and

abundance of round cell infiltration in lacrimal and salivary tissue were noted, as was the association with rheumatoid arthritis in some patients.

Sjögren's syndrome has been defined by a workshop on diagnostic criteria held in Pisa in 1988 under theegis of the Commission of the European Community as a 'chronic inflammatory disorder of tear and salivary glands, reflecting general involvement of exocrine tissues, leading to dry eyes and a dry mouth and its sequelae. It may or may not be associated with systemic features and/or a defined autoimmune disease and connective tissue disease.' The same group subsequently developed diagnostic criteria (the Vitali criteria) which are currently considered to be the best evaluated. They are based on a short questionnaire of 1) ocular symptoms and 2) oral symptoms. Other essential criteria are 3) ocular signs (by Schirmer's test or Rose Bengal staining; 4) lymphocytic infiltrates on lip biopsy; 5) salivary gland involvement (scintigraphy, sialography or decreased salivary flow rate); and 6) demonstration of serum autoantibodies (rheumatoid factors, antinuclear antibodies and/or Ro or La antibodies).

Primary SS can exist with dry eyes and dry mouth as the sole disorder. However, many such patients exhibit extraglandular clinical features which do not in themselves constitute a distinct connective tissue disease and are included in the spectrum of primary SS. These include fatigue, fever, Raynaud's phenomenon, arthralgia, intermittent or chronic synovitis, myalgia, myositis, interstitial pneumonitis, purpuric vasculitis, renal tubular acidosis, chronic liver disease and peripheral neuropathy.

Bunim and Talal in 1963 first reported an increased incidence of lymphoma in SS, and subsequent follow-up at the National Institutes of Health, USA, of a cohort of patients over 8 years led to the conclusion that the risk of lymphoma in SS was about 6.4 cases per thousand patients per year, and represented a 40-fold higher incidence over a control population. Malignant lymphoma needs to be distinguished from pseudolymphoma, which also occurs in SS and is characterized by lymphoproliferation in exocrine tissues and peripheral lymphoid organs, giving rise to lymphadenopathy and splenomegaly but which clinically behaves as a benign disorder. Monoclonal immunoglobulins are detectable in many patients with SS, including those with pseudolymphoma and malignant lymphoma, emphasizing that hidden in the polyclonal B cell response are individual expanded clones which occasionally undergo oncogenic transformation.

The basis of classification into 'primary' and 'secondary' SS has received support from clinical, serological, and immunogenetic studies. For example, in

patients with primary SS, the occurrence of arthritis and immunoglobulin M (IgM) rheumatoid factor simulates diagnostic features of rheumatoid arthritis (RA), but such patients do not develop deforming arthritis with cartilage and bone erosions of the type seen in rheumatoid arthritis. Furthermore, in primary SS antibodies to Ro and La occur in about 50% of patients whereas these antibodies are rare in RA. In Caucasians with primary SS, the human leukocyte antigen (HLA) phenotype is usually HLA-B8, DR3, DRw52, whereas in Caucasian patients with secondary SS and RA, HLA phenotyping usually reveals either HLA-DR4 and/or DRw53.

Patients with primary SS and extraglandular features may, however, be more difficult to distinguish from secondary Sjögren's syndrome associated with systemic lupus erythematosus (SLE) since clinical, serological, and immunogenetic markers overlap considerably. Similarities include the presence of Raynaud's phenomenon, purpura, leukopenia, anti-La and anti-Ro antibodies, hyperglobulinemia, hypocomplementemia, and the presence of HLA-B8, DR3, DRw52 and C4 null genes. However, anti-double-stranded DNA in high titers and anti-Sm antibodies are markers of SLE and are not normally found in the serum of patients with primary Sjögren's syndrome. Features which distinguish SLE from primary SS include an immune complex-mediated diffuse glomerulonephritis, photosensitive rashes, alopecia, pleurisy, pericarditis, hemolytic anemia and thrombocytopenia.

Epidemiology and immunogenetics

Since only a handful of studies have been performed, only tentative conclusions can be drawn about the prevalence of the disorder. Disease prevalence had previously been estimated to be 0.2% of the population, with a female:male ratio of 9:1. However, in more recent studies in elderly populations, the prevalence of SS was estimated to be approximately 2% in the USA, 3.3% in Scotland and 2.7% in Sweden. Since it has been also estimated that 10–15% of the rheumatoid population suffer from SS, it may be predicted that an additional 0.1–0.4% of the population suffer from SS, assuming 1–3% prevalence of RA, giving an overall prevalence of approximately 3%. Thus Sjögren's syndrome may be one of the commonest autoimmune disorders in the general population.

Family studies of patients with SS carried out by Arnett and his associates have revealed a higher than expected prevalence of autoimmune diseases, including SS, RA, SLE and thyroid disease, in up to 30% of relatives, suggesting that genetic factors are

important in susceptibility to disease. Several studies have shown an association with HLA-DR3 and the linked genes B8, DQ2 and the C4 null gene. This haplotype is common in the healthy population (20–25%) and its components are in tight linkage disequilibrium so it has been difficult to identify the component which confers risk of SS. It is now known that the immune response genes are more strongly linked to autoantibody specificity than disease. In West European Caucasian patients with anti-Ro/La antibodies the frequency of DR3 is increased to 60–90% in both SS and SLE. In Black patients with anti-Ro/La antibodies the frequency of DR3 is increased to 80%. One of the first studies which attempted to identify the part of the haplotype associated with anti-Ro and La found that patients heterozygous for HLA-DQw1 and DQw2 had the highest anti-Ro antibody levels. These findings might explain studies of Greek and Israeli patients with primary SS in whom the only significant HLA association was with DR5 as opposed to DR3. This apparent discrepancy can be explained by the fact that the HLA-DQA1 allele is in linkage disequilibrium with both HLA-DR3 and HLA-DR5 haplotypes. Based on a structural analysis of the disease-related alleles Reveille proposed that glutamine at position 34 of the DQA1 chain and leucine at position 26 of the DQB1 chain are important in regulating anti-Ro and La responses. Scofield and Harley confirmed and extended these studies by sequence analysis and showed that the presence of both leucine and glutamine substitutions in a total of four alleles was significantly associated with anti-Ro antibodies.

The etiological role of viruses

In common with other autoimmune diseases, it is believed that polygenic genetic susceptibility factors interact with environmental factors to induce SS. Potential viral triggers include sialotropic and lymphotropic viruses such as the herpesviruses, in particular Epstein-Barr virus (EBV), cytomegalovirus (CMV) and human herpesvirus type 6 (HHV-6). Evidence for involvement of any of these viruses has been conflicting, with some studies finding elevated titers of antibodies to all three viruses in patients with SS but others finding them normal. EBV has been detected in parotid and labial salivary glands by DNA hybridization techniques. Salivary epithelium can contain up to 50 copies of EBV DNA per cell in healthy people without inducing an immune response, suggesting that the gland is an important site of persistence. The extent of EBV infection load in salivary glands in SS is still controversial with conflicting reports. While these inconsistent data may

reflect the different sensitivities and specificity of the methods or a bias introduced by studies based on small numbers of patients, a role for EBV and the other herpesviruses in the induction of Sjögren's syndrome remains unsubstantiated.

Retroviruses are known to infect cells of the immune system and can cause abnormalities of immune regulation including suppression, destruction or stimulation of T cells, excess antibody production and lymphomas. A subgroup of patients with human immunodeficiency virus (HIV) infection develop diffuse infiltrative lymphocytosis (DILS) of salivary glands and other organs with predominantly CD8⁺ T cells. They may present with a clinical picture almost indistinguishable from primary SS. In addition there is a high frequency of extraglandular disease including lymphocytic interstitial pneumonitis, lymphocytic hepatitis, lymphocytic interstitial nephritis and lymphocytic aseptic meningitis. In spontaneously occurring SS retroviral A-type particles were identified in lymphoblastoid cells cocultured with homogenates of salivary glands from SS patients but there has not been any further information such as sequence data to characterize the virus. A number of studies have detected antibodies to HIV- or human T lymphotropic virus type I (HTLV-I)-related *gag* sequences but these appeared to be broadly cross-reactive rather than indicating the presence of a specific retrovirus.

Animal models provide further support for the role of retroviruses in SS. Mice with the murine acquired immune deficiency syndrome (MAIDS) caused by the murine leukemia virus develop lymphocytic infiltrates of their salivary glands and other organs. The HTLV-I *tax* transgenic mouse develops a sialadenitis characterized by focal proliferation of ductal epithelial cells within the major and minor salivary glands followed by lymphocytic infiltration. Recently, a possible role for HTLV-I *tax* has been suggested in human disease. Using polymerase chain reaction (PCR) and *in situ* hybridization techniques, Mariette and coworkers detected HTLV-I *tax* but not *gag*, *pol* or *env* genes in labial salivary gland sections from two of nine patients with SS and none of nine control subjects. A Japanese study has found very similar results. Using PCR they found expression of HTLV-I *tax* gene without *pol*, *gag* or *env* in four of 14 patients with SS. In this case confirmation of identity was provided by sequence data which showed 100% homology between the nucleotide sequences from the four SS patients and that of the HTLV-I pXIV gene derived from the MT-2 cell line. These studies have not been confirmed in a series of 49 British patients from our unit. Using a highly sensitive PCR-based assay for proviral DNA

in salivary gland biopsies, *tax* was not detected in any of the samples, except one from a patient who was known to be seropositive for HTLV-I.

Humoral and cellular immune reactions

In addition to a polyclonal hyperglobulinemic response during active phases of disease, primary SS is characterized by the presence of many autoantibodies. Typically, IgM, IgG and IgA rheumatoid factors (RF) are observed in blood. Antinuclear antibodies are detectable in most patients with primary SS, and speckled, homogeneous, and nucleolar patterns by immunofluorescence have all been observed in individual patients. Anti-Ro antibodies are more frequently detectable than anti-La antibodies, but the latter are more diagnostically specific for primary SS. Anti-La almost invariably coexists with anti-Ro but anti-Ro may exist on its own in primary SS. The frequency of detection is dependent on the technique used, with solid-phase binding assays being more sensitive than precipitation reactions. Purification of Ro and La antigen by biochemical techniques and the availability of recombinant cDNA-derived antigens has led to tests of greater specificity and diagnostic accuracy.

In SLE, the finding of anti-Ro antibodies in renal eluates of patients with nephritis, correlation with skin rashes, and the development of congenital heart block in infants born to mothers with anti-Ro, some of whom have primary SS, has been cited as evidence for pathogenicity of those autoantibodies. Similarly, anti-La antibodies have been found to be associated with heart block and are enriched in the saliva of patients, suggesting that these too may be pathogenic.

The occurrence of anti-La and anti-Ro has led to extensive work on the molecular identity of La and Ro antigens and much speculation on the mechanisms of induction of autoantibodies. La is a 48 kDa polypeptide with several potential autoepitopes and Ro antigen exists as two distinct polypeptides with molecular masses of 60 kDa and 52 kDa. La and the two Ro polypeptides are complexed together with cytoplasmic RNAs of unknown function though La can also exist in free form where it is thought to be involved in termination of RNA polymerase III transcription. Antibodies to all of these polypeptides and to multiple epitopes exist in individual patients, suggesting that these antigens, possibly in the form of the Ro/La/RNA ribonucleoprotein complex, are involved in driving the antibody response. In resting eukaryotic cells La is predominantly intranuclear in location, but following cellular activation or viral infection, La redistributes to the

nucleoli, cytoplasm and the cell membrane. Recent work has suggested that the transport of La to the membrane is an event in apoptosis when La, along with other nuclear matrix proteins is transported to the cell membrane in the form of cytoplasmic blebs. In virally infected cells these blebs also contain viral antigens which may direct the immune response towards La in susceptible individuals. Currently, there is no direct evidence for this mechanism, though the observation of surface expression goes some way towards explaining how the immune response can be directed towards what was previously thought to be an intranuclear antigen.

Cellular studies have been performed on peripheral blood mononuclear cells and on infiltrating cells in salivary tissues. In most patients, CD4⁺ memory T cells predominate in the tissue infiltrates and many T cells are activated, as judged by the expression of HLA class II antigens. However, the T cells express little if any IL-2R α chain (Tac antigen) which is another T cell activation marker. HLA class II antigens are increased on ductal and acinar tissue and this has raised the possibility that T cell-derived interferon γ (IFN γ) may be inducing these molecules. Some support for this has been the recent demonstration that T cell clones from salivary gland produce high levels of IFN γ . By immunohistochemistry the cytokine is detected on ductal and acinar tissue suggesting it is bound to its receptors. These findings support the current view that interactions between the activated epithelial cell and T cells in the gland are central to the pathogenesis of SS. They are also consistent with the hypothesis that the T cells are responding to viral and/or autoantigens presented by the glandular epithelial cells.

Treatment

Treatment of dry eyes and a dry mouth is essentially symptomatic, with tear and saliva substitutes, and in the case of a dry mouth, an emphasis on dental and oral hygiene and early detection and treatment of infections. Some benefit has been claimed from the use of bromhexine and evening primrose oil, but this has not been validated by extensive clinical trials. More recently attention has turned to disease-modifying drugs and several studies have suggested benefit from treatment with hydroxychloroquine. Corticosteroids and immunosuppressive drugs are indicated in some patients with extraglandular disease.

SKIN, AUTOIMMUNE DISEASES

Jan D Bos, Department of Dermatology, Academisch Medisch Centrum, University of Amsterdam, Amsterdam, The Netherlands

Autoimmune diseases of the skin may be divided into several groups according to different criteria. For example, one may make a distinction between autoimmune diseases that are systemic in nature but have prominent skin involvement and those that are primarily cutaneous in nature and are only rarely associated with symptoms in other organ systems. An alternative way of distinguishing subsets of dermatological autoimmune diseases is by dividing them into groups that are certainly autoimmune, probably autoimmune, and possibly autoimmune (Table 1). In this entry, emphasis will be on auto-

immune diseases of the skin that have clinical pathology mainly limited to the integument and which are almost certainly autoimmune in nature. Thus, cutaneous lupus erythematosus, autoimmune bullous diseases and scleroderma will be described in some detail.

Cutaneous lupus erythematosus

The existence of skin diseases related to sun exposure is an ancient observation as exemplified by the description of a condition inflicted by sun and called

Table 1 Autoimmune diseases of the skin^a

Autoimmune	Probably autoimmune	Possibly autoimmune
Pemphigus	Psoriasis	Pyoderma gangrenosum
Pemphigoid	Lichen ruber planus	Parapsoriasis
Epidermolysis bullosa acquisita	Alopecia areata	(Sarcoidosis)
Linear bullous IgA disease	Actinic reticuloid	
Herpes gestationis	Morphea	
(Cutaneous lupus erythematosus)	(Scleroderma)	

^aAll except those in brackets are mainly limited to the skin.

'herpes esthiomenos' by Hippocrates. The distinction between different photodermatoses came in the nineteenth century, when Casenave was the first to use the term lupus erythemateux for a skin disease characterized by scarring, violaceous lesions especially in sun-exposed parts of the face. Kaposi (1872) recognized that this was not only a skin disease but that systemic manifestations may also occur (lupus erythematosus disseminatus et aggregatus). The recognition of circulating antinuclear factors in 1958 by Friou and the subsequent detection of immunoglobulin deposition at the dermo-epidermal junction (DEJ), both resulted in the concept of lupus erythematosus (LE) as a disease resulting from autoimmune processes.

At present, we are aware of the existence of a heterogeneous group of diseases belonging to the LE spectrum. These may be categorized as cutaneous LE, subacute LE, systemic LE, drug-induced LE, ANA-negative systemic LE, lupus-like syndrome in homozygous C2 and C4 deficiency, late onset systemic LE, Japanese LE and neonatal LE.

Specific and nonspecific forms of cutaneous LE

In cutaneous LE, a primary distinction is made between specific and nonspecific dermatological abnormalities. 'Specific' refers to the histopathology of the lesion. Characteristic microscopic signs of specific cutaneous LE include epidermal atrophy; hydropic degeneration of cells of the epidermal basal layer (apoptosis); follicular plugging; thickening of the basal membrane zone (BMZ); a mononuclear cellular infiltrate localized subepidermally around the postcapillary venules and around the (capillary venules of) skin appendages; and finally, dilatation of vascular capillaries. All these histopathological signs may occur in variable intensity. A secondary distinction in the specific LE group is made by recognizing acute, subacute and chronic forms and variants (Table 2). Rare clinical manifestations of chronic cutaneous LE include LE profundus (Kaposi-Irgang), hypertrophic discoid LE, lupus tumidus and mucosal LE. These variants will not be discussed further.

Nonspecific cutaneous LE then is a collection of dermatological abnormalities that do not show the specific histopathological signs described above. Included in this group are vascular abnormalities such as Raynaud's phenomenon; (necrotizing) vasculitis; livedo reticularis; erythromelalgia; perniones; thrombophlebitis; diffuse (frontal) alopecia; sclerodactylia; hyper- or hypopigmentation; calcinosis cutis; urticaria; Rheumatoid nodules; and finally, oral ulcers. Nonspecific dermatoses are especially common in systemic lupus erythematosus (SLE). Overlap syndromes such as mixed connective tissue disease (MCTD), pemphigus erythematosus and scleroderatomyositis, in which some of these abnormalities may also be encountered exemplify the complexity and wide spectrum of pathogenic events that form part of the SLE syndrome.

Autoantibodies and cutaneous LE

A basic finding in lupus erythematosus is the occurrence of a wide variety of circulating autoantibodies. It is unclear whether these autoantibodies are primarily or secondarily formed. Primary autoantibody formation may be the result of intrinsic dysregulation of antibody formation or, alternatively, may be triggered by exogenous antigens, such as from retroviruses. Secondary autoantibody formation may occur as a result of tissue damage with the subsequent release of previously hidden autoantigens. In NZB/NZW mice, that develop antibodies to DNA and glomerulonephritis, anti-DNA titers precede the development of renal disease. In patients, anti-DNA titers rise before exacerbation of systemic disease occurs. These findings indicate that autoantibody formation is not a secondary event.

The phenomenon of neonatal LE, in which autoantibodies are passively acquired from the mother, and in which cutaneous disease disappears when these autoantibodies fade away from the child's circulation, also emphasizes the primary role of autoantibodies in LE pathogenesis.

Table 2 Clinical forms of histopathologically specific cutaneous lupus erythematosus (LE)

<i>Clinical types</i>	<i>Acute LE</i>	<i>Subacute LE</i>	<i>Chronic LE</i>
Subtypes	Butterfly rash Disseminated erythema Bullous LE	Annular Psoriasiform Exanthematous	Localized (face) Cutaneous Disseminated LE profunda and others
Photosensitivity	High	Medium to high	Medium
SLE association	>95%	50%	<5%
Natural course	Days to weeks	Months	Years

Immunopathogenesis of cutaneous LE

The spectrum of cutaneous LE, including neonatal LE lesions, specific LE and variants, and nonspecific LE is large and difficult to describe in general immunopathological terms. Vasculitis resulting from immune complex deposition (leukocytoclastic) may be found in some of these conditions. The best studied form of cutaneous LE is the histopathologically specific type of lesion, where two main hypotheses have been formulated and tested. In one, emphasis is on immunoglobulin deposition at the DEJ, with complement activation and formation of the membrane attack complex (MAC) C5b-C9. In the other, emphasis is on cytotoxic T cells which, through their Fc receptors for immunoglobulins, may recognize autoantibodies bound to epidermal cells (antibody-dependent cellular cytotoxicity – ADCC).

The presence of immunoglobulins and complement at the DEJ is highly suggestive for the presence of immune complex (IC) formation at that site. Thus, a pathogenetic model of cutaneous LE based on initial IC deposition, complement activation and acute inflammation, followed by a chronic inflammatory state has been proposed. Such a model could be supported by the identification of C5-C9 in LE skin lesions. In a recent direct immunofluorescence study of cutaneous LE, granular MAC deposition at the DEJ was found in 29 of 38 biopsies (76%).

Complement activation and deposition of MAC thus are common events in cutaneous lesions of LE. In view of the existence of complement regulatory proteins, both in soluble form as well as inserted in cell membranes, it is interesting to look at studies performed in this area. At least clusterin and S protein have been found to be colocalized with MAC, indicating inhibition of complement activation as part of MAC formation. A major problem with the complement activation model of cutaneous LE pathogenesis is that acute inflammation, starting with influx of polymorphonuclear granulocytes, is not a feature in any stage of skin lesions. Also, human intact keratinocytes have been found to be resistant to complement-mediated lysis, probably because they express the membrane-inserted complementary regulatory proteins (CRPs) decay-accelerating factor (DAF), membrane cofactor protein (MCP) and CD59.

The ADCC hypothesis has been worked out by Norris and coworkers. It is based on the lesional presence of immunoglobulins and effector cells, mainly of the T cell type. These lymphocytes may act in ADCC reactions. The damage to epidermal cells with keratinocyte necrosis might follow influx of CD8⁺ cytotoxic T cells which can adhere to increased

numbers of adhesion molecules (ICAM-1) expressed on keratinocytes as a result of stimulation by interferon γ secreted by cutaneous activated CD4⁺ T_H1 cells. The intraepidermal cytotoxic T cells would exert their effect through production of perforins or tumor necrosis factor α .

The ADCC hypothesis is especially interesting in view of the photosensitivity in LE. In general, the action spectrum of photosensitivity is in the ultraviolet B (UVB) (280–320 nm) range, but UVA (320–400 nm) may also lead to flares, and testing has shown sensitivity to UVA, UVB as well as to visible light in most patients. After UV exposure, certain autoantigens are expressed on keratinocyte cell membranes, including Ro/SSA and nRNP. These autoantigens then become available for binding by their specific antibodies in the extracellular fluid. Subsequently Fc receptors on effector lymphocytes recognize these keratinocyte-bound immune complexes, with subsequent lysis of these cells. It may be that both membrane attack formation and cytotoxicity may occur due to UV induction of nuclear antigen expression on basal keratinocyte membranes and subsequent binding of interstitial antibodies directed against (some of) these nuclear antigens (Figure 1).

Immunotherapy of cutaneous LE

Therapy in specific cutaneous LE starts with general measures such as avoidance of sun irradiation and the use of sunscreens that filter out UV. Immunosuppressive therapy consists of the administration of strong topical steroids, preferably in intermittent schemes. If unsuccessful, systemic agents such as chloroquine, hydroxychloroquine, prednisone, acitretin, diaminodiphenylsulfon (DDS, dapsone), gold

Figure 1 In specific cutaneous lupus erythematosus, ultraviolet irradiation leads to expression of previously hidden nuclear antigens on keratinocyte cell membranes. These antigens become available for binding with antibodies to nuclear antigens that these patients have circulating as well as in interstitial fluid. Antigen-antibody complex formation may then lead to membrane attack complex (MAC) formation and cellular cytotoxicity (ADCC) leading to keratinocyte degeneration.

preparations, thalidomide, clofazamine, azathioprine, cyclophosphamide and methotrexate are of use. Flowcharts or clinical protocols for the use of these systemic agents have not been developed as yet.

Autoimmune bullous dermatoses

Since the recognition of circulating antibodies against skin components as well as antibody deposition in the skin of pemphigus and pemphigoid, a large number of immunological studies have been performed to identify the precise subtypes of these presumed autoantibodies, their role in pathogenesis, and the antigens to which they bind in the skin. It has become apparent that the most important group of autoimmune skin diseases is characterized by blister formation as a result of interference by autoantibodies with the normal intercellular adhesion of epidermal keratinocytes (intraepidermal bulla formation) or with the structures responsible for adhesion of epidermis to dermis (subepidermal bulla formation).

Clinical forms of autoimmune bullous dermatoses

The pemphigus group of autoimmune bullous dermatoses is characterized by loss of adhesion of epidermal keratinocytes (acantholysis). As a result, there is intraepidermal blister formation. This follows the binding of autoantibodies to important adhesion proteins, particularly the desmoglein subfamily of the cadherin supergene family. Included in the pemphigus group are pemphigus vulgaris (PV), pemphigus vegetans (PVe), pemphigus foliaceus (PF), pemphigus erythematosus (PE) and the relatively new variants paraneoplastic pemphigus and IgA pemphigus. The pemphigoid group of autoimmune bullous dermatoses have autoantibodies against various components of the epidermal-dermal junction complex, mainly localized around the BMZ. Included in this group are bullous pemphigoid, cicatricial pemphigoid, herpes (or pemphigus) gestationes, linear IgA bullous disease (including chronic bullous disease of childhood), and acquired epidermolysis bullosa acquisita. Bullous pemphigoid is the most common of the immunobullous disorders, mainly affecting the elderly.

Detection of autoantibodies in autoimmune bullous dermatoses

Autoantibody detection generally follows advances in immunological methods. The standard approach is by direct immunofluorescence (DIF) techniques using lesional, perilesional, and/or normal uninvolved skin and detecting antibody subclasses and

complement cascade components using labeled anti-human antibodies. With this method, a fisherman's net type of fluorescence is observed in the pemphigus group, highlighting binding of autoantibodies to components of the intercellular adhesive structures of the epidermis. In the pemphigoid group, DIF reveals fluorescence at the BMZ, mostly in a linear fashion. Indirect immunofluorescence (IIF) is used to detect circulating or blister fluid-derived autoantibodies, using normal human skin, cavia lip, or monkey oesophagus as substrate. Titers of antibodies correlate with disease activity in the pemphigus group but not in the pemphigoid group. IIF can be useful in the pemphigoid group to detect the precise level of binding in the BMZ. Immunoelectron microscopic techniques have been used to further define the precise location of autoantibody binding, while immunoblotting and immunoprecipitating techniques are available in specialized centers to determine the pattern of antigens to which autoantibodies are directed in a given patient.

Pathogenesis of autoimmune bullous dermatoses

The pathogenesis of immunobullous diseases as far as their induction is concerned remains unknown. Immunogenetic associations (HLA), drug exposure and infections have been indicated to play various roles alone or in combination. Once the disease is induced, cellular and humoral mechanisms play different roles in different entities.

Eosinophilic granulocytes and mast cells are thought to be important in bullous pemphigoid. Proteolytic enzymes derived from eosinophils, such as metalloproteases (gelatinase), may be involved in destruction of components of the BMZ. T cells have been implicated in the chronic stages of bullous pemphigoid and have been linked to the scarring in cicatricial pemphigoid (especially of the conjunctivae). Neutrophilic granulocytes and T cells have been implicated in the pathogenesis of dermatitis herpetiformis and in linear bullous IgA disease. Acquired epidermolysis bullosa seems to have a spectrum in which neutrophils play some role in certain subtypes but none in others. Finally, in the pemphigus group, evidence for a role of cellular mechanisms is generally lacking.

Humoral factors, particularly autoantibodies, are of course essential in the pathogenesis of autoimmune bullous disorders. As described above, they can be found bound to the tissue and/or in the circulation in all entities. The precise role of autoantibodies in dysadhesion is best studied in the pemphigus group. Various experimental models have clearly shown that pemphigus sera can induce acantholysis, and complement activation is not necessary to obtain

that effect. Another indication for the primary role of autoantibodies in disease formation is the correlation between titers of autoantibodies and disease activity. In pemphigoid, it has been more difficult to precisely establish the dysadhesive effects of autoantibodies, due to differences in the species-specific epitopes involved. Recent studies have, however, indicated a role for pemphigoid autoantibodies in the immunopathogenesis of blister formation.

Immunotherapy of autoimmune bullous dermatoses

Pemphigus and pemphigoid are primarily treated with high doses of oral prednisone, up to 200 mg per day. In limited cases, topical steroids may be given a try. In pemphigoid, a combination of tetracyclines and niacinamide has been shown to have good results and this combination might be given a try before deciding to give systemic steroids. Azathioprine is given as a corticosteroid-sparing drug in prednisone-treated patients. Other systemic drugs used are cyclophosphamide and cyclosporine. The IgA-mediated diseases dermatitis herpetiformis and linear IgA disease, the rare bullous variant of SLE and IgA pemphigus respond to treatment with dapsone or the sulfonamides sulfapyridine and sulfamethoxypyridazine.

Scleroderma

Scleroderma is a chronic disease with variants limited to the skin only and systemic forms. Systemic scleroderma is discussed elsewhere in this volume. From a dermatological point of view, subvariants of systemic scleroderma include progressive systemic sclerosis, CREST-syndrome, and mixed connective tissue disease (MCTD). Cutaneous variants of this disease are also known as localized scleroderma, but generally called morphea.

Morphea

Essentially, in cutaneous manifestations of scleroderma, there is an increase in the connective (collagen) compartment of the dermis. These may be

secondary to vascular abnormalities that precede this fibrotic process. Recent findings have implicated decreased expression of complement regulatory proteins (CRPs) on endothelial cells in involved skin of systemic as well as localized scleroderma. As a result, naturally formed immune complexes as well as spontaneous C3b formation led to incipient vascular damage, because protective CRPs are diminished.

Classical morphea is characterized by the gradual appearance of indurated, often hyperpigmented patches with an erythematous border. Initially, when there is active progression of the disease, these so-called lilac rings contain superficial dermal mononuclear infiltrates. Later, the inflammatory component disappears and the end-result of dermal fibrosis is left. Spontaneous resolution may occur, both in limited and cutaneously disseminated cases of morphea. Clinical variants of morphea include linear morphea and morphea or scleroderma '*en coup de sabre*'. Treatment of morphea is generally not possible, spontaneous resolution has to be awaited.

SKIN, CONTRIBUTION TO IMMUNITY

Martien L Kapsenberg and **Jan D Bos**, Laboratory of Cell Biology and Histology, University of Amsterdam, Amsterdam, The Netherlands

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The skin is the largest organ of the human body. Amongst other functions, it serves as a general defense system. Normal skin contains two functionally and anatomically different layers: the epidermis, which forms a physical barrier and primarily contains keratinocytes, and the dermis, which consists of connective tissue and contributes to the flexibility of the skin. During evolution the immune system has evolved as a complementary line of defense that efficiently copes not only with exogenous organisms that have crossed the corneal layer of the epidermis but also with endogenous hazardous elements such as newly formed malignant cells. Malignant cells are generated, with a high incidence in skin, presumably due to ultraviolet (UV) light exposure.

Various cell types are responsible for the immune reactivity in skin. They are involved in the homing of immune cells (endothelial cells, keratinocytes), in natural immunity (macrophages, neutrophils, natural killer cells) or in acquired immunity (antigen-presenting cells, T lymphocytes, mast cells). This complexity of cells, their products and their interactions in skin has been denominated the 'skin immune system'.

Skin immune system

In the epidermis, keratinocytes have an important role in nonspecific immune defense through the production of various soluble mediators. An important epidermal cell of the specific skin immune defense is the Langerhans cell. These cells form an almost closed network of dendrites within the prickle keratinocyte layer and function as the sentinels of the antigen-specific skin immune response. They trap antigen, transport it to the skin-draining lymphoid organs where they recruit antigen-specific T cells. Langerhans cells belong to the group of bone marrow-derived dendritic cells, and function purely to trap and present antigen to T lymphocytes. Antigen-trapping by Langerhans cells is facilitated by a high capacity of fluid phase and receptor-mediated endocytosis, the latter via various types of mannose receptors and Fc receptors. Furthermore, Langerhans cells constitutively express several molecules functional in antigen presentation, such as class II major histocompatibility complex (MHC) molecules, costimulatory molecules B7.1, B7.2 and interleukin 15 (IL-15), and

the adhesion molecules lymphocyte functional antigen 3 (LFA-3) and the intercellular adhesion molecule 1 (ICAM-1). Langerhans cells differ from other dendritic cells in that they contain structures in the cytoplasm referred to as Birbeck granules; these are rod- or racket-shaped membrane structures of unknown function.

Another remarkable feature of Langerhans cells is the high expression of CD1a. CD1a has a structural similarity with MHC molecules and is able to present certain bacterial lipids and glycolipids, as well as peptide antigens, to T cells. In normal human skin there is a slow circulation of Langerhans cells: they enter the epidermis as precursor cells, mature and subsequently emigrate from the skin after between a few days up to several weeks following their initial entry. In this way the specific immune system is continuously made aware of the antigenic microenvironment of the skin.

Human epidermis contains occasional T cells, mainly of the CD8⁺ type. In contrast to mouse epidermis, human epidermis contains low numbers of $\gamma\delta$ T cell receptor-bearing cells, that do not exceed their relative frequency in peripheral blood (5–10%). The papillary dermis, close to the epidermis, contains a capillary network and harbors various bone marrow-derived cell types involved as effector cells in natural and acquired immune reactivity of the skin. The human papillary dermis in normal skin contains modest numbers of extravascular neutrophils and eosinophils and relatively dense populations of macrophages and mast cells. A recently recognized aspect of potentially reactive connective dermal tissue is the occurrence of perivascularly located T cells. These T cells contact antigen-presenting cells scattered around the capillary vessels. A substantial proportion of these are CD4⁺ T cells of the memory phenotype with an $\alpha\beta$ T cell receptor and expressing the cutaneous lymphocyte-associated antigen (CLA), a molecule which directs homing into the skin.

Skin immune response

As yet, there is no direct evidence to consider skin itself as an independently operating immune organ. The inability to mount a separate local primary antigen-specific T cell response, and the virtual absence of B cells, B cell follicles and germinal center formation distinguish skin from connective tissues that

contain well-organized areas of lymphoid tissue, such as mucosal-associated lymphoid tissue (MALT). Clearly the elicitation of an immune response in skin, leading to immunity, sensitization or induction of tolerance, requires the participation of skin-draining lymph nodes. This consideration prompted Streilein to introduce the concept of a skin-associated lymphoid tissue (SALT), comprising the combined activity of constituents of skin and the draining lymphoid organs.

Skin provides an immunization site giving rise to generalized T and B cell priming, as mounted in the skin-draining lymphoid organs. Skin also participates in the efferent phases of both systems and local immune reactivities, providing a reliable reflection of the sensitivity status, evident from patch, scratch or prick tests. However, the occurrence of skin-specific diseases that cannot be explained by the local presence of antigen may provide arguments in favor of an additional skin-specific immune response. For instance, the occurrence of cutaneous T lymphomas may imply that subsets of T lymphocytes do exist that preferentially migrate into and home in skin, probably through the expression of CLAs.

The role of the skin immune response in the maintenance of physiological homeostasis is evident, especially in relation to infectious diseases and immunosurveillance. In addition, the skin immune system is involved in the pathogenesis of a large variety of inflammatory, autoimmune as well as allergic dermatoses.

Mechanisms of the skin immune response

A first line of skin immune defense follows from the induction of the expression of a large series of soluble and membrane-bound molecules by epidermal as well as dermal skin cells. These factors contribute to vasodilatation and the attraction, homing and activation of immune cells. A typical example of this nonspecific immune reaction is irritation reaction induced by small chemicals acting as haptens. Much information on the mechanisms in the antigen-specific skin immune response is obtained from animal model experiments with contact allergens that are able to bind protein, thus providing carrier (T cell) epitopes for the haptenic allergen. The contact allergic response is considered to be a classical example of delayed-type hypersensitivity.

Epicutaneous application of contact allergens is rapidly followed by penetration into the epidermis and trapping by Langerhans cells. Driven by the concerted action of IL-1 β and tumor necrosis factor α (TNF α), these antigen-loaded Langerhans cells leave

the epidermis at a relatively high rate and can be detected at high frequencies in draining lymph 6–24 h after allergen exposure. These Langerhans cells settle in the paracortical T cell areas of the draining lymph nodes, where they mature into interdigitating cells, which show a considerably higher expression of molecules involved in antigen presentation, such as MHC, adhesion and costimulatory molecules. Lymph node interdigitating cells, derived after 24 h of epicutaneous antigen exposure, are very efficient presenters of antigen to naive antigen-specific T cells *in vitro*, indicating their potential to induce selective expansion of allergen-specific T cells in lymph nodes *in vivo*. The important role of T cells in contact allergy is demonstrated by the fact that naive animals can be sensitized by adoptive transfer of T cells from syngeneic sensitized animals.

There is also evidence that bypassing Langerhans cells results in tolerance. Application of antigen to stripped epidermal skin sites or to areas with a low density of Langerhans cells (mouse tail) does not lead to sensitization but results in tolerance induction. Macrophage-like cells or dermal dendritic cells may be important in this tolerance induction. UV exposure of skin prior to sensitization may also induce tolerance, following from an UV-induced alteration of the Langerhans cell function.

The elicitation phase of the contact allergic response is less well understood. Probably, allergen is taken up by local antigen-presenting cells, such as epidermal or dermal dendritic cells, which activate allergen-specific T cells that have settled in the skin after sensitization. Upon activation these cells produce mediators, allowing the further entry of circulating contact allergen-specific T cells. Various chronic inflammatory skin diseases are associated with infiltrates of CD4⁺ T cells. Whereas allergen-specific CD4⁺ T cells have been identified in contact allergy and constitutional eczema, the antigen-specificity of the CD4⁺ T cells in diseases such as psoriasis and pityriasis rosea are unknown.

SOMATIC MUTATION

Nancy S Green, Departments of Pediatrics and Cell Biology, Albert Einstein College of Medicine, Bronx, New York, USA

Anne Davidson, Departments of Medicine and Microbiology and Immunology, Albert Einstein College of Medicine, Bronx, New York, USA

Immunoglobulin heavy and light chains are encoded by a series of gene segments that undergo rearrangement and joining early in B cell ontogeny. The multiplicity of variable (V) region segments, the randomness of their recombination and the imprecision of their joining account for the diversity of the pre-immune immunoglobulin (Ig) repertoire. B cell exposure to antigen and specific B–T cell interactions result in the induction of V region somatic mutation. Somatic mutation is the predominant mechanism for generating postrecombination diversity of the humoral immune response and results in the *in vivo* evolution of high-affinity antibodies that provide protective immunity. Recent experimental data are yielding important insights into the site, mechanism and regulation of the somatic mutation process.

Ig gene mutation rates are estimated to be 10^{-4} – 10^{-3} per base pair per cell generation, approximately 10^6 times higher than in the rest of the mammalian genome. This rate appears to allow optimal B cell clonal diversity without introducing excessive numbers of stop codons. The analysis of Ig gene sequences from many hybridomas demonstrates that mutations are restricted to the V region and one kilobase of its flanking sequences. One hallmark of Ig hypermutation is that the constant region rarely undergoes mutation.

The histologic locale of Ig hypermutation is the germinal center of secondary lymphoid organs. Analysis of microdissected or fluorescence-activated cell sorter (FACS)-sorted murine and human germinal center B cells has enabled investigators to sequence V region genes from limited cell populations in order to define the timing and site of the mutation event. Ig mutations are first seen in germinal center B cells by day 7 of a primary immune response and continue to accumulate in a step-wise fashion to day 18. Hypermutating centroblasts in

germinal center dark zones exit into the light zones, where they encounter both antigen, presented by follicular dendritic cells, and antigen-specific helper T cells. Antigen-responsive B cells probably undergo repeated rounds of germinal center hypermutation and selection. Germinal center B cells that are not selected undergo apoptotic death. Memory B cells also appear to be generated at this time and may not continue to mutate following further antigen exposure. Although hypermutation is a process largely restricted to Ig genes, one study has reported a small number of mutations in the T cell receptor α chain of T cells derived from the identical histologic site as mutating B cells. This suggests that the hypermutation event is highly dependent on the local microenvironment.

Independent of selection, all V region bases may not be equally likely to mutate. Analysis of heavy and light chain genes of hapten-binding antibodies have led to the conclusion that the nucleotide motif AGY (where Y = pyrimidine) is an innate 'hot spot' for mutation. Analysis of the serine codons AGY or TCN in human V genes revealed that the hot spot AGY is much more prevalent in complementarity-determining regions (CDRs), whereas AGY and TCN are found in equal proportions in frameworks. These findings suggest that evolution has selected the more mutable AGY for positions within the Ig where mutation would be favorable for enhanced plasticity of the humoral response.

Ig hypermutation is primarily a T cell-dependent process. T-independent immune responses rarely include mutated antibodies, while T-dependent responses can generate V regions with up to 30 mutations. In patients with X-linked hyper-IgM syndrome who have deficient T–B cell signaling due to the absence of CD40 ligand, Ig genes exhibit fewer mutations. It must be noted, however, that in some

species Ig genes may mutate despite little or no T cell help.

Relatively little is known about the molecular basis of V region hypermutation. V region mutations are nearly always single base substitutions; insertions, deletions or gene conversion are rare in human and mouse V genes, although they can be a major mechanism for the generation of immunoglobulin diversity in other species. The mechanism may involve error-prone replication, transcription or repair, active mutagenesis or even reverse transcription. Most of the critical Ig sequences and all of the proteins involved in both the process and the regulation of hypermutation have yet to be determined. More information may soon become available now that *in vivo* and *in vitro* models for the study of somatic mutation are available. Recent studies have defined rearranged κ light chain transgenes that undergo hypermutation at frequencies similar to those of endogenous Ig genes. Requirements for the 3' κ enhancer and the intronic κ enhancer with its adjacent matrix attachment regions have been demonstrated for κ transgene hypermutation. Furthermore, mutations were found even when the Ig promoter was replaced by a human globin promoter. Non-Ig sequences replacing the V coding region in a κ transgene acted as substrates for hypermutation. These results suggest that V regions may mutate because of their Ig context rather than their innate sequence, and that Ig flanking sequences outside of the V region are responsible for the regulation of Ig hypermutation. The simultaneous mutation of both heavy and light chain genes, as well as the reported occurrence of mutations in Ig transgenes integrated into non-Ig sites suggest that *trans*-activating mechanisms are also operative. V region transcription and possibly transcription initiation are required for mutation to occur, even in nonproductive alleles.

Murine B cell lines can accumulate spontaneous point mutations in endogenous Ig alleles 100-fold less frequently than observed *in vivo*. Recently, B cell culture systems with hypermutating transfected Ig constructs, as well as *ex vivo* cultures of splenic B cells mutating an endogenous Ig gene, have been reported. These cell cultures may achieve *in vivo* mutation rates and do so by cumulative base substitutions. The process appears to require primed B cells and, for spleen cells, both surface Ig cross-linking and T cell-derived signals.

Dysregulated Ig hypermutation may contribute to the development of autoimmunity as pathogenic autoantibodies are often encoded by mutated sequences. Use of a bcl-2 expressing fusion partner that has apoptosis-sparing effects has recently allowed for the capture and characterization of autoantibodies that have arisen *in vivo* following immunization with a bacterial antigen. This work demonstrates that autoantibodies are often generated during an immune response and that B cells bearing such antibodies are normally tolerized or deleted.

SOUTHERN BLOTTING

Raymond Dalglish, Department of Genetics, University of Leicester, Leicester, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Southern blotting is the transfer of DNA from an electrophoresis gel on to a dimensionally stable membrane support resulting in an hybridizable 'image' of the DNA banding pattern. Typically, restriction enzyme-digested DNA is size-fractionated by agarose gel electrophoresis. The double-stranded DNA is then denatured *in situ* by soaking the gel in alkali and transferred by capillary action to the membrane (usually nylon or nitrocellulose). The now single-stranded DNA is fixed to the membrane and may act as a target for hybridization with a specific nucleic acid probe. The probe, which is also single-stranded, will form hybrids with target DNA sequences on the filter to which it is complementary and, following extensive washing of the filter to remove unbound probe, specific hybridization is detected by a method dependent on the means by which the probe was labeled.

Autoradiography is used for the detection of radiolabeled probes. The sizes of the detected DNA fragments may then be determined by reference to DNA size markers on the original electrophoresis gel. These sizes may be of use in determining restriction enzyme maps of genes, revealing variations known as restriction fragment length polymorphisms (RFLPs). Southern blotting may also reveal alterations in gene structure such as insertions, deletions and rearrangements arising from recombination events.

Historical background

The ability to hybridize DNA strands to one another derives from the complementary nature of DNA so elegantly demonstrated in Watson and Crick's model of the structure of DNA. The earliest applications, carried out in solution, concerned the renaturation (annealing) of DNA that had been made single stranded by denaturation, and demonstrated the complex nature of genomic DNA by defining components that renatured at different rates. Similar studies involving the formation of DNA/RNA hybrids demonstrated tissue- and cell-specific differences in RNA expression. Hybridization later evolved to become more the process which we recognize today, with the development of the concepts of unlabeled target sequences (usually a heterogeneous mixture of sequences) and a labeled probe capable of detecting specific sequences within the target. A further development was the immobilization of the

target sequences on an inert matrix – initially nitrocellulose powder, and later nitrocellulose membrane.

The major breakthrough in hybridization came with the demonstration by Southern in 1975 that DNA fragments separated by gel electrophoresis could be easily transferred to a sheet of nitrocellulose membrane. This allowed characterization of DNA sequences not only by their hybridization behavior but also by the simultaneous determination of their sizes. The basic concept of blotting was later adapted to many other situations where spatial identification of a specific target was required. Blotting of bacterial colonies or phage plaques allows identification of specific clones in gene libraries and specific RNAs or proteins may be identified by blotting procedures known as northern and western blotting respectively.

The DNA to be analyzed

Southern blotting can be applied to the detection of specific DNA fragments both in simple and complex analysis situations, as typified by individual gene clones and total genomic DNA. In the latter case, adequate amounts of genomic DNA may be readily isolated from peripheral blood but, where much larger amounts are required, for example to act as reference DNA samples, placentas provide an essentially limitless source. Generally, around 5–10 µg of DNA is required for each analysis and it is cleaved with restriction enzymes prior to gel electrophoresis.

Restriction enzyme digestion

The choice of restriction enzymes is dictated by a number of factors. Often, the choice will be guided by a knowledge of the restriction enzyme sites in and around the gene to be analyzed. Where no such prior knowledge exists, three further considerations must be made. First, the frequency with which a restriction enzyme cuts DNA is a function of the length of the cut-site recognition sequence; the longer the sequence, the less frequently the enzyme will cut. Secondly, in humans, this frequency is reduced if the recognition sequence contains a CpG dinucleotide which occurs less frequently than expected due to a secondary consequence of DNA methylation. Finally, some restriction enzymes are inhibited depending on whether or not the recognition sequence is methylated. Such methylation is often tissue-specific in nature. For most applications,

DNAs are cut with restriction enzymes producing fragments in the size range 0.5–15 kb.

Electrophoresis of DNA

The cut DNA is size-fractionated by gel electrophoresis and the choice of separation matrix is determined by the sizes of the DNA fragments. For most applications, agarose is the matrix of choice because of its ease of use. For fragments smaller than a few hundred base pairs, acrylamide has been used because of its greater resolving power but acrylamide gels pose practical problems at the blotting stage. In recent years, specialist agaroses have been developed with much improved resolution of small DNA fragments. Conventional agarose gel electrophoresis is incapable of resolving DNA fragments larger than ~15 kb and for such fragments it is often necessary to use field inversion gel electrophoresis (FIGE) or pulsed field gel electrophoresis (PFGE). The latter is capable in some instances of separating intact chromosomes.

Preparing the gel for blotting

Following electrophoresis, the gel is usually photographed to provide a permanent record. Next, it is soaked in dilute hydrochloric acid to partially depurinate the DNA. When the gel is later soaked in sodium hydroxide to denature the DNA, single-stranded nicks are introduced at depurinated sites in the DNA the effect of which is to fragment larger DNA segments which would otherwise blot with a much reduced efficiency. Such treatment is mandatory for the blotting of FIGE and PFGE gels.

The choice of membrane

As originally described by Southern, the blotting technique involved the transfer of DNA from the gel on to a sheet of nitrocellulose. This material has

many drawbacks, including fragility and the limited number of times that a blot can be rehybridized due to leaching of the target DNA from the membrane. Nowadays, nitrocellulose has almost been entirely replaced by neutral and positively charged membranes based on nylon. As well as alleviating the problems associated with nitrocellulose, they have an increased efficiency and capacity to bind DNA. This has resulted in being able to carry out Southern blot analyses with less target DNA than was previously possible.

The blotting procedure

Most people remain faithful to the basic transfer scheme originally devised by Southern. In essence, all that is required is that there be a membrane in contact with one surface of the gel and absorbent material (dry paper towels) to draw buffer (typically 20× or 10× SSC, standard saline citrate) and DNA toward the membrane. The process is aided if there is a reservoir of buffer so that blotting does not diminish as the gel becomes dehydrated. An exploded view of a typical Southern blot transfer is shown in Figure 1. The choice of the blotting buffer is somewhat dependent on the membrane being used, but 20× SSC is common for purely historical reasons as that was what was required to achieve binding of DNA to nitrocellulose. With the advent of nylon membranes, there has been considerable experimentation with the blotting buffer. Many advocate lower concentrations of salt and some methods even dispense with the neutralization step, blotting the gel in the alkaline denaturation solution.

A number of alternatives to the blotting apparatus depicted in Figure 1 have been devised. These include downward blotting with the membrane and absorbent material below the gel and a reservoir of buffer above. This is said to improve the efficiency of transfer by avoiding dehydration and compression of the gel. Where efficiency of transfer is of lesser

Figure 1 Schematic view of a typical Southern blot apparatus. (A) weight; (B, G) glass plates; (C) paper towels; (D) filter paper; (E) hybridization membrane; (F) gel; (H) filter paper wick; (I) buffer.

importance, it is possible to make two blots simultaneously from a single gel which is sandwiched either side by a membrane and absorbent material and the transfer is dependent entirely on the buffer in the gel. For each of these methods the use of paper towels is usually entirely adequate, though a number of manufacturers offer highly absorbent blotting pads which are said to improve the efficiency of blotting. The length of time required to blot most of the DNA from a gel on to the membrane is the subject of much discussion but, for most applications, 2 hours appears to be adequate.

Alternative techniques, including vacuum blotting and electrophoretic blotting have been devised but are only used rarely, the latter usually being necessary for the blotting of acrylamide gels. The final step of the blotting procedure is the permanent fixing of the DNA to the membrane. This is achieved with exposure to UV light for nylon membranes and by baking at 80°C for nitrocellulose.

Choice of probes

The most commonly used probes are cloned segments of genomic DNA or complementary DNA (cDNA). Both have advantages and disadvantages which stem from the complex organization of higher eukaryotic genes and genomes. In general, more satisfactory results are obtained with genomic DNA probes because they contain all the DNA sequences of a gene – both the introns and exons. Consequently, such probes correspond exactly in sequence with the target to which they are to be hybridized. However, care must be taken in the selection of genomic DNA probes to ensure that they do not contain dispersed repeat DNA sequences such as Alu which would cause them to hybridize to virtually all DNA fragments in a genomic DNA blot. Probes derived from cDNA are often judged subjectively poorer because the target sequences to which they are complementary are often dispersed over many DNA fragments resulting in relatively lengthy detection times. Paradoxically, cDNA probes, if full-length, do have the advantage of being ideal for the simultaneous detection of all genomic DNA fragments of an entire gene. Though infrequent, some cDNA clones harbor repetitive DNA sequences and so are unsuitable as hybridization probes.

The problem of probes which contain repetitive DNA sequences can be approached in two ways. The first is to subclone regions that are free of such sequences and the second is to prehybridize the blot with unlabeled repetitive DNA to block all repetitive target DNA sequences.

Synthetic oligonucleotides of defined sequence

may be used as probes as they can be designed to be allele-specific. However, they have major disadvantages in that hybridization and posthybridization washing conditions need to be critically controlled and the specific activity of probe that can be achieved is relatively low (see below).

Labeling of probes

The most common method for the labeling of probes uses random deoxynucleotide hexamer primers. The DNA to be labeled is made single stranded by heating, the primers are allowed to anneal and they direct the synthesis of complementary DNA using the Klenow fragment of DNA polymerase I. Labeling of the newly synthesized DNA is achieved by including labeled precursors of DNA synthesis in the reaction. The label can be radioactive or chemiluminescent, with the latter becoming more widely used in recent years.

Strand-specific probes are most easily generated by *in vitro* transcription of probe sequences cloned into vectors containing viral promoters upstream of the cloned probe. Such probes are labeled during transcription by the incorporation of labeled precursors.

End-labeling of probes with T4 polynucleotide kinase or terminal transferase is sometimes used but results in a low specific activity probe due to there being only one label per probe molecule. This method is usually reserved for the labeling of oligonucleotide probes.

Hybridization and stringency

A probe has the ability to hybridize to targets to which it is identical in sequence or targets which are not identical but which have considerable sequence similarity. The extent to which a probe will hybridize to targets to which it is not identical in sequence is determined by a parameter known as 'stringency'. Stringency is defined by a combination of ionic strength and temperature with high stringency being characterized by low ionic strength and high temperature. Hybridization is typically carried out at a temperature approximately 25°C below the expected melting temperature of the DNA duplex to be formed and at high ionic strength (65°C in 3 × SSC) because such low stringency conditions favor a rapid rate of hybridization. As an alternative to 3 × SSC, 0.5 M sodium phosphate, 7% SDS is commonly used. The length of hybridization is dependent on a number of factors but is typically between a few hours and overnight. During hybridization, both perfect and mismatched hybrids are formed between the probe and target, with stringency being achieved dur-

ing the posthybridization washing of the filter which is commonly carried out at 65°C but at much lower ionic strength (typically $0.1 \times \text{SSC}$ or $0.5 \times \text{SSC}$). Mismatched hybrids are relatively less stable than perfect matches and will be disrupted by the low ionic strength. If a series of blots are to be washed at different stringencies, it is much more convenient to vary the stringency with changes in the ionic strength than with temperature changes.

Although the rate of hybridization is determined primarily by the probe concentration, the ionic strength and the temperature, increases in the rate can be achieved by the addition of chemical accelerators to the hybridization solution. These include dextran sulfate and high molecular weight polyethylene glycol which are thought to work by increasing the effective probe concentration in the vicinity of the membrane. Proprietary rapid hybridization solutions are available from some manufacturers.

Many methods have been devised for the incubation of blots with probes. The main problems are evaporation of the hybridization solution and its containment, especially if the probe is radiolabeled. Solutions to the problem have included custom-made hybridization chambers and the use of disposable heat-sealed plastic bags. Currently, the favored method is incubation in glass hybridization bottles which are rotated around their long axis in an oven equipped with a rotisserie.

Probe detection

The method used to detect the regions to which the probe has hybridized to a membrane is dependent on the nature of the label used in generating the probe. Frequently, the label is radioactive (e.g. ^{32}P , ^{33}P or ^{35}S) and detection is by autoradiography using X-ray film. Detection of single-copy genomic DNA sequences usually requires the use of intensifying screens at low temperatures (-70°C). Exposure times will depend on many factors and is best determined empirically – it may range from a few minutes to several weeks. Chemiluminescent probes are also detected with X-ray film and, in general, detection times can be shorter than with radio-labeled probes.

A relatively recent advance in detection has been the introduction of the use of electronic imagers which are capable of detecting radioactivity and chemiluminescence as well as direct fluorescence. Their major advantages are increased sensitivity and linearity of response compared with X-ray film.

Re-use of blots

It is often desirable to re-use a blot when there are limited amounts of the target DNA available, which may be the case in clinical analyses. A probe may be easily stripped from a filter by a short wash in warm alkali; after a neutralization step the filter may then be hybridized with another probe. Southern blots on nylon membranes can be re-used many times.

Applications

Southern blotting has application in instances where the structure of a gene (cloned or uncloned) is to be investigated. It may be used to determine a restriction enzyme map of a gene or to investigate natural variation or mutational events in a gene such as insertions deletions or rearrangements resulting from recombination. If appropriate controls are included and the procedure is carried out with care, Southern blotting may be used in a quantitative fashion to investigate phenomena such as gene amplification or loss of heterozygosity. Dimorphism of restriction enzyme sites within the population which results in restriction fragment length polymorphisms (RFLPs) was first discovered by Southern blotting and this later led to the discovery of other forms of variation in genomes that have been crucial to the mapping of genes and to our understanding of mutational processes.

With regard to immunology, the principal application of Southern blotting remains the investigation of the clonal rearrangements of the immunoglobulin and T cell receptor genes involved in the immune response. This can be illustrated by considering B lymphocytes, each of which carry a productively rearranged immunoglobulin allele as well as an allele with the germline structure or one that has undergone a nonproductive rearrangement. Each rearrangement event will be specific to a single cell in the population of B cells and Southern blot analysis of total B cell DNA would reveal only the germline arrangement of immunoglobulin genes as any individual rearranged alleles would be represented negligibly. As a result, bands from rearranged alleles fall far below detection limits. The structure of rearranged genes only becomes apparent by Southern blotting where there has been clonal expansion of a single progenitor B cell such as occurs in lymphoproliferative disorders. In such instances, Southern blotting may be used to characterize the structure of the rearranged gene in the expanded clone.

Southern blotting versus PCR

In many applications the use of Southern blotting has now been superseded by polymerase chain reaction (PCR) amplification which has the advantages of greater speed and sensitivity. However, PCR remains dependent on the need for precise DNA sequence data to allow the design of primers, whereas Southern blotting may be performed in the absence of such data. Depending on the design of the PCR primers and the particular gene rearrangement being investigated, PCR may fail to produce any amplification product where Southern blotting would be likely to provide some information concerning the rearrangement. Where PCR really scores, in addition to its speed and sensitivity, is in its ability to amplify genes in an allele-specific manner. Faced with such advantages from PCR, Southern blotting risks becoming a lost art.

SPECIFICITY

Jiri Novotny and **Malcolm Davis**, Bristol-Myers Squibb Research Institute, Princeton, New Jersey, USA

The immune antibodies all have in common the property of specificity, that is, they react as a rule only with the antigens that were used for immunizing and with closely similar ones, for instance with proteins or blood cells of one species, or particular bacteria, and related varieties.

The specificity of antibodies, whose range of activity was found to extend far beyond the proteins and to include simple chemical substances, underlies the practical applications of serology and constitutes one of the two chief theoretical problems, the other being formation of antibodies. It is known, however, that the selectivity is not absolute when proteins or cells of related origin are tested with the immune serum; indeed, using chemically well defined compounds, overlapping reactions occur regularly, provided the substances are sufficiently similar in chemical constitution. The word *specificity* then signifies

that the reaction with one of the antigens, namely, that used for immunization, is stronger than with all the others.

Historical background

The above citation, from Karl Landsteiner's classical writings *Die Spezifität der serologischen Reaktionen* in 1933, summarizes experimental manifestations of specificity. The concept of specificity itself was first clearly formulated in 1906 by Paul Ehrlich who adapted Emil Fisher's earlier (1884) 'lock and key' theory of enzyme substrate interaction to immune reactions. Ehrlich stated that the affinity of an antigen for the corresponding specific antibody depended on complementarity of surface structure, analogous to that of a lock and its key. Many chemists devoted much effort to analyzing the equilibria

involved in neutralization of toxins, and in the precipitation of antigens, by antibodies. As early as 1907, Svante Arrhenius described antibody-antigen reactions in terms of simple chemical equilibria, akin to biomolecular chemical reactions.

Obermeyer and Pick in 1907 and Landsteiner and Lampl in 1917 observed that simple chemical compounds (haptens) – for example, nitrobenzene and azido groups, are capable of eliciting specific antibodies when attached to ‘carrier’ proteins. Introduction of organic chemistry into immunology broadened the research considerably and allowed relative specificities of a series of chemical derivatives to be compared. With the realization of biological importance of oligosaccharides (most importantly, the blood group glycoproteins, cf., for example, Michael Heidelberger’s work in 1935), sugar derivatives gained importance as haptens. O. T. Avery, F. Karush and E. A. Kabat carried out studies on anti-hapten antibody affinities, the role of multivalence, and the relative importance of oligosaccharide structure and length to specificity and cross-reactivity.

Peptides were used as immunogens to mimic protein antigenic epitopes in model studies aimed at the basis of antibody specificity; Crumpton and Wilkinson and Atassi were among the pioneers in this field. In 1966, Michael Sela introduced novel synthetic methods of peptide chemistry into immunochemistry, and investigated antigenicity of nonnatural D-amino acid polymers. Among his discoveries were that antibodies to peptides are often specific towards the particular spacial shape of the peptide (conformational epitopes) rather than its amino acid sequence, and that production of specific antibodies is under genetic control. Another popular hapten, 2,4-dinitrophenol, was introduced, and its antibody response thoroughly studied, by Herman Eisen in 1954. David Pressman and his colleagues assembled valuable data on stereoisomers in homologous series of organic compounds, such as arsonates and benzoyl amino acid derivatives.

In 1940, Linus Pauling proposed that antibodies are protein molecules whose polypeptide chains are able to fold around, and thereby adopt shapes complementary to, a variety of chemical structures. This hypothesis was put in doubt by experiments carried out by Christian Anfinsen and coworkers in the early 1960s. They showed that the amino acid sequence alone carries the complete information for protein three-dimensional structure. Edgar Haber and Whitney and Tanford demonstrated independently, in 1964 and 1965, that denatured antibody Fab fragments regain, when refolded, their original specificity. It thus seemed that the different antibody specificities have their origin in differences in amino

acid sequences of antibody molecules. In 1965, Hilschmann and Craig and Frank Putnam’s group were able to demonstrate sequence differences among different immunoglobulin light chains (Bence Jones proteins). Amino acid and gene sequence data that accumulated since proved beyond doubt that different amino acid sequences of immunoglobulin light and heavy chain variable regions give rise to different antibody specificities.

If elicited antibodies are polyclonal mixtures of molecules each carrying a different binding site, a question arises of whether the specificity observed in serological reactions is due to many partially overlapping but different specificities of the chemically distinct molecules. This now seems unlikely, as specificity profiles of single antibody molecules were shown not to be qualitatively different from those of polyclonal preparations.

In the last decades, atomic coordinates of several antigen-antibody complexes have become available from X-ray crystallography. These include Fab fragments complexed with small haptens (phosphorylcholine, fluorescein), medium-sized antigens (nonadecapeptide) as well as protein antigens (monoclonal Fab fragments in complex with avian lysozymes, antibody-anti-idiotypic antibody Fab complexes, Fab complexes with influenza neuraminidase and hemagglutinin, bacterial phosphocarrier protein HPr, staphylococcal nuclease). These achievements make it possible, in principle, to understand the physical basis of antibody specificity.

Essential theoretical concepts related to specificity

Specificity of protein-protein, protein-ligand, antibody-antigen, etc. interaction comes from a large difference between binding constants characterizing binding of specific and nonspecific ligands. Thermodynamically, the higher binding constants for specific ligands arise from stronger overall ‘forces’ (Gibbs free energy differences) between the antibody and the antigen.

Quantitatively, the notion of binding specificity derives from comparison of association constants, K_{AS} , characterizing the reaction

Molar concentrations of the three molecular species are measured at equilibrium, and the strength (specificity) of the complex is estimated from its relative concentration, i.e. the ratio $K_{AS} = [\text{complex}]/[\text{antibody}][\text{antigen}]$. Related expressions involve the dissociation constant, $K_{DS} = 1/K_{AS}$, affin-

ity (K_{DS} expressed in molar units) and $pK_A = \log K_{AS}$. The experimentally measured K_{DS} relates to the Gibbs free energy of complex formation, ΔG , as $\Delta G = RT \log K_{DS}$ (R , the gas constant, is the product of the Boltzmann constant, k , and the Avogadro constant, L : $R = 8.314 \text{ kJ mol}^{-1} \text{ K}^{-1}$; T is temperature in degrees kelvin). Changes in Gibbs free energy, a thermodynamic quantity, can in principle be obtained from atomic structures of all the molecules involved in the reaction, provided all the physical forces responsible for complex formation are accurately known. Traditionally, the Gibbs free energy is partitioned into two components, the enthalpy, H (the internal potential energy of the system), and the entropy, S (indicative of distribution of energy among all the different states available to the system): $\Delta G = \Delta H - T\Delta S$.

Physical origins of specificity

Biological specificity arises from a cumulation of weak noncovalent interactions between complementary molecular surfaces. According to Linus Pauling, David Pressman and others, the principal enthalpic components of Gibbs free energy of antigen antibody reactions are van der Waals interactions, hydrogen bonds and electrostatic interactions among charged protein atoms. Among the entropic effects, hydrophobic force is of utmost importance. Diminution of water-exposed nonpolar molecular surface (in, for example, antigen-antibody complex formation) releases surface-bound water molecules into solution, increasing solvent entropy as well as the free energy of the reaction. In the first approximation, the magnitude of hydrophobic force is directly proportional to the contact surface between the two molecules of the complex.

The noncovalent forces responsible for binding are short range: van der Waals forces, hydrophobic force and hydrogen bonds have vanishingly small values at distances greater than 2–4 Å. While the first two types of forces are isotropic (spherically symmetrical), hydrogen bonds are strictly directional and require orientation of the participating groups. Electrostatic forces act at a distance but the high dielectric constant of water limits their reach effectively. Thus, the trapping of charged atoms at a protein-protein interface distinctly increases their effective electrostatic field. A consequence of all this is that the two molecular surfaces, antigenic epitope and antibody paratope, will enter into a stable complex only if they have complementary molecular shapes over a large area.

Although quantitative aspects of the above biophysical components to binding are still debated,

current estimates may be summarized as follows. 1) Van der Waals or dispersion/repulsion (London) interactions probably constitute most of what is termed shape complementarity in binding, in that they would penalize intermolecular contacts that provide either overlap of atoms, or cavities, either directly or through induced strain. Well-packed contact regions at antigen-antibody interfaces, though, are probably not much more favorable than the antibody/solvent and antigen/solvent contacts experienced by the free component of the complex. Surface tension data from organic liquid/water systems shows that the work of adhesion between hydrocarbon and water interfaces is essentially the same as that between two hydrocarbon interfaces. Furthermore, dispersion forces are relatively small in magnitude, and their possible differences amount to even smaller magnitudes. 2) The hydrophobic effect is the major stabilization factor of complex formation contributing, according to various estimates, between 25 and 72 cal (6–17 J) of Gibbs free energy stabilization per 1 Å² of protein-protein contact area. 3) Electrostatics of binding involves both desolvation of surface charges and creation of new charge-charge (coulombic) interactions at the (low dielectric) protein-protein interface. Recent electrostatics calculations, e.g. the finite difference solutions of the Poisson equation of the electrostatic fields generated by the antibody and the antigen, showed the desolvation to be energetically so costly that the total electrostatic binding energy disfavors complex formation by a significant amount (e.g. ≈20 to 40 kcal in the free energy difference). 4) On complex formation, immobilization of a freely rotatable torsional degree of freedom (a side-chain exposed to solvent) carries a free energy penalty of about 0.6–0.7 kcal. If many degrees of conformational freedom are lost on complex formation, sizeable amounts of free energy need to be expended on immobilization of flexible surface groups. Hence an excessive conformational freedom of antigens and antibodies acts against the strength (and specificity) of binding. Indeed, the highest binding constants (in the picomolar range) have been observed in antibodies directed against small, rigid organic molecules such as fluorescein or digoxin, while antibodies against molecules endowed with many degrees of freedom (oligosaccharides, peptides) have binding constants which are significantly lower (typically in micromolar range).

Specificity, affinity and molecular structure

From the above discussion, a direct connection between antibody affinity and specificity emerges:

specificity is merely another manifestation of dramatic differences in antibody affinity towards the 'specific' and 'nonspecific' antigens. Surface shape and electric charge distribution of antibodies are the likely molecular determinants of specificity. Opposing electrostatic charges must approximately match each other across the protein-protein interface for the complex to be possible at all, given the large charge desolvation penalty. Although surface charge distribution (including hydrogen bond donor/acceptor pairs) can be said to be an important determinant of specificity, a substantial price, in kilocalories of Gibbs free energy difference, has to be paid for desolvation of (full and partial) atomic charges when the antigen and the antibody associate. The hydrophobic effect (i.e. nonpolar surface desolvation), and molecular surface complementarity consequential to it, then emerges as the major stabilizing force of the complex.

If antibody affinity and specificity are intimately related, it is relevant to ask whether the molecular mechanisms of specificity in low- and high-affinity antibodies are essentially the same, or whether they are significantly different. As immune response matures, the specificity spectrum of antibodies often changes from broad specificity and low affinity to narrow specificity and high affinity. Most of the detailed atomic structures of antibodies and antibody-antigen complexes available to us from X-ray crystallography are those of monoclonal antibodies selected for high affinity. Highlights of those structures are large complementary contact areas between antigen and antibody (Figure 1), attractive charge-charge interactions at the antigen-antibody interface (Figure 2) and numerous hydrogen bonds spanning the antibody-antigen interface.

In virtually all the known protein structures, binding sites have the shape of cavities or grooves. In antibodies, the antibody binding site is located at the generally concave interface between the light and heavy chain variable domains. In one case, a small hapten (phosphorylcholine) enters deeply into the interdomain pocket; in another case the principal residue of a protein antigen (glutamine 121 of the hen egg-white lysozyme) is buried in the interface, while the rest of antigen-antibody contact area is rather flat, if irregularly undulated. It is natural for the curvature of binding-site cavities to match that of the antigens: binding sites that accommodate small ligands have high curvatures and appear as pockets; those directed towards large protein antigens have a low curvature, being more akin to valleys and grooves than to deep crevices (Figure 3).

Why should the concave surface be favored as a specific combining site? Although no definitive

Figure 1 Surface complementarity between the antigen, hen egg-white lysozyme and the antibody HyHEL-5 binding site. In this cross-section through the antigen-antibody complex, 5 Å thick, centers of atoms are connected by sticks and atomic volumes are shown as Conolly dot surfaces. Atom color-coding on the color plate: oxygen, red; nitrogen, blue; sulfur, yellow; carbon in lysozyme, white; carbon in V_L domain, magenta; carbon in V_H domain, brown. The intermolecular interface, approximately traced by a line dividing the antigen atoms (lower part) from those of the antibody (upper part), consists of tightly packed regions, and occasional loosely packed regions, 'cavities'. The intermolecular cavities, for example the one delimited by lysozyme residue Arg 68 and the antibody residues L 91, H 33 and H 35 (blue arrow, on the top), are not any larger, however, than the occasional intramolecular cavities. Crystallographic coordinates by Sheriff *et al.* (1987). (See also color Plate 6A.)

answer is available at present, at least four good reasons can be cited. First, diffusion away from cavities is significantly slower than from flat surfaces, or through the solvent. Primitive 'binding' properties of simple concave organic molecules such as crown ethers or cavitands demonstrate this very clearly. Second, electrostatic fields are enhanced or focused in cavities, even though solvent quenches the field at other, flat or convex parts of protein surface. Third, hydrophobicity of a surface is a function of its curvature relative to the size and curvature of a water molecule, and concave surfaces are more hydrophobic than flat or convex surfaces. Fourth, a hydrodynamic drag that develops at concave sites as a ligand molecule approaches may give rise to a steering torque that forces the ligand into the pocket. The magnitude of this torque force has been as significant, perhaps even larger than, the electrostatic torque.

Induced fit and crossreactivity

Do antigens and/or antibodies change structure on binding ('induced fit hypothesis', first explicitly proposed for antibodies by Pauling in 1940) or is the binding essentially an association of two rigid bodies

Figure 2 Electrostatic fields at the surface of the HyHEL-5 antibody binding site. This monoclonal antibody is specific to lysozyme, a protein with an exceptionally high positive charge. Using the crystallographic coordinates of the HyHEL-5 V_H and V_L domains (Sheriff *et al.*, 1987), molecular surface envelope was generated by the program GRASP (A Nicholls, Columbia University, 1991) and was color-coded by the electrostatic field produced by all the formally charged residues in the molecule (cf. the color plate: red, negative potential; blue, positive potential; color intensity proportional to the strength of the field). At the center of the binding site there is a deep, electronegative cavity 'below' which is a protruding side-chain of the Arg residue L93, with a weaker, positive, electrostatic field. In the HyHEL-5-lysozyme complex, the central negatively charged cavity becomes occupied by the two positively charged lysozyme side-chains, Arg 45 and Arg 68. The positive field generated by the antibody residue Arg L93 gives rise to a dipole, close to the antibody surface, perhaps helping to preorient the antigen at its approach to the binding site. (See also color **Plate 6B**.)

(the 'lock and key paradigm' of Fischer)? The X-ray crystallographic structures in fact reveal both types of binding modes. Examples of lock and key complexes, currently much more numerous, include the McPC 603 antiphosphorylcholine myeloma, D1.3 antilysozyme and the NC41 and NC10 antineuraminidase monoclonal antibodies, and the 26-10 antidi-oxin antibody. The best examples of large induced-fits on complexation are the anti-peptide antibodies 17/9 and 50.1 where the whole H3 loop pivots as if on two anchor points. Given the relatively high cost of conformational entropy (≈ 0.6 kcal per aliphatic side-chain torsion or 0.4 kcal per backbone torsion, see above), it may well be that those antigen-antibody systems where tight binding is required evolved towards rigid (lock and key) binding.

May the induced fits be operational in cross-reactivity? The only structurally well-documented case of cross-reactivity among haptens is that of the high-affinity ($\approx$ nM) mouse monoclonal antiprogestosterone DB3 antibody, which binds four different progesterone-like steroids with comparable affinities. X-ray

crystallography of these cross-reacting antigen-antibody complexes showed no changes to the gross (i.e. backbone) structure of the binding site on engaging the various ligands. Instead, cross-reactivity was accompanied by two distinct modes of hapten orientation (i.e. the steroid β ring with two methyl groups) with respect to the Trp side chain H50, one of the major hapten-contacting residues (**Figure 4**). Incomplete binding surface complementarity between the haptens and the antibody, and limited side-chain rearrangement(s), seemed to be the key structural feature that facilitated cross-reactivity.

Cross-reactivity among macromolecules (proteins) presents more difficult issues, if only because the molecular sizes and surfaces involved are much larger than those of small haptens. The fact that a delimited patch of protein surface can support several overlapping and different epitopes has, by now, been well established. There are two cases now where cross-reactive epitopes could be studied in atomic detail: 1) a degenerate binding of the same antigenic motif in the influenza N9 neuraminidase by two different monoclonals, NC41 and NC10; and 2) the two different antigens, the hen and guinea fowl lysozymes, engaged by the same monoclonal antibody F9.13.7. Neither case disclosed any obvious chemical features, or similarities, between the different epitopes, or the different binding sites, that would predispose them for cross-reactive binding. In the N9 neuraminidase complexes, $\approx 80\%$ of the NC41 and NC10 epitopes overlapped and one might have expected about two-thirds to three-quarters of the 'energetic' (see below) neuraminidase residues to be identical, and to contribute comparable binding energies, in the two complexes. This was clearly not the case, however, as established both by experiment and by calculations. The two antibodies, NC41 and NC10, engaged different side-chains of the same neuraminidase surface to create stable complexes (cf. **Figure 5**). A question thus arises of whether an area of a protein surface constitutes a single antigenic epitope, or whether it is a multitude of different overlapping epitopes? The term 'epitope' being an operational one, the answer to this question may also be formulated operationally. Some 50–60% of protein surfaces is made of polar atoms, including those that are formally charged. The charged atoms mostly occur at prominent surface convexities so that, naturally protrusions and their polar atoms constitute the best anchor points for a firm attachment of the antibody-binding sites (see below). Depending on topography of the larger, adjacent surface area, however, and relative dispositions of the multitude of surrounding polar atoms (both capable of and, when in the complex, required to, make hydrogen bonds),

Figure 3 Comparison of antidigoxin and antilysozyme binding sites. In these 'elevation plots', points of the molecular surfaces, generated by the program GRASP, have been color-coded according to its distance normal to a three-dimensional envelope of the molecule. The envelope was defined, and constructed, as a smooth, curved plane connecting the 'highest' peaks of the molecular surface (M. Davis, manuscript in preparation). On the attached color plate, and reproduced here in black and white, the deepest protrusions on the surface of the molecule are shown in blue, the most elevated points of the surface are shown in red. The binding site of the 26-10 antibody directed against the hapten digoxin is a deep, narrow well (high 'global' curvature); the binding sites of the antilysozyme antibodies D1.3 (crystallographic coordinates by Bhat *et al.*, 1990), HyHEL-5 and HyHEL-10 (coordinates by Padlan *et al.*, 1989) are all larger and more shallow (low 'global' curvature). The D1.3 binding site contains a smaller, deep 'local' hole in its surface (complementary to the lysozyme residue Gln 121), the HyHEL-5 binding site contains a similar but shallower hole (complementary to Arg 68, cf. **Figure 1**). The HyHEL-10 elevation plot shows virtually no local depressions. (See also color **Plate 6C**.)

very many alternative solutions may exist for approximately complementary binding-site surfaces.

Functional (energetic) epitopes and cross-reactivity

The availability of X-ray crystallographic structures on the one hand and gene mutation techniques on the other makes it possible to probe into the role of individual amino acid residues in antibody specificity: a protein antigen can be mutated at a single amino acid position, three-dimensional structure of the mutant can be determined, and its affinity towards an antibody can be compared with that of the 'wild-type' antigen. Conversely, a single-residue mutation can be introduced into an antibody combining site and its effect on antigen binding can be measured. This mutational analysis of antigen-antibody interaction has been complemented with theoretical structural analysis, e.g. the rigorous free energy perturbation calculations or the semiquantitative, empirical estimates of Gibbs free energy changes accompanying antigen-antibody complex formation.

One of the major concepts emerging from the combination of the experimental and theoretical techniques has been that of an energetic (functional) epitope.

Immunochemists often observed that a small portion of an antigenic determinant was of crucial importance in defining its specificity. The term 'immuno-dominant' (Sela, 1969, quoting Heidelberger) has commonly been used to describe this phenomenon. Does 'immunodominance' have an identifiable molecular basis? The empirical Gibbs free energy calculations on antibody-antigen (and also enzyme-inhibitor) complexes consistently indicated that only a small number of amino acids, approximately 30% of the total contact surface area, contributed actively to binding energetics. In the antibodies, the bottom part of the antigen-binding cavity often dominated the energetics of binding, whereas in lysozyme, the energetically most important residues defined small (2.5–3 nm²) 'energetic', or 'functional', epitopes. Thus, a concept of protein antigenicity emerged that invoked the active, attractive contributions mediated by the energetic antigenic epitopes and the passive surface comp-

Figure 4 DB3 antibody binding site in complex with four different cross-reacting steroid haptens. The elevation plots shown here and on the attached color plate were prepared as described in the legend to **Figure 3**. Surface color-coding is from red (most elevated) to blue (the deepest). Crystallographic coordinates by Arevalo *et al* (1994). Upper left, DB3 with progesterone; upper right, DB3 with 3-aetiocholanolone (5- β -androstane-3,17-dione); lower left, DB3 with 5- α -pregnane-3- β -hemisuccinate; lower right, DB3 with 3-progesterone-11- α -OI-succinate. Haptens are shown in stick representations; carbons are color-coded white, oxygens red. It can be seen that the overall shape of the binding site does not change on engaging the cross-reacting ligands; rather, the steroids orient themselves differently with respect to the binding site cavity. At the periphery of the binding site, however, changes to the shape of the surface can be seen, due to surface side-chain rearrangements. (See also color **Plate 7**.)

Figure 5 The two energetic epitopes (NC41 and NC10) on the surface of the influenza N9 neuraminidase. The calculated 'energetic' epitopes (Tulip *et al*, 1994) were color-coded, on the color plate, from green (residues with free energy contributions stabilizing the complex), through white ('neutral' residues), to red (residues whose contributions to the free energy of binding destabilize the complex). Although the two epitopes overlap by about 80%, their binding free energy attribution is strikingly different. (See also color **Plate 8**.)

lementarity contributed by the surrounding contact area. The concept offered a resolution of an apparent paradox: on the one hand, a multitude of side-chain-side-chain interactions at the interface (≈ 16 side-chains in the antibody as well as in the antigen) and, on the other, the experimentally derived size of the binding site no larger than 4–6 amino acids. A number of experimental data consistent with the hypothesis of an energetic epitope have accumulated, including those obtained on antibodies to the human growth hormone, human placental lactogen, the λ repressor, hen egg-white lysozyme, N9 neuraminidase, cytochrome *c* and cyclosporine.

The concept of a 'functional (energetic)' epitope has also given us an additional perspective on cross-reactivity (cf, for example, the NC41 and NC10 neuraminidase epitopes, **Figure 5**) and antigenicity. Antigenic analysis of the human growth hormone, the most extensive study of this kind currently at hand, showed that the functional epitopes correlated best with the most protruding regions of the molecule. Both the experimental data and the computer-assisted analysis of frequency of side-chains on protein surfaces accessible to large spherical probes (antibody domains) showed prominence of long, formally charged or dipolar side chains, Arg, Lys, Glu,

Gln, Asp and Asn, in the functional epitopes. The conjecture that antigenicity is mostly determined by surface protrusion provided a natural link between the two extreme antigenicity theories ('distinct antigenic epitopes exist' versus 'the whole surface is antigenic') by introducing the concept of antigenic probability that varies along the surface.

SPLEEN

CE Grossi, National Institute for Cancer Research, University of Genoa, Genoa, Italy

PM Lydyard, Department of Immunology, University College London, London, UK

The human spleen is a highly vascular organ which receives blood from the splenic artery and drains into the portal venous system. It is a discriminatory filter which removes aged erythrocytes and platelets from the circulation through phagocytic cells (macrophages) in a specialized section of the splenic venous compartment, the venous sinuses of the red pulp. This is a system of highly anastomosing vascular channels separated by cellular cords consisting of macrophages, lymphocytes and plasma cells with additional cells derived from the circulation, i.e. red cells, granulocytes and platelets. Another major component of the splenic parenchyma is the white pulp, which consists of lymphoid sheaths organized

around branches of the splenic artery (periarteriolar lymphoid sheaths, PALS). As in other peripheral lymphoid tissues, the PALS are organized into T-dependent and B-dependent zones. The latter are occupied by secondary lymphoid follicles with germinal centers. The periphery of the PALS, at the boundaries between the white and the red pulp, is termed the marginal zone. This displays a unique vascular organization and is important to the function of the white pulp.

Besides providing a blood cell reservoir capable of releasing erythrocytes, granulocytes and platelets into the blood when needed, the spleen functions as the site for destruction of red cells and platelets

which are phagocytosed by macrophages. The lymphoid tissue of the white pulp provides the environment for specific humoral and cellular immune responses mediated by B and T cells, predominantly against antigens circulating in the bloodstream.

Structure of the spleen

The human spleen is surrounded by a capsule of dense connective tissue containing relatively little muscle and therefore incapable of the extensive contraction exhibited by the muscular capsule of the spleen in dogs and cats. A rich branching network of trabeculae from the internal capsular surface subdivides the organ into communicating compartments. The capsule is deeply indented in one part of the spleen to form the hilus where blood vessels, lymphatic vessels and nerves enter and exit. Arterial vessels branch into the trabeculae and from there enter the pulp or parenchyma of the organ. Veins also run in the trabeculae, entering from the pulp. Lymphatics are found in the capsule and trabeculae but not in the pulp.

The splenic pulp is supported by reticular connective tissue and is mostly red due to the presence of blood, hence red pulp. This is made up by thin-walled blood vessels, the splenic sinuses (or sinusoids), and thin plates of cells which lie between the sinuses, the splenic cords. Clusters of lymphocytes are grossly visible as gray-white zones surrounded by the red pulp. This is the white pulp. These lymphoid clusters are seen around arterial branches forming the PALS. The splenic pulp, at the junction between the white pulp and the red pulp forms the marginal zone (Figure 1).

At the hilus, the splenic artery branches into trabecular arteries which leave the trabeculae and enter the PALS, where they are termed central arteries. The central artery runs out into the red pulp and usually terminates in the cords ('open' circulation) or into the sinuses ('closed' circulation) of the red pulp. Other branches of the central artery reach the marginal zone where they open into a marginal sinus and a perimarginal cavernous sinus which drain into venous sinuses. Veins of the pulp enter the trabeculae as trabecular veins which are continuous with the splenic vein which lies outside the organ.

The white pulp of the spleen is lymphoid tissue consisting of lymphocytes, macrophages and other free cells lying in a reticular meshwork and surrounding arterial vessels to form the PALS (Figure 2). These are lymphoid aggregates of cylindrical form and contain secondary follicles with germinal centers and mantle zones, similar to those found in the

Figure 1 Organization of lymphoid tissue in the spleen. The white pulp is composed of the periarteriolar lymphatic sheaths (PALS) frequently containing germinal centers with mantle zones. The white pulp is surrounded by the marginal zone. (Marginal zones contain specialized antigen-presenting cells, macrophages and a special subset of B cells.) The red pulp contains venous sinuses separated by splenic cords. Blood enters the tissues via the trabecular artery and becomes the central artery which gives rise to many branches; some end in the white pulp, supplying the germinal centers and mantle zones, but most empty into or near the marginal zones. Some arterial branches run directly into the red pulp, mainly terminating in the cords. The venous sinuses drain blood into pulp veins and then trabecular veins. (Reproduced with permission from Roitt IM, Brostoff J and Male D (eds) (1998) *Immunology*, 5th edn. London: Mosby.)

lymph node cortex. The lymphoid follicles are also supplied with blood by branches of the central artery.

The marginal zone consists of a fine meshed spongework of reticular fibers. Its cells are arranged to form a structure similar to that of the cellular cords in the red pulp. A marginal sinus is located directly adjacent to lymphatic follicles. It consists of a series of flattened vascular spaces that lie between the white pulp and the marginal zone. A perimarginal cavernous sinus is situated outside the marginal zone or directly adjacent to the lymphoid follicles, in areas where the marginal sinus is absent.

The red pulp is a system of cellular cords lying between the venous sinuses. After distributing branches to the white pulp and marginal zone, the central artery branches into straight, slender vessels

Figure 2 Spleen section showing the periaarteriolar lymphoid sheath (PALS). This view shows the lymphoid tissue arranged around an arteriole. The T cells are found close to the central arteriole and the B cell area has a germinal center. In the 'unstimulated' state the B cell area consists of a primary follicle. The lymphoid tissue is separated from the red pulp by the marginal zone. This contains blood vessels and is the site of entry of bloodborne lymphocytes into the splenic lymphoid areas. H & E stain, $\times 125$. (Reproduced with permission from Roitt IM, Brostoff J and Male D (eds) (1998) *Immunology*, 5th edn. London: Mosby.)

called penicilli which may terminate as such or become finer arterial capillaries. These terminal arterial capillaries may be surrounded by a sheath of closely packed macrophages (sheathed capillaries). A few arterial capillaries may connect with the venous sinuses, but many of them open directly in the reticular meshwork of the cellular cords. The venous sinuses are long vascular channels with a unique endothelium and basement membrane. Endothelial cells are elongated and lie parallel to the long axis of the vessel. They lie side by side with slit-like spaces separating them. The endothelium is perforated by large, regularly arranged, polygonal fenestrae. This arrangement is traditionally likened to a barrel in which the wooden staves correspond to the endothelium and the hoops to the reticular fibers that support the endothelial wall without a basement membrane. Sinuses are tributaries of the veins of the pulp, which in turn drain into the trabecular veins (Figure 1).

The cellular cords are supported by a reticular meshwork. The interstices of this cordal meshwork are typically crowded with erythrocytes, macrophages, platelets, plasma cells and granulocytes.

Macrophages, which differentiate from circulating monocytes, are often the predominant cells.

Functional anatomy of the spleen

Many arterial capillaries open freely into the cellular cords of the red pulp, consequently, plasma is separated from cells in the splenic circulation. Concentration of blood cells in the spleen enhances its storage function. Approximately one-third of the platelets of the body are normally stored in the spleen, in ready reserve. The spleen monitors circulating erythrocytes and platelets, permitting intact cells a through passage but detaining and destroying aged or damaged cells. This role is carried out in the sinuses and cords of the red pulp and is a function of macrophages. Since these cells express IgG Fc receptors, red cells or platelets coated with IgG (auto)antibodies are avidly phagocytosed in the spleen. Aged erythrocytes appear to lose sialic acid on their surface, exposing mannose and galactose residues which may be recognized in the spleen and cause such erythrocytes to be phagocytosed.

Another distinctive function of the spleen is that of clearing particulate materials from the circulation. Particles are phagocytosed in the marginal zone, cords or sheathed capillaries.

The spleen also functions as a peripheral lymphoid tissue where effector T or B cells differentiate in response to antigens. Recirculating T and B cells take a distinctive pathway through the spleen. They enter the white pulp from the marginal zone, where they are selectively released from the circulation. Within the white pulp, T cells segregate predominantly in the periaarteriolar sheaths whereas B cells home into the lymphoid follicles. Lymphocytes leave the spleen white pulp via the venous sinuses. The lymphatic vessel system does not extend to the splenic pulp but remains confined to the capsule envelope and the major trabeculae. Bloodborne antigens are taken up by the spleen and reach the white pulp via macrophages and antigen-presenting cells found in the marginal zone. It thus appears that the marginal zone is the major route of entry to the white pulp for lymphocytes seeding into the spleen and for antigens and antigen-presenting cells. It is of note that the marginal zone also harbors the majority of natural killer (NK) cells found in the spleen (5–15% of the lymphoid cells). The reason for this selective localization and the function of splenic NK cells is presently unknown. Cells in the marginal zone are predominantly macrophages. However, it has been shown that a particular subset of B cells resides in the marginal zone and these cells respond to type II thymus-independent antigens. Antibody production against

circulating antigens is a major function of the spleen. Activated B cells primed in the white pulp migrate to the red pulp where the majority of the mature plasma cells are found.

STAPHYLOCOCCUS, INFECTION AND IMMUNITY

Åsa Ljungh, Department of Medical Microbiology, Lund University, Lund, Sweden

Staphylococci are ubiquitous organisms living on the skin and mucous membranes of humans and other mammals, on birds, certain plants, and in food. They have a spherical shape, stain gram-positive, form grape-like (Gr. *staphylos*, grape) clusters since they divide in more than one plane, produce catalase, and grow as yellow-white colonies. The cell wall, containing teichoic acids, is rigid and confers tolerance to drying, high salt and sucrose concentrations, and to certain disinfectants. About 30 different species are now recognized (Table 1). *Staphylococcus aureus* is by far the most pathogenic of these species, despite the fact that it, like other members of the genus, forms part of the normal microflora of human skin and mucous membranes. Staphylococci can produce a variety of toxins, enzymes and cell surface proteins

mediating binding to different extracellular matrix and plasma proteins, several of which have been claimed to act as virulence factors. The majority of these are antigenic and elicit production of antibodies which may confer protection to the host. Production of these substances is regulated by super-regulatory genes, such as *agr*, which in turn is controlled by environmental factors, such as the concentration of magnesium ions.

Characteristics of the organisms and their antigens

Coagulase and fibrinogen binding

An important character of *S. aureus* and a few other species is their ability to coagulate plasma and to

Table 1 Selected staphylococcal species and disease spectrum

Species	Coagulase	Characteristic	Disease spectrum
<i>S. aureus</i>	+	Human	Furuncles, wound infections Septicemia Endocarditis, osteomyelitis, arthritis, abscesses Toxin-related disorders Postinfluenzal pneumonia
<i>S. intermedius</i>	+	Animal	Furunculosis, abscesses
<i>S. schleiferi</i>	+	Animal	Furunculosis, abscesses
<i>S. hyicus</i>	Variable	Animal	Furunculosis, abscesses
<i>S. lugdunensis</i>	–	Human	Endocarditis, wound infections, arthritis
<i>S. epidermidis</i>	–	Neutropenia Biomaterial	Septicemia Localized infection with subsequent spread
<i>S. hemolyticus</i>	–	As for <i>S. epidermidis</i>	
<i>S. simulans</i>	–	As for <i>S. epidermidis</i>	
<i>S. hominis</i>	–	As for <i>S. epidermidis</i>	
<i>S. saprophyticus</i>	–	Novobiocin-resistant	Urinary tract infection
<i>S. cohnii</i>	–	Novobiocin-resistant	Biomaterial infections, urinary tract infections
<i>S. xylosus</i>	–	Novobiocin-resistant	Opportunistic pathogen

form a fibrin barrier around localized infectious foci. This is mediated by production of one enzyme, coagulase, and by three specific surface-exposed proteins which bind fibrinogen, thereby inducing polymerization of fibrinogen to fibrin.

Hemolysins

At least four different extracellular proteins have been described which lyse erythrocytes and are cytotoxic to a number of other cells. Human strains of *S. aureus* commonly produce α -lysin whereas strains isolated from bovine and other animals produce β -lysin. The δ -lysin has a broad cell specificity with amphipathic properties (detergent-like).

Leukocidin

Although α -lysin is toxic to leukocytes, *S. aureus* strains also produce a separate toxin, the two Pantón-Valentine factors, exerting synergistic toxic activity to human leukocytes.

Enterotoxins

These belong to a family of proteins of which five immunologically distinct toxins, staphylococcal enterotoxins (SE) A–E, are recognized. They cause staphylococcal food poisoning, presenting with vomiting and diarrhea (Table 2). These toxins differ substantially from enterotoxins of gram-negative pathogens, such as *Vibrio cholerae* and *Escherichia coli* which bind to a specific receptor on intestinal cells. Instead, staphylococcal enterotoxins have been suggested to bind to neurons in the gastrointestinal tract, and may act as neurotoxins. They are also immunomodulating toxins, like TSST (see below).

Toxic shock syndrome (TSS)

In the early 1980s this syndrome of fever, hypotension, a skin rash with subsequent desquamation, and symptoms from at least three organ systems was defined. It was initially related to tampon usage in young women, but since then TSS has been described in postoperative wounds and burns. One toxin, TSST-1 has been identified but also SEB and SEC can be involved (Table 2). TSST-1 has structural similarity with enterotoxins and with pyrogenic streptococcal toxins. It acts as a superantigen, like the

enterotoxins, has mitogenic properties, and induces production of specific cytokines such as tumor necrosis factor.

Staphylococcal scalded skin syndrome (SSSS)

This syndrome is an uncommon cause of epidermolysis, painful desquamation of the skin surface, mainly in infants. It is caused by phage group II strains of *S. aureus* which produce toxin A and/or B (synonyms: epidermolytic toxin, exfoliatin) (Table 2).

Extracellular enzymes

Staphylococcal strains can produce a range of enzymes, such as proteases, various nucleases and lipase which may act as spreading factors. One other enzyme, staphylokinase, activates plasminogen in a similar way to urokinase and a streptococcal kinase, forming plasmin, a potent proteolytic substance. Staphylokinase has a broad host specificity and acts also on plasmin from a number of animal species. It is produced only by *S. aureus* strains, and acts as a spreading factor by breaking down the fibrin barrier and blood clots.

Protein A

This surface exposed protein is produced only by *S. aureus* strains. When the *agr* gene is not activated, protein A is produced. It binds to the Fc part of immunoglobulin molecules, and probably confers resistance to phagocytosis. Furthermore, it mediates activation of complement and of the coagulation cascade.

Binding of fibronectin and other extracellular matrix proteins

In the late 1970s fibronectin binding by bacteria was first described for *S. aureus*. This launched intense research in the area of microbial interaction with various other extracellular matrix and plasma proteins, and expression of specific binding of fibronectin, collagen, vitronectin and laminin is now recognized as common properties of a number of different bacterial, fungal and parasitic pathogens. In *S. aureus* separate proteins have been identified

Table 2 Staphylococcal toxin-related disorders

Organism	Disease	Virulence factor(s)	Immune control
<i>S. aureus</i>	Food poisoning	Enterotoxins, SE A–E	Antibody blocks toxin
<i>S. aureus</i>	Scalded skin syndrome	Toxin A and/or toxin B	Antibody blocks toxin
Staphylococci	Toxic shock syndrome	TSST-1, SEB, SEC	Antibody blocks toxin

mediating binding of these different proteins. Fibronectin binding has been proposed to enhance tissue colonization, collagen binding to target pathogens to collagenous tissues, like joints and bone, and expression of laminin binding to enhance targeting to basal membranes, e.g. in the kidney. Vitronectin binding by microbes is of great interest since it may enhance tissue colonization, like fibronectin binding, and may enhance complement activation by blocking the inhibitory activity of vitronectin on the terminal step in the complement cascade.

Glycosaminoglycan binding

Of the glycosaminoglycan (GAG) family of molecules, heparin is present in blood whereas others, such as heparan sulfate, chondroitin sulfate and dextran sulfate, form part of the extracellular matrix (ECM). Bacteria, such as *S. aureus* and the causative agent of gastritis, *Helicobacter pylori*, bind heparan sulfate and heparin, and the cell receptor for the viral pathogen herpes simplex is heparan sulfate. Since GAGs are present in the ECM, binding to GAG molecules may enhance tissue colonization. Several growth factors, such as basic and acidic fibroblast growth factors and platelet-derived growth factor, bind heparin. Microbial binding of heparin may delay wound healing by sequestration and inactivation of growth factors.

Hemagglutination

One surface-exposed hemagglutinin has been identified in uropathogenic strains of *S. saprophyticus*. It recognizes *N*-acetyl lactosamine, and may act as an adhesin for the human urinary epithelium.

Species differentiation

The ability to coagulate plasma from various animal species clearly differentiates *S. aureus* and a few other staphylococcal species from other staphylococci. Based on biochemical tests and DNA homology studies about 30 coagulase-negative species have been identified. Of these, *S. epidermidis* is the most frequently isolated species. Strains resistant to novobiocin, an antibiotic which is not used for treatment, form a separate group consisting of *S. saprophyticus* and a few other species. Sensitivity to bacteriophages by *S. aureus* (phage typing) is used as an epidemiologic marker to follow, for example, nosocomial spread. To verify identity between strains, however, molecular biology methods such as restriction enzyme analysis of isolated DNA are required. Such methods are commonly replacing phage typing.

Antibiotic sensitivity

Staphylococci frequently acquire resistance to various antibiotics. In hospital environments the vast majority of *S. aureus* strains produce β -lactamase, and are resistant to various penicillins. Strains may acquire resistance to penicillinase-stable penicillins, such as methicillin, by incorporation of *mec* gene(s). These methicillin-resistant *S. aureus* strains, MRSA, may be resistant to several other antibiotics and to heavy metals, and constitute a serious problem in hospital hygiene. Methicillin-resistant coagulase-negative staphylococci, MRSE, may likewise be resistant only to penicillins or also to several other antibiotics. MRSE constitute an increasing problem in hospital hygiene.

Disease spectrum

S. aureus acts as a primary human pathogen and can cause localized superficial skin infections, like furuncles and wound infections. It is also an important agent of tissue-invasive infections (Table 1). After spread to the bloodstream they may cause endocarditis, e.g. in intravenous drug addicts, osteomyelitis and other deep infections. *S. lugdunensis*, though coagulase-negative, has a spectrum of disease similar to that of *S. aureus*. It was first recognized as a cause of endocarditis in the Lyon area of France, and was therefore named 'lugdunensis' (meaning 'from Lyon'). *S. epidermidis*, *S. hemolyticus* and several other coagulase-negative species are so-called opportunistic pathogens which can cause tissue-invasive infection in immunocompromised hosts. However, with the increasing use of foreign materials for temporary (e.g. intravascular and intraventricular catheters) or permanent implantation (e.g. orthopedic prostheses, heart valves and intraocular lenses), the *S. epidermidis* group has emerged as the most important agent of biomaterial-associated infections. *S. saprophyticus* is a common cause of urinary tract infection, particularly in younger women. Staphylococcal strains producing enterotoxins, epidermolytic toxins and TSST may cause different toxin-related infections (Table 2). Of these, TSST can also be produced by coagulase-negative staphylococci.

Immune responses of the host

Since staphylococci form a large part of our normal microbial flora, most people produce antibodies to various staphylococcal antigens, such as the cell wall-associated teichoic acid and the extracellular protein α -hemolysin. They do not appear to confer resistance to staphylococcal infections. The use of detection of antibodies to these antigens as a diagnostic marker

is of limited value, and requires demonstration of a significant rise in antibody titer. However, high levels of antibodies to TSST, enterotoxins and exfoliatins seem to be protective. Since these toxins are recognized as immunomodulatory, with mitogenic activity and inducing cytokine production, they may modulate the immune response. In biomaterial-associated infections staphylococci are embedded in a polysaccharide matrix on the biomaterial surface, the so-called biofilm, which prevents presentation of antigens to the host. Hence, no diagnostic antibody test is available for these kinds of infections, and no protective antibodies have been identified.

Vaccines

Research activity to develop a vaccine against *S. aureus* infections up to the 1960s was in vain, and interest in this field was fading during the 1970s. However, with the emerging spread of antibiotic resistance among staphylococci we encounter a new interest to pursue this nonantibiotic approach to pre-

vent staphylococcal infections. So far, no promising vaccine candidate has appeared.

STATISTICS, USE IN IMMUNOLOGY

Amelia Dale Horne, Division of Biostatistics and Epidemiology, Center for Biologics Evaluation and Research, United States Food and Drug Administration, Rockville, Maryland, USA

Immune response data are usually analyzed in one of two basic forms: the individual concentrations or titers themselves (often subsequent to data transformation) or the proportion of subjects responding to a stimulus in a prescribed manner.

Analysis of concentrations or titers

Measures of antibody responses to vaccines and other immune stimuli are typically highly skewed. Thus, they tend to violate the normality requirement for applying statistical methods based on the normal distribution. However, these data are frequently log-normal, which means that they tend to be approximately normally distributed on the log scale. Frequently used transformations are the natural log, log to the base 2, or the common log (base 10). Statistical analyses requiring normally distributed data are then applied to the log-transformed data.

Commonly used methods

Geometric mean (GM) Because of skewness, the arithmetic mean is usually not an accurate measure

of central tendency. Other ways of characterizing skewed data are the median and its confidence interval and various other percentiles.

One of the simplest ways to summarize immune response data is by the geometric mean and its confidence interval. The GM of a group of n concentrations is the n -th root of the product of the n concentrations. It is usually calculated, however, as the antilog of the arithmetic mean of the log-transformed data. For untransformed concentrations $C_1, C_2, C_3, \dots, C_n$, the GM is calculated as

$$GM = \text{antilog} (\Sigma \log C_i / n)$$

Confidence limits are obtained by finding the antilogs of the lower and upper limits calculated from the log-transformed concentrations. Confidence intervals are informative in virtually all evaluations, but are especially recommended for assessing equivalence or similarity of groups being compared.

When a few immune responses are recorded as zero and thus cannot be log transformed, it is usually

possible to find a constant which, when added to all data values prior to transformation, produces data that are approximately normal. This constant is subtracted from the calculated GM and both confidence limits to compensate for being added before transformation.

***t*-Test and ANOVA (analysis of variance)** Student's *t*-test is used when two independent groups are compared, while the ANOVA extends the *t*-test to more than two groups. Both methods are parametric and assume normality of the data and equality of variances across comparison groups. Both analyses are performed on log-transformed data and compare the means of the groups. The variable analyzed may be either the log fold increase (baseline log concentration subtracted from poststimulation log concentration) or the log concentration.

The ANOVA is also appropriate when there is more than one explanatory factor, in which case a multifactor ANOVA may be used. ANOVA models may be parameterized in several different ways.

ANCOVA (analysis of covariance) If adjustment for a continuous baseline variable is desired in conjunction with a *t*-test or ANOVA, then ANCOVA may be appropriate. Baseline concentrations or subject characteristics, such as age, are frequently controlled baseline covariates in immune response analysis.

Regression This method is used when interest is in the association between immune response and one or more explanatory factors. The regression model assumes that such an association exists and attempts to describe the nature of the relationship quantitatively. This method is also useful if interest is in predicting immune response based on some associated factor, such as age, maternal antibody level, preimmunization antibody level, etc.

Nonparametric methods There are various nonparametric methods of analysis available, which do not require normality and in general make fewer assumptions about the data than do the above methods. The Mann-Whitney-Wilcoxon test, and Kruskal-Wallis test are nonparametric methods commonly used to analyze immune response data. These methods test for differences in central tendency between groups being compared. When there are only two groups being compared, the Kruskal-Wallis test is equivalent to the Mann-Whitney-Wilcoxon test. When differences between only two groups are assessed, these methods are the rank analogs of the two-sample *t*-test. When there are more than two

groups, the Kruskal-Wallis test is the nonparametric analog of the ANOVA.

Advanced methods

Repeated measures analyses If immune response data are collected longitudinally (over time) from the same individuals, the data may be modeled through repeated measures analysis. Such methods may be useful for examining the association between one or more covariates and immune response over time. This method differs from the usual multiple regression (which assumes no correlation among measurements) in that the correlations inherent in measurements collected on the same individuals at multiple time points are accounted for in the analysis. These models may contain fixed or random effects, or both, depending on the desired scope of inference. A type of repeated measures analysis, a Bayesian random-effects regression model for longitudinal data, has been used to estimate the appropriate timing of revaccination with hepatitis B vaccine, based on postbooster antihepatitis B virus surface antigen titers measured over time. There are other types of longitudinal methods, such as generalized estimating equations (GEE), which also may be applied to immune response data measured over time.

Percentile regression This is another methodology which has been applied to longitudinal immune response data. It is a repeated measures type of analysis which allows the estimation of specific percentiles of the immune response distribution for given covariate values. This method of analysis may be informative when interest is in effects on different levels of the distribution of immune responses.

Mixture models Often when log transformation of immune response measurements fails to produce data that are approximately normally distributed, it is because a larger-than-expected number of the responses are left-censored (lie below the lower limit of assay detection). In such cases, there may be a mixture of two different distributions characterizing the data – one for responses above the detection limit and another for those below. A Bernoulli/lognormal mixture model has been applied to the analysis of antibody data from a high-titer measles vaccine, the Bernoulli representing a point mass distribution characterizing the nonresponders, and the lognormal assumed for the remaining censored parametric continuous distribution. Response distributions other than the lognormal also may be appropriate.

Analysis of proportions responding

Another widely used approach to evaluating immune response is through the proportion of individuals responding in some specified manner. For a single group of subjects, a meaningful analysis is simply the point estimate of the proportion responding and its confidence interval. The following methods are for comparing two or more groups, or for evaluating the effects of covariates.

Commonly used methods

Chi-square and Fisher's exact test Both these methods compare proportions responding in a specified manner to immune stimuli. Fisher's exact test is used alternatively to the chi-square.

Advanced methods

Logistic regression Logistic regression differs from simple or multiple regression in that the response variable is discrete and typically dichotomous rather than continuous, and also in that the distribution of the errors is binomial rather than normal. Thus, this method is adaptable to the study of binary immune response status (e.g. positive or negative). It may be used to assess the association between immune response and one or more explanatory factors, or it may be employed for classifying subjects as does discriminant analysis (see below).

Proportional hazards (Cox) regression This method, a type of survival or time-to-event analysis, has been used to evaluate the effect of covariates on time to seroconversion. Survival methods are especially useful when individual subjects in a study are not followed for equal periods of time, or when there is censoring (which occurs when an individual is lost to follow-up during the study). In order for this analysis to be informative about serological data, blood samples must be drawn at numerous time points. However, it may not be possible to know precisely when seroconversion actually occurs – only when it is discovered through a laboratory test.

Discriminant analysis This technique has been used to assess the effects of covariates on seroconversion status in response to vaccination. The basic purpose of discriminant analysis is to classify an individual with specified covariate characteristics into one of two or more population groups. In serological analysis, these groups are usually only two, responders and nonresponders. The linear discriminant function is appropriate when the explanatory variables in

each comparison group are approximately multivariately normally distributed with equal variances/covariances. If explanatory factors are qualitative rather than continuous, then logistic regression, which does not require normality, may be preferable.

Assay comparison studies

Frequently, immune responses of the same group of individuals are measured in different laboratories, perhaps using different assay techniques. Or a new assay may be compared to an established assay. In both cases, it is of interest to compare the different assay methods.

Correlation coefficient Pearson's correlation coefficient is commonly used in assay comparison studies. It is often, however, misinterpreted. The correlation coefficient is properly interpreted as a measure of association only. It is not a measure of agreement. Thus, high correlation cannot be taken as evidence that two assays yield the same results; it is a necessary, but not sufficient, condition for concluding that two sets of values are equivalent.

Error-in-variables model If assays of immune response could be measured with great accuracy, then two assays could be compared via a simple linear regression model. Since biological assays are rarely very precise, a model which incorporates this imprecision, or error in both measured variables, is usually recommended. The error-in-variables model is of the form

$$Y_i = \beta_0 + \beta_1 X_i + (\epsilon_i - \beta_1 \cdot \delta_i)$$

where X and Y are the results observed using assays X and Y , respectively, and δ and ϵ represent random error components of the observed X and Y values, respectively. The parameters to be estimated, β_0 and β_1 , represent the constant and proportional biases, respectively, inherent in estimating values of assay Y from those of assay X . β_0 and β_1 are estimated by the method of maximum likelihood, given that an estimate of the error variance ratio $\lambda = \sigma_\epsilon^2 / \sigma_\delta^2$ is known.

Graphical methods

Data analysis is enhanced by visual displays of the data. Although there is a large repertory of graphical techniques available, the following methods are those commonly used and informative in the understanding of immune response data. Examples of

these graphs can be found among the references suggested for further reading.

Histogram (frequency distribution, bar diagram) This graph is a simple, well-known tool for visualizing many types of data. Histograms are especially useful as one of several ways of assessing the normality of data when parametric methods requiring normality are used.

Pre- versus postimmunization concentrations In vaccine studies, prevaccination antibody concentrations are sometimes plotted on the horizontal axis against postvaccination concentrations on the vertical axis, usually on the logarithmic scale. A person's prevaccination and postvaccination concentrations are represented on the graph by a single point. A 45-degree line drawn from the origin of the graph represents nonresponse, and other lines drawn parallel to it indicate n -fold responses. This type of graph allows visual detection of unusual pre- versus post-immunization associations and distributions.

Cumulative distribution plot (also called ogive) This graph is based on the cumulative distribution function (CDF):

$$C_x(x) = \Pr(X \leq x)$$

where X is a random variable, and the expression on the right means 'the probability that X is equal to or less than a specific value x '. The horizontal axis represents the range of immune response values of interest, often on the logarithmic scale, while the vertical axis indicates percentages, from 0 at the bottom to 100 at the top, of subjects having equal or lesser response values. If two groups of responders are being compared, the difference between their CDFs may be statistically analyzed via the nonparametric Kolmogorov-Smirnov test. The Kolmogorov-Smirnov statistic also may be obtained through another graphical technique called the pair chart.

Reverse cumulative distribution (RCD) plot This graph is based on the function

$$R_x(x) = \Pr(X \geq x)$$

where now the expression on the right means 'the probability that X is at least a specific value x '. RCD plots are especially useful in vaccine studies, because interest is mainly in determining the proportion of subjects who meet or exceed some threshold level of response. The horizontal and vertical axes are the same as those of the CDF plot.

Note that $R_x(x)$ is similar to the well-known survival function $S_x(x)$ given by

$$S_x(x) = \Pr(X > x)$$

differing only in the equality sign on the right-hand side of the equation. When immune response is measured on a continuous scale, $R_x(x) = S_x(x)$, and survival analysis techniques, such as a logrank test, may be used to compare two RCDs statistically, if the curves do not cross significantly. Alternatively, when the scale is continuous $R_x(x) = 1 - C_x(x)$, so that the RCDs also may be analyzed by the Kolmogorov-Smirnov test. When response data are discrete, $R_x(x)$ and $S_x(x)$ may differ enough that a logrank test should be applied to the $S_x(x)$ functions instead.

STREPTOBACILLUS, INFECTION AND IMMUNITY

Ian KM Smith, Department of Veterinary Pathology and Infectious Diseases, The Royal Veterinary College, University of London, London, UK

The genus *Streptobacillus* appears little related taxonomically to other bacteria. There is a single, reasonably well-characterized species, *S. moniliformis*. Other, ill-defined though probably related organisms have also been recovered from pathological material, including pneumonia in calves (*S. actinoides*). These *S. moniliformis*-like agents are heterogeneous with protein patterns quite distinct from those of typical *S. moniliformis* and their taxonomic position, distribution and pathogenicity is obscure.

The genus contains Gram-negative, facultatively anaerobic, nonmotile, nonacid-fast, typically pleomorphic rods, whose appearance depends on, and varies with, their age and environment. Modally the slender cell (up to 1.5 µm long) has pointed or rounded ends and may possess mid-length a fusiform or bulbous swelling. Long, wave chains or filaments, often also with the swellings and up to 150 µm long, produce floccules and impart a 'breadcrumb' appearance to growth in broth. In culture the organism is fastidious and requires for growth (which is slow even at the optimum temperature 35–37°C) rich media liberally supplemented by native protein, a humid environment and possibly enhanced amounts of CO₂; strictly anaerobic isolates are known. There is no growth in milk. During growth the bacteria possess the striking property of reversibly producing L-forms or transitional-phase variants *in vivo* and *in*

vitro. This behavior might be related to the low content of glucosamine and muramic acid in the wall of the modal cell. The bacillary form is sensitive *in vitro* to the antimicrobial drugs in common use clinically, sulfonamides apart.

Despite their moderate importance as pathogens of animals and their zoonotic potential, streptobacilli are relatively unexplored in all respects. Most aspects of their taxonomy, nutrition, biochemical behavior, antigenic structure, epidemiology and the molecular basis of their pathogenicity await detailed investigation.

The antigenic structure of *S. moniliformis* has been little studied by modern procedures. Antisera reacting with the whole cell have been described and a high-titered humoral response, recognized by agglutination or complement fixation, is mounted by clinical cases in humans or in experimentally infected animals. The superficial structures of the bacilli contain about 64% protein, 28% lipid and 6% carbohydrate and there is at least one antigen present which is absent from the L-phase. The protection conferred experimentally on mice against infection with the bacillary phase might be attributable to this antigen(s), as vaccine prepared from the L-form is unprotective. Scans of whole-cell lysates of strains of *S. moniliformis* by SDS-PAGE indicate the presence of some 40–50 proteins ranging from 18 to 100 kDa.

All strains share four major components accounting for 20–30% of the total protein and which are about 60–67 kDa. Variability among 31 isolates from various species was apparently greatest in two regions, namely that encompassing those proteins >67 kDa and that involving those about 42–44 kDa. The role of these components in pathogenicity, pathogenesis and immunity needs detailed examination.

Streptobacillus moniliformis is distributed worldwide and apparently has its principal habitat in the oronasopharynx of rodents, particularly the laboratory rat, which appear clinically healthy. The prevalence of the organism in the wild or the laboratory rat is not precisely known; the agent may be present in half the latter. *Streptobacillus moniliformis* is accorded significance mostly because it is naturally pathogenic for humans. The disease it produces takes two forms. One is streptobacillary fever, which is acquired through a rat bite. The other is Haverhill fever, which occurs in small, common-source epidemics. Clinically, either form of the disease in humans exhibits protracted pyrexia, skin rashes and arthralgia. Before antibiotic treatment was available the disease tended to run a prolonged course and had as sequelae endocarditis, pneumonia, abscesses in various organs and a persistent, nonsuppurative arthritis. A putative association between sporadic streptobacillary fever and the weasel, squirrel, dog, cat and pig has been recorded. The possibility of such species constituting reservoirs of the infection for humans is uninvestigated but seems unlikely in at least some instances. For example, dog and cat bites in humans are common but rarely if ever have as a sequel the distinctive clinical syndrome associated with infection by *S. moniliformis*. Whereas the epidemiology of streptobacillary fever is clear, with infection being established in the right circumstances by the bite of a rat, the epidemiology of the rare Haverhill fever is more obscure. Haverhill fever is often attributed to the consumption of contaminated milk or water but there is no clear-cut evidence that rodents shed the agent in urine or feces. The circumstantial association between the disease and the consumption of raw milk or untreated or inadequately treated water, presumably contaminated with rodent dejecta, is certain, but the direct microbiological link was incomplete in the two clearly established outbreaks investigated and reported.

Streptobacillus moniliformis is no mere commensal of rodents. Spontaneous epizootics of disease have been recorded in the laboratory rat (taking the forms of bronchopneumonia, middle-ear disease and conjunctivitis), the laboratory mouse (fetal absorption, abortion, septicemic disease, polyarthritis) and the guinea pig (cervical adenitis). Spontaneous dis-

ease (tenosynovitis, arthritis) in turkeys also occurs and outbreaks have been traced to the bites of wild rats, the agent in the turkeys and trapped rats being bacteriologically and antigenically the same, as determined by agar-gel diffusion tests.

Immune responses of host

The course of the disease in human beings and other animals, the possibility of persistent sequelae and the relative high mortality rate before the antibiotic era all suggest that the immune response to infection with *S. moniliformis* is imperfect. Humans and other animals obviously mount an immune response to the infection but which components are important in its curtailment is uncertain and whether the resolution of an established infection depends upon antibody production alone is untested. Experimentally, antibody (passive or active) also incompletely diminishes the consequences of challenge with the organism in the mouse.

Evasive strategies by the organism

In the susceptible host episodes of bacteremia occur and the organism establishes itself in, for example, the central nervous system, endocardium, other serosae and bones and joints (particularly in younger animals), where it is possibly sheltered from immune mechanisms to some extent. Macrophages readily phagocytose even the unopsonized organism but are destroyed by it through unknown processes. Thus the host counters the infection inadequately or slowly, partly for such anatomical or physiological reasons.

Vaccines

Experimentally in mice even simple inactivated preparations of *S. moniliformis* induce a measurable but incomplete protection against challenge. However, the apparent rarity of clinical disease in humans or other animals from infection with *S. moniliformis* has meant that little attention is paid to immunization and vaccination against it. This position is unlikely to change. Hence studies of the molecular biology or immunology of *S. moniliformis* and the disease it produces lack impulsion. The one possible exception exists in colonies of experimental rodents. In that case processes more certain than immunological procedures can be used to eliminate the infection and the disease through the establishment of barrier-maintained, pathogen-free stock.

STREPTOCOCCUS, INFECTION AND IMMUNITY

Richard J Hamill and **Daniel M Musher**, Department of Veterans Affairs Medical Center, Infectious Disease Section, Houston, Texas, USA

The genus *Streptococcus* is composed of a number of species that cause disease by means of a wide array of pathogenetic properties, including stimulation of an intense inflammatory response by activating the complement cascade, production of toxins and tissue-damaging enzymes, and initiation of immune-mediated diseases such as rheumatic fever or glomerulonephritis (Table 1).

Various components of the streptococci are important for determining virulence and stimulating an immune response, as well as for classification by serologic means. When present, the outermost

component of many streptococci is a hyaluronic acid capsule which interferes with ingestion by phagocytic cells. This capsular material resembles ground substance in the connective tissue of the host, and is, therefore, essentially nonantigenic. The outermost part of the cell wall contains two antigenically distinct major protein fractions, M and T proteins; M proteins are located on fimbriae that extend radially from the cell wall through the capsule. Based on differences in these proteins, more than 80 serotypes of group A streptococci have been identified, with little serologic cross-reactivity among them. The M

Table 1 Examples of mechanisms by which streptococci cause disease

Organism	Disease	Pathogenesis	Immune control
<i>S. pyogenes</i>	Cellulitis, fasciitis	Enzymes (hyaluronidase) destroy tissues; streptococcal pyrogenic exotoxin β degrades extracellular matrix proteins	Antibody to M protein promotes phagocytosis
<i>S. pyogenes</i>	Scarlet fever	Toxins (pyrogenic exotoxins) damage capillary integrity	Antibodies block toxin (neutralize?)
<i>S. pyogenes</i>	Acute glomerulonephritis	Circulating immune complexes deposit in glomeruli of kidney	
<i>S. pyogenes</i>	Acute rheumatic fever	Antibodies to M proteins are reactive with cardiac antigens	
<i>S. pneumoniae</i>	Pneumonia	Intense inflammatory response fills alveolar spaces	Antibody to capsular polysaccharide promotes phagocytosis

protein is a virulence factor impairing phagocytosis by preventing the interaction of the organism with complement components, an effect that is enhanced by the ability of M protein to precipitate fibrinogen on the surface of the organism. Strains that are deficient in M protein are avirulent; they are phagocytosed and killed by polymorphonuclear leukocytes (PMNs) in the absence of type-specific antibody. Type-specific antibody to M protein facilitates phagocytosis, is protective against reinfection and imparts longlasting immunity. The T proteins are useful for typing of organisms, as in epidemiologic studies, but appear to play no role in immunity. In close association with M proteins in the fimbriae of streptococci are lipoteichoic acids which interact with fibronectin on the surface of mammalian cells and determine bacterial adherence.

Interior to the protein layer is the group-specific carbohydrate, which enables β -hemolytic streptococci to be distinguished, by immunologic tests, into approximately 20 groups designated A through H and K through V (Lancefield groups). Although antibodies to group carbohydrates do not appear to contribute to immunity, they may have a role in nonsuppurative immunologic sequelae of streptococcal infection because of cross-reaction with mucoproteins in human tissues.

The inner layer of the cell wall consists of the basic mucopeptide structural unit common to all bacteria. This peptidoglycan forms the rigid skeleton of the cell wall, giving the bacteria their shape. When injected into rabbits, peptidoglycan produces effects much like endotoxin as well as causing a generalized Shwartzman reaction. Antibody to peptidoglycan is cross-reactive with a number of different gram-positive organisms. Peptidoglycan has been said to be the cell wall component that most vigorously activates the alternative complement pathway; streptococci produce disease in part by evading phagocytic defenses and then activating complement.

Streptococci elaborate a number of toxins and extracellular enzymes which also contribute to the clinical manifestations of disease. Streptococcal pyrogenic exotoxins (erythrogenic toxins), elaborated by bacteriophage-infected strains, are responsible for the characteristic rash seen in scarlet fever. Antibody produced in response to pyrogenic exotoxin is protective against reinfection, accounting for the rarity of this syndrome in adults. The streptococcal toxic shock syndrome may be due to one or several superantigens elaborated by streptococci, including pyrogenic exotoxins A, B, C and streptococcal superantigen. These molecules have significant amino acid homology with the staphylococcal enterotoxins A through F and toxic shock syndrome

toxin 1 and share several biologic functions, such as pyrogenicity, enhancement of susceptibility to endotoxin shock and suppression of immunoglobulin production. Subsequent stimulation of T cells results in elaboration of the cytokines interleukin-1, interleukin-2, interleukin-6, interleukin-8, tumor necrosis factor α , and interferon γ which may be responsible for many of the signs and symptoms observed in the streptococcal toxic shock syndrome.

Streptococci infect skin and soft tissues, causing erysipelas, cellulitis and/or fasciitis. Pharyngitis and tonsillitis occur when soft tissues in the pharynx are infected, and peritonsillar abscess may result. These organisms also cause pneumonia, pericarditis, meningitis and urinary tract infection. Disease results from intense stimulation of inflammation and damage to tissues by extracellular toxins and enzymes. Streptococcal pyrogenic exotoxin B, for instance, is a cysteine protease which is well conserved among most strains of *S. pyogenes*, and cleaves fibronectin and degrades vitronectin, two extracellular matrix proteins present in most tissues. Streptococci may also resist efforts at control by the host by producing a C5a peptidase that cleaves surface-bound C5a and, consequently, delays migration of PMNs into infected foci, or a leukocidin that may kill PMNs following ingestion of streptococci.

Antibodies to more than 25 extracellular products appear after streptococcal infection. Five of these antibodies have been especially useful in serodiagnosis: 1) antistreptolysin (ASO); 2) anti-DNase B; 3) antihyaluronidase; 4) anti-NADase; and 5) anti-streptokinase. Immune responses to these extracellular products differ somewhat, depending on the focus of infection. After an episode of pharyngitis, 95% of individuals develop antibodies to multiple antigens and 80% have a fourfold increase in ASO titers. Conversely, ASO responses are slight or absent after skin infection, probably because streptolysin O becomes inactivated by skin lipids. Anti-DNase B responses, on the other hand, are brisker after pyoderma than after pharyngitis.

Group A streptococcus

Several immunologic diseases result from infection with *S. pyogenes*, the group A streptococcus. Acute glomerulonephritis, characterized by hematuria, proteinuria, hypertension and edema, may appear 6–14 days after infection caused by a limited number of group A streptococcal serotypes. Attack rates are related to the magnitude of the immune response, with high levels of antibodies to streptococcal cell membrane antigens being found in the serum of affected patients. Electron microscopic demon-

stration of subepithelial lumps in renal biopsy specimens, along with hypocomplementemia, suggests that the renal injury is due to deposition of preformed immune complexes. The identity of the streptococcal components involved in this disorder remain unknown.

Acute rheumatic fever, a syndrome of migratory arthritis, carditis and/or chorea appears about 18 days after pharyngitis due to a group A streptococcus. Several theories regarding the pathogenesis of this disorder exist, but most widely accepted is that autoimmune phenomena are responsible, based on the similarity of streptococcal antigens to various human tissue antigens. Strains of group A streptococci that cause rheumatic fever appear to have in common M proteins with an antigenically conserved surface-exposed domain. Epitopes of these M proteins have been shown to share antigenic determinants with cardiac muscle myosin or sarcolemmal membrane antigens.

Guttate psoriasis is a well-described form of psoriasis characterized by the abrupt appearance of small psoriatic lesions over much of the skin; it occurs primarily in children and young adults a few weeks after streptococcal pharyngitis. This disorder appears to be a result of superantigenic stimulation of T cells by streptococcal pyrogenic exotoxin C with subsequent selective accumulation of $V\beta 2^+$ T cells in the areas of the skin lesions.

Pneumococcus

Streptococcus pneumoniae (pneumococcus), the most frequent cause of bacterial pneumonia, can be singled out from the other streptococci. The surface layer of pneumococci consists of a polysaccharide coating or capsule which enables these bacteria to elude ingestion and killing by macrophages and PMNs; some 90 antigenically different capsular types have been recognized. Pneumococci commonly colonize the nasopharynx of healthy children and adults, generally persisting for 6 weeks to 6 months. Invasion may occur soon after colonization as a result of many poorly defined factors, including concurrent, nonbacterial upper respiratory infection and numerous other conditions that compromise immunologic capacity. Once tissue barriers have been penetrated, pneumococci readily proliferate. Cell wall constituents (especially teichoic acid) and capsular polysaccharide activate the complement cascade via the alternative pathway. Antibody to cell wall constituents is present in nearly all normal adults because common antigens are shared among gram-positive bacteria; the resulting antigen-antibody reaction also activates complement by the

classical pathway. This activation generates C5a, leading to an intense inflammatory response which, in pneumococcal pneumonia, is the principal component of the disease. Some pneumococcal toxins may also play a role. For example, pneumolysin damages ciliary action and stimulates ingress of PMNs, causing many of the histologic features of disease in experimental animals.

The most effective mechanism by which the normal host can resist pneumococcal infection is by producing immunoglobulin G (IgG) or IgM that reacts with capsular polysaccharide. Such antibody opsonizes these bacteria for ingestion and killing by so-called professional phagocytes. Anticapsular antibody appears after colonization or infection. Nevertheless, most adults lack antibody to the majority of commonly infecting pneumococcal serotypes, indicating a relatively low level of resistance in the community.

Normal adults have ample antibody to phosphocholine-containing determinants of pneumococcal cell wall. However, the reaction between this antibody and the bacterial wall takes place beneath the capsule, and the resulting complement fragments and bound Fc are not accessible to phagocytic cells. Despite demonstration of a protective effect of antiphosphocholine antibody in experimental animals, this mechanism is generally thought not to be protective in human subjects.

As a result of these considerations, it is not unexpected that individuals who have impaired capacity to produce immunoglobulin are especially susceptible to pneumococcal pneumonia. Included are those with congenital or acquired hypogammaglobulinemia, acquired immune deficiency syndrome, multiple myeloma, lymphoma, chronic renal insufficiency or chronic liver disease. Probably the greatest increase in pneumococcal pneumonia is seen in persons infected with the human immunodeficiency virus. Pneumococcal pneumonia occurs with greatly increased incidence in individuals who have pre-existing bronchopulmonary disease, either acute such as influenza, or chronic such as bronchitis or emphysema, because local factors that might allow clearance of inhaled pneumococci are not operating normally. Individuals who lack a normal spleen are at risk of overwhelming sepsis once pneumococcal infection occurs.

Vaccines

Development of vaccines to prevent streptococcal infection has been problematic because of the concerns regarding autoimmune responses. When sufficiently large doses of M protein have been given to

provoke type-specific antibody responses, local and systemic reactions have been frequent, possibly because M proteins have superantigen characteristics. Recently, M proteins derived from limited pepsin digestion of streptococci have been purified to homogeneity and the heart reactive epitopes have been separated. Immunization with these purified M protein preparations has generated type-specific opsonic antibodies without cross-reactive heart antibodies. Another approach to immunization, namely the stimulation of antibodies directed to the adherence moiety of streptococci, lipoteichoic acid, is limited by the poor immunogenicity of this constituent unless complexed to a protein molecule.

Vaccination with capsular polysaccharides has been shown to be effective in preventing *S. pneumoniae* infection in otherwise healthy adults who are exposed to epidemic pneumococcal infection, usually because of working and/or living in crowded conditions such as military camps. It has been difficult to demonstrate conclusively the benefits of vaccination in those individuals who are more susceptible because of chronic pulmonary disease and advancing

age. Although this prophylactic treatment is recommended for immunologically compromised individuals, these subjects are least likely to respond with adequate production of antibody.

STRESS AND THE IMMUNE SYSTEM

Roger J Booth, Department of Molecular Medicine, Faculty of Medicine and Health Science, The University of Auckland, Auckland, New Zealand

What is stress?

In order to explore the relationship between stress and the immune system we need first to examine what we mean by the term 'stress'. It is a word borrowed originally from physics and engineering where it denotes a force with the potential to deform or distort an object. In the context of our lives, stress is generally taken to refer to a situation that results in a challenge or threat to our adaptive capacity – something that disturbs our dynamic equilibrium or homeostatic balance. In other words, it is a perceptual or cognitive assessment made by an individual about the impact of a particular circumstance or constellation of events on his or her life.

How can stress be studied?

One of the difficulties therefore of studying the effects of stress in the lives of people or animals is that of evaluating the impact and comparability of

stressful situations on different individuals. In an attempt to circumvent this difficulty, many studies of stress and the immune system have been conducted by the controlled application of 'standard stressors' to populations of laboratory animals (Table 1). Here, a particular situation (usually involving some form of physical insult) is judged by the experimenter to be stressful on the basis of the subsequent behavior of the animals. Such studies have been valuable in delineating some of the pathways of interconnection between autonomic, neuroendocrine and immune system activities, as we shall see later. They have highlighted, for example, the distinction between the effects of acute and chronic stressors, the potential modulating and exacerbating effects of 'control' and 'helplessness' respectively, and the fact that corticosteroids, while clearly important immunomodulators, are not obligatory players in neuroimmune responses to stressors.

Although an analogous approach in human studies has been to submit volunteers to 'stressful' situations and to assess short-term effects on immune variables,

Table 1 Investigating stress*How can stress be studied?*

- Apply 'stressors' to animals or people and observe behavioral and physiological changes
- Compare groups of individuals living under circumstances that differ in their degree of 'stressfulness'
- Observe individuals at various times in their lives and correlate effects with their personal assessments of stressfulness

What questions can be asked?

- Are there correlations between stress-associated immune effects and disease or illness?
- What immune variables are affected by stress?
- Are there differences between the effects of short-term and chronic stressors?
- Is there a distinction between interpersonal and nonsocial situations?
- What are the mechanistic pathways within an individual's physical makeup through which stress might be acting on the immune system?

much human stress research has focused on 'naturally stressful' events in people's lives and selected subjects undergoing the same particular event. Accepting the notion that stress is an individual assessment, a further approach has sought to relate self-reported stress, usually accessed through standardized stress and anxiety questionnaires, to immune activity. Although there are many problems inherent in the use of questionnaires and self-reports, this approach has merit in that it relates stress to the context and meaning of individual lives and opens the possibility that altered perceptions might correspondingly alter physiological and immunological impact.

Stress and immunity in animal studies

Numerous animal studies have demonstrated that a wide variety of stressors can alter many aspects of the immune response. Much of the animal work has concentrated on applied, physical stressors (**Table 2**) but there have been some studies with more 'naturalistic' or ethologically relevant stressors such as maternal separation in young animals, social defeat and exposure to the odors emitted by littermate animals under stress. A wide variety of immune measures have been found to be affected by stress. These include nonspecific, mitogen-induced proliferative responses of lymphocytes, development of antigen-specific cytotoxic T cells, generation of specific antibody responses, macrophage activation, alteration of Th1/Th2 balance, secretion of cytokines and the expression of cytokine receptors. Stressors have also been shown to alter the migration patterns of immune cells between and into compartments of the

immune system. Indeed it is difficult to find many measurable aspects of the immune system that cannot be altered by some stressor.

Although a variety of stressful behavioral manipulations that affect immunity also influence susceptibility to a variety of disease states, the stressors used do not all produce the same effects. The impact and direction of the effects of stress on immune behavior and on disease susceptibility depend on such factors as the quality, quantity and duration of the stressor (e.g. acute application of a particular stressor inhibits immune responsiveness, while more chronic exposure can sometimes enhance immunity); the temporal relationship between exposure to the stressor and the introduction of antigen or pathogenic stimulation; socioenvironmental conditions (e.g. whether the animals are housed individually or in groups, or how often the animals are handled during the neonatal period); and various host factors such as species, strain and sex. For example, stressors can accelerate the growth of transplanted tumors in animals, but such an effect could be mediated through nonimmune mechanisms, such as through stress-induced changes in blood flow to tumor sites. Nevertheless, immune effects are probably important here too because natural killer (NK) cell activity is also compromised, and if the stress effect on NK cells is pharmacologically blocked, there is no stress-related

increase in tumor growth. Conversely, if NK activity is reduced using a monoclonal antibody directed against NK cells, tumor growth rates increase in a manner similar to the stressful situation.

Many of the stressors in animal research have involved physical 'insults', but the impact of stress on immunity cannot be explained simply in physical terms. What the stressor means for the animal and the attitude which it adopts towards the situation can also be profoundly influential. For example, being placed into the established territory of another rat, even for a brief period of time, severely inhibits the production of antibodies to antigens administered before the intruder is introduced into the new territory. Moreover, in such confrontational situations it is the adoption of submissive behaviors by the introduced animal which correlates most closely with reduction of antibody production. Antibody responses in nonsubmissive animals are relatively unaffected. Other work has demonstrated that if an animal perceives a stressor to be controllable or escapable then effects on immune responses are much less than in inescapable situations.

Stress and immunity in human studies

In humans, some studies have been conducted into the effect of short-term, laboratory-based stressors on immune variables but most investigations have centered on more 'naturalistic' stressful situations (Table 2). Where perception of environmental stressors has been assessed using such indicators as daily mood, hassles, anxiety, social support or various coping measures, there has generally been a correlation between high perceived stress and depression of humoral and/or cell-mediated immunological measures. Often the most significant correlation has been with depression of NK cell activity. The notion that a critical parameter is the *perception* of stress clearly has important implications and illustrates how much the way we respond psychologically to our environment can affect the way we respond physiologically.

Four examples serve to illustrate this. In a 1-year study of a group of medical students, there was a strong association between examination stress, increased incidence of illness, and depression of various immunological measures. At times of examination stress, those students who were chronic carriers of latent Epstein-Barr virus (EBV) exhibited increased antibody titers against EBV, which is indicative of virus reactivation. In a further group of students who were immunized with hepatitis B virus vaccine at examination time, those who seroconverted early were significantly less stressed and anxi-

ous than those who did not, and the students who reported greater social support also gave a stronger immune response to the vaccine. In another study, volunteers completed questionnaires assessing degrees of perceived psychological stress and then were inoculated intranasally with rhinovirus under controlled conditions in an isolation unit. They were then monitored for the development of evidence of infection and common cold symptoms. The results showed that perceived psychological stress at the outset correlated strongly with increased risk of acute respiratory infection, increased viral shedding in the nasal mucosa and decreased antiviral antibody titers. Recent research on elderly people experiencing the chronic stress of long-term caring for relatives with dementia discovered that, compared with a suitably-matched control group, their inflammatory cytokine responses were diminished, they healed wounds more slowly, and their immune responses to influenza virus vaccination was down-regulated.

Importance of context

These examples emphasize that it is the context in which the event occurs for an individual rather than the event itself that constitutes the stress. Whether or not that context includes chronic stress may also modulate the immune effects of an acute stressor. For example, in a recent study, the effects on NK and T cell responses of acute psychological stressors was most marked in people reporting high levels of chronic stress at the time.

Thus, there will be conditions under which stressors interfere with immunity, have no effect or even enhance immune responses. For example, a stressor may interfere with immunity only if it occurs at or immediately before the time of antigen exposure, or may alter one immune variable but not another. This means that we cannot generalize about the effects of a particular stressor on immune function as a whole, particularly when one realises that most human stress studies assess blood-associated immune variables but blood contains less than 10% of the total lymphoid pool and is certainly not representative of the populations of cells in secondary lymphoid organs. Further, the immune system contains a high degree of redundancy, and so the fact that an event might alter a particular immune measure need not necessarily indicate any alteration of immune responsiveness within the whole individual.

Influence of the nervous system on the immune system

Until the last decade, a common view was that the

immune system is essentially autonomous – a closed system driven by challenges from foreign antigens and self-regulating, predominantly through the actions of cytokines. Yet the striking similarities in overall behavior between the immune system and the nervous system were also appreciated. For example, both are involved in the receipt and processing of information. In the case of the nervous system this is sensory information, while for the immune system it is molecular topological information. Both systems respond to a diverse range of stimuli and in each case the response is specific for stimulus. In each, there are a range of available responses and the system adapts its resources to provide what is appropriate in any situation. Neither the immune system nor the nervous system can know in advance exactly what stimuli are likely to occur and so each system has the capacity to respond to unexpected stimuli. Both systems have the ability to remember specific stimuli and to modify and tailor subsequent responsiveness. In essence, both systems are involved in the generation and maintenance of a distinct individual or 'self' in the context of an environment containing

many other individuals ('nonself') and this led people to wonder how coordinated and inter-related the activities of these two integrative systems might be.

It is now clear that there are extensive pathways of bidirectional communication between the immune and nervous systems, and the existence of neural-immune interactions allows us to make more sense of relationships between behavioral-psychological events and immune activity. For, if neural processes regulate immune processes, then there are pathways by which psychological factors such as stress could affect immunity (**Figure 1**). Conversely, if immune processes alter neural function, then they can also potentially have an impact on behavior, emotion and thought.

The brain has two ways of controlling peripheral organs and processes – a cabling network and a fluid-based communication hierarchy – and both are able to influence the operation of the immune system. The cabling network is called the autonomic nervous system and consists of sympathetic and parasympathetic branches which innervate visceral organs – heart, liver, stomach, kidneys, etc. Histochemical staining

Figure 1 Autonomic and neuroendocrine systems. The nervous system operates to affect visceral processes through autonomic sympathetic and parasympathetic nerves, and through neuroendocrine hormones via the hypothalamus–pituitary axis controlling endocrine gland output.

techniques to identify small nerves have revealed extensive innervation of all lymphoid tissue (both primary and secondary lymphoid organs) by noradrenergic nerve fibres. Norepinephrine (noradrenaline) is the predominant neurotransmitter released by these nerves although epinephrine (adrenaline) and serotonin can also be used. In lymph nodes, the nerves appear to terminate predominantly in the T cell-rich regions, suggestive of possible links to immunoregulatory functions, particularly as receptors for norepinephrine and catecholamines have been found on lymphocytes, macrophages and cells of the granulocyte lineages.

The fluid-based communication hierarchy through which the brain can communicate with peripheral organs comprises the glands and hormones of the neuroendocrine system. This centers particularly on the hypothalamus, pituitary and adrenal glands. In the brain, the paraventricular nucleus of the hypothalamus is able to synthesize and release certain hormones into the portal blood system at the base of the brain. Some of these hormones act close by on the anterior lobe of the pituitary gland, causing it to synthesize and release other hormones, which, in turn, travel in the bloodstream to signal various peripheral endocrine organs. In times of stress, one of the important products of the hypothalamus is a substance called corticotropin-releasing hormone (CRH), which activates pituitary synthesis and release of adrenocorticotrophic hormone (ACTH). ACTH is released into the blood and ultimately arrives at the cortex of the adrenal gland, where it causes the release of steroid hormones called glucocorticoids.

Autonomic pathways to the immune system

The limbic system of the brain, which is pivotal in aspects of affective and cognitive behavior, directly regulates the neurohormonal and autonomic outflow of the nervous system. As the hypothalamus is central to this process, it is pertinent that perturbations of the hypothalamus also affect immune responses. For example, experimentally introducing lesions into the anterior lobe of the hypothalamus of rats depresses antibody responses, while electrically stimulating the hypothalamus at the time of immunization enhances antibody responses. Lesions in hypothalamus and hippocampus have also been found to alter such immune responses as NK activity and T cell functions. Focusing further down the autonomic nervous system, we find that the ultrastructural features of the contacts made between the sympathetic nerve termini in lymphoid tissues and

lymphocytes are similar to nerve synapses, indicating the likelihood of some sort of intimate control or regulatory function. So it is no surprise that if the nerves to a lymphoid organ are cut or chemically damaged, the immune responsiveness of that lymph node is altered. Further, using specific antagonists to block hormone receptors on lymphocytes also alters the course of immunity. Thus, elevation of norepinephrine and epinephrine levels, which accompanies stress, may also produce changes in lymphocyte, monocyte and leukocyte circulation patterns and functions. Both lymphocytes and macrophages have β -adrenergic receptors which are increased in density following acute stressors. Moreover, β -adrenergic agonists generally downregulate immune system function.

Neuroendocrine pathways to the immune system

Corticosteroids, produced by the adrenal cortex as a result of stress-induced signals from the hypothalamus through the pituitary, have profound immunosuppressive effects on a variety of immune parameters, as outlined in Table 3. They decrease the production of many cytokines and mediators of inflammation and decrease the effects of certain inflammatory molecules on various target tissues. This, together with the more general immunosuppressive characteristics of corticosteroids, is why they are used clinically to treat immunoproliferative disorders and some autoimmune conditions, and to control rejection of transplanted tissues. However, removal of adrenal function by adrenalectomy, or suppression of corticosteroid synthesis with drugs, eliminates many but not all of the immunosuppressive effects of stress, indicating that other molecules mediate stress-induced immunological effects as well.

In addition to corticosteroid effects, a number of the nonsteroidal hormones, produced by other neuroendocrine organs in response to hypothalamic-pituitary messages, also influence immune responses; for example, sex hormones diminish *in vivo* responses, while growth hormone, thyroxine and insulin elevate responses under certain conditions. Numerous neuropeptides and neurotransmitters,

Inhibit <i>in vitro</i> B and T cell responses
Alter lymphocyte migratory patterns
Decrease cellularity of the thymus

which exert multiple functions as intercellular messengers within the nervous system, may also modify functional properties of cells of the immune system (Figure 2). For example, in addition to the elevation of CRH, corticosteroids and the catecholamines with stress, levels of β -endorphin, which is derived along with ACTH from cleavage of the pro-opiomelanocortin polypeptide, are also elevated, as are levels of several other opiates. Opiates function to alleviate pain during a fight-or-flight encounter but also inhibit immune responsiveness. In contrast, two anterior pituitary hormones, growth hormone and prolactin, are immunoenhancing and appear to act as a balance to corticosteroids and catecholamines.

Neurological mediators could act directly on cells of the immune system to produce their effects or they could act indirectly by inducing immunological mediator production from other cell populations. Receptors for many of the neuropeptides, neurotransmitters and endocrine hormones have been found on cells of the immune system and so at least some of their effects may be a consequence of direct binding to lymphocytes or monocytes.

Immune system pathways to the nervous system

If the immune system is also able to influence the nervous system then effects should be evident during

times of immune activity. The fact that when we have a cold or 'flu' we feel drowsy, feverish and unsociable alerts us to the possibility of immune activity affecting the nervous system and behavioral and cognitive patterns as a consequence. Indeed, hypothalamic electrical activity has been observed to increase at the time of peak B cell responsiveness to administered antigen, and neurotransmitters such as norepinephrine in the hypothalamus also show profound changes at this time. Potentially there are at least two ways in which this could occur. Lymphocytes themselves have only limited access to the brain and so responding lymphocytes could secrete neurological mediators or, alternatively, cytokines produced during the course of the immune response could directly affect neural tissues. In practice, both these pathways probably operate (Figure 3).

A variety of neuroendocrine mediators can be synthesized by cells of the immune system under various conditions of activation. In fact, in many ways it seems as if lymphoid tissues can behave rather like the pituitary gland itself. For example, CRH can stimulate macrophages to secrete interleukin 1 (IL-1), which in turn induces B cells to secrete ACTH and β -endorphin. Like pituitary production of ACTH and β -endorphin, this effect can also be downregulated by corticosteroids. In addition, some cytokines (e.g. IL-1, IL-2, IL-3, IL-6, IL-8, tumor necrosis factor α (TNF α) and interferon γ (IFN γ))

Figure 2 Some neuroendocrine pathways to the immune system. Many of the hormones released by the hypothalamus, pituitary and endocrine glands affect the activity of lymphocytes. In stress, hormones and neurotransmitters from the adrenal cortex (corticosteroids) and medulla (principally catecholamines and enkephalins) are especially important.

Figure 3 Some immune system pathways to the nervous system. Various cytokines released by activated cells of the immune system modulate the activities of the autonomic and neuroendocrine systems. In addition, lymphocytes and other immune cells release some neurotransmitters and neurohormones.

exert effects on the central nervous system and in some cases (notably IL-1 and IL-3) may act as intrinsic neuromodulators within the brain. However it is the neural effects of the cytokine IL-1 (and coordinately IL-6 and TNF α), released by macrophages during immune and inflammatory responses, which are the most well studied.

Activation of macrophages produces IL-1 and subsequently leads to altered electrical activity in the brain, and metabolism of the neurotransmitters norepinephrine, serotonin and dopamine in certain brain regions. These neural changes can also be produced by injected IL-1 and can be blocked by an IL-1 receptor antagonist. Does this mean then that immune-produced IL-1 acts directly on the brain? Certainly neurons in the preoptic nucleus have receptors for IL-1 (as well as IL-6 and TNF α) but because IL-1 is a relatively large, lipophobic protein it may have difficulty crossing the blood-brain barrier easily. An active transport mechanism could exist to carry IL-1 across the barrier, or alternatively, IL-1 might

cross the vascular endothelium in regions of the brain, such as the preoptic nucleus of the hypothalamus, where the barrier is weak or absent. Another possibility is that IL-1 stimulates peripheral nerves, such as the vagus, to send afferent input to the brain. This possibility was highlighted by recent findings that if the vagus nerve was cut just below the diaphragm, stress-induced, IL-1-mediated effects on the brain were considerably diminished.

Conclusions

Clearly then, there are extensive bidirectional pathways of communication between the immune system and the brain (Figure 4). Perceived stress, through this neuroimmune network, can influence immune responses. But stress is not a generic event, and different stressors, or stressors perceived differently, produce different mixes of autonomic activation and hormones. For example, one stressor might lead to intense autonomic activation and consequent plasma

Figure 4 A summary of neuroimmune physiological interactions. The extensive set of hormones, cytokines and other modulatory processes shared between the immune and nervous systems illustrate the degree to which the two systems cannot be considered as operating independently of one another in living organisms.

Figure 5 Coherence among neural, immune and psychosocial domains. Psychosocial processes (such as the perception of stress), acting through the neuroimmune network, clearly have the potential to modulate immune responsiveness. Conversely, immune activity influences how we think, feel and act. Thus, these three integrative systems – immune, neural and psychosocial – are coherently coordinated into the self-determination process of an individual.

catecholamine release but relatively little activation of the pituitary and adrenal glands and their hormones. Another might produce the opposite pattern. In addition, emotions, thoughts, personality, coping processes and other psychological and social variables will modulate autonomic and hormonal consequences of exposure to stressors and in turn the immune consequences.

Conversely, immune system-derived information acting on the nervous system, during the course of an infection for instance, could also be responsible for triggering changes in behavior patterns similar to stress-associated behaviors. For example, animals

exposed to stimuli which arouse fear or anxiety reduce social interactions, curiosity, food and water ingestion and sexual activity. Administration of IL-1 or substances that stimulate macrophages to secrete IL-1 produce very similar behavior changes.

All this suggests that the immune system may truly act as a sensory organ, conveying to the brain information about antigens through lymphocyte-derived hormones, while at the same time being modulated by neural factors (stress related or otherwise). As illustrated in Figure 5, therefore, the immune, neural and psychosocial domains are coordinated as coherent self-generative processes within an individual's life such that it is the context, interpretation and meaning of stress for the individual that determines its immune effects.

STRESS PROTEINS

Tim Elliott, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, UK

The stress response

Cells respond to a variety of stressful stimuli by coordinately increasing the synthesis of up to two dozen specific proteins. The DNA loci involved in the stress response are the most highly conserved genetic regions known. Although the best studied of these stressful stimuli is an increase in temperature or 'heat shock', others include nutrient deprivation, oxygen radicals and metabolic disruption. Accordingly, the proteins which are induced in response to these stimuli are often called heat shock proteins (hsps) or more generally, stress proteins. Many higher eukaryotic cells have been shown to undergo a stress response during intracellular infection and also dur-

ing malignant transformation. Induction of transcription of stress proteins is coordinated by a shared nucleotide sequence in the 5' noncoding region which serves as the promoter for hsp mRNA synthesis.

Stress proteins

Stress proteins are grouped into major families (generally named according to their approximate molecular weight in kDa). Much of the current knowledge relating to these protein families is outlined in Table 1. Within a family, hsps show remarkable sequence homology across the phylogenetic spectrum and are indeed among the most highly con-

Table 1 Members of the major stress protein families

Family	Members	Organism	Localization	Normal function
hsp110	C23 nucleolar protein	Mammals	Fibrillar nucleolus	RNA binding, ribosome stabilization?
hsp90	HtpG (C6.25)	<i>E. coli</i>	Cytosol	ATP-dependent chaperone
	hsp82	<i>S. cerevisiae</i>	Cytosol	
	Hsc82		Cytosol	
	hsp83	<i>D. melanogaster</i>	Cytosol	
	hsp90	Mammals	Cytosol	ATP-dependent chaperone
	grp95	Mammals	ER	
hsp70	DnaK	<i>E. coli</i>	Cytosol	ATP-dependent molecular chaperone
	SSa1-4p	<i>S. cerevisiae</i>	Cytosol	
	SSb1/2p	<i>S. cerevisiae</i>	Cytosol	
	Kar2p	<i>S. cerevisiae</i>	ER	Required for protein translocation across lipid bilayers
	SSclp	<i>S. cerevisiae</i>	Mitochondria	
	hsp72 (hsp70)	Mammals	Cytosol	
	hsp73 (hsc70)	Mammals	Cytosol	
	BiP (grp78)	Mammals	ER	ATP-dependent molecular chaperone Binds hydrophobic protein surfaces bearing the general motif: X W/F X W/F X W/F/L/I X W/F/Y X
hsp60	mtp70	Mammals	Mitochondria	
	GroEL	<i>E. coli</i>	Cytosol	ATP-dependent protein foldase in conjunction with hsp10 as a large oligomeric complex
	Tcp1p	<i>S. cerevisiae</i>	Cytosol	
	hsp60 (mif4p)	<i>S. cerevisiae</i>	Mitochondria	
	TCP1	Mammals	Cytosol	
	hsp58 (hn cha60)	Mammals	Mitochondria	
Small hsps (14–50)	SecB (16 kDa monomer)	<i>E. coli</i>	Cytosol	SecB tetramer facilitates transport of partially folded proteins across cytoplasmic membrane. Binds positively charged stretches of amino acids
	hsp26	<i>S. cerevisiae</i>	Cytosol	Coalesce to form heat shock granules in stress
	hsp25–27	Mammals	Cytosol	
	a-crystallin	Mammals	Cytosol

Ubiquitin (8 kDa)		All species	Cytosol	Targeting aberrantly synthesized proteins for cytosolic degradation by the 26S proteasome

served proteins in existence. For example, there is over 50% sequence homology between hsp70 from mycobacteria and humans. Yeast ubiquitin, another stress protein, differs from its mammalian counterpart by only three amino acids. Despite this homology, subtle differences exist in the apparent functions, inducibility and cellular location among related hsps for a given species.

The major stress proteins can accumulate to very

high levels of stressed cells, but occur at low to moderate levels in cells that have not been stressed, indicating that they play a role in normal cells. For example, in most mammalian cells hsp90 and hsp60 are abundant at normal temperatures whereas hsp70 is hardly detectable. Nevertheless, all are further induced by stress. For some proteins, the effect is dramatic: *Escherichia coli* hsp60 and hsp70 account for 1.5% of total cell protein at normal temperatures

whereas they account for 30% of total protein after heat shock.

In addition to increased synthesis, many hsp's alter their intracellular distribution in response to stress; an observation which may relate to their role in thermotolerance.

The function of stress proteins

A common feature of hsp's is their ability to function as molecular chaperones. This term describes their ability to bind to denatured proteins, preventing their aggregation, and provides the key to understanding the function of hsp's under normal conditions and in conditions of stress.

Normal function

The binding of hsp's to denatured proteins is regulated by the hydrolysis of ATP. The ATPase activity of hsp60, hsp70 and hsp90 is stimulated by their binding to unfolded proteins, with ATP hydrolysis promoting dissociation of the complex.

hsp70 has been implicated: 1) in the assembly of immunoglobulins, by binding to heavy chains in the endoplasmic reticulum (ER) prior to their assembly with light chains; 2) in the folding of influenza hemagglutinin; and 3) in the translocation of proteins across the mitochondrial membranes and possibly also the ER membrane. This is achieved by binding to unfolded protein substrate as it appears in the mitochondrial matrix (or ER lumen), thus pulling it in and stabilizing it in an unfolded state and preventing it from precipitating. A structure of the substrate binding unit of DnaK has been solved and shows a unique peptide-binding site comprising a channel which can be closed by a lid.

hsp90 may function in a similar way to hsp70 although it forms longer lived complexes with some substrates, displays a higher degree of substrate specificity and (perhaps consequently) is less effective in facilitating the experimental refolding of *in vitro* denatured substrates.

hsp60 has a characteristic oligomeric structure of 14 subunits arranged in a stack of two heptameric rings. Successive rounds of substrate binding, ATP hydrolysis and substrate release allows newly synthesized proteins to fold in a controlled way in the core of this stack. The hsp60 14mer normally functions in association with a heptameric ring of hsp10, which stimulates ATPase activity and acts as a lid on the stack. The proper folding of one protein substrate molecule requires several rounds of ATP hydrolysis by the hsp60/hsp10 oligomer. Newly synthesized proteins may therefore first bind to hsp70 or hsp90, before being passed to hsp60 for folding.

Ubiquitin, which has been included in this entry because of its upregulation during stress, is not a molecular chaperone, but is normally employed in the intracellular turnover of cytosolic proteins as a molecular 'tag' for unfolded proteins which are destined for degradation by the 26S proteasome. In some systems, the enzymes which attach ubiquitin to protein substrates via an isopeptide bond (E2s) are also heat inducible.

Function in thermotolerance

Abundant evidence indicates that hsp's play a vital role in thermotolerance. For example, mild heat shock (enough to induce hsp synthesis) protects cells against a subsequent, otherwise lethal sudden temperature increase. Microinjection of hsp-specific antibodies into cultured cells abrogates their ability to survive the effects of elevated temperatures. Clues to the role of hsp's in thermotolerance have been sought from their normal cellular roles. Thus, these proteins may stabilize partially unfolded states of proteins whose tertiary structure is disrupted by heat. This interaction would prevent heat-damaged proteins from aggregating and forming a toxic intracellular precipitate in the same way as for newly synthesized prefolded proteins. Heat shock proteins may also dissociate aggregates of denatured proteins. hsp60 in conjunction with hsp70 might even recover native proteins from these denatured states. In addition to simply stabilizing heat denatured proteins, hsp's are thought to maintain thermotolerance by promoting their degradation. This could be achieved by keeping an unfolded protein in a protease-sensitive conformation, or by stabilizing a more active conformation of the protease itself. Ubiquitin plays a key role in the degradation of abnormal proteins which would be expected to accumulate during stress. Indeed, ubiquitin may be induced by the intracellular accumulation of denatured proteins.

Stress proteins as target antigens

In infection

Heat shock proteins have been shown to be among the dominant antigens recognized by both the regulatory (helper T lymphocytes) and effector (B lymphocytes and cytotoxic T cells (CTLs)) arms of the adaptive immune system for a variety of pathogenic infections and experimentally induced immune reactions.

B cell responses In mice, immunization with a mycobacterial lysate elicits antibody responses to only a limited number of *Mycobacterium tubercu-*

losis or *M. leprae* antigens, including hsp70, hsp60, hsp18 and hsp12. In a World Health Organization sponsored workshop, a collection of 24 murine monoclonal antibodies raised against *M. leprae* were found to recognize six proteins, of which three were stress proteins. Seven of these antibodies identified six different epitopes of hsp60. Similar results were obtained with monoclonal antibodies raised against *M. tuberculosis*. Mycobacterial stress proteins are also recognized by the sera of patients suffering from tuberculosis (and tuberculoid leprosy). hsp60 is the dominant target antigen of serum antibodies in a wide variety of other bacterial infections including those due to *Coxiella*, *Legionella*, *Treponema* and *Borrelia*. In fact, an immunodominant antigen long known to be shared by most bacterial species called 'common antigen' turns out to be hsp60. Antibodies to hsp70 have been found in the sera of patients with diverse parasitic infections, for example malaria, trypanosomiasis, leishmaniasis and schistosomiasis. In addition, hsp90 is a target for antibodies in malaria and trypanosomiasis and a member of the small hsp family is recognized by sera from some patients with schistosomiasis.

T cell responses Twenty per cent of the CD4⁺ T cells cloned from the draining lymph nodes of mice immunized with *M. tuberculosis* recognize hsp60. Some of these have been shown to secrete interleukin 2 (IL-2). hsp60 is also a major target antigen in mycobacteria-infected humans. Typically 25–30% of the mycobacteria-reactive CD4⁺ T cell clones isolated from infected individuals react against *M. leprae* hsp60. Around 12 separate epitopes have been mapped in the hsp60 protein of mycobacteria which are recognized by MHC class II restricted CD4⁺ T cells. CD4⁺ T cells recognizing hsp60 have also been isolated from individuals immunized with heat-killed *M. tuberculosis*. Mice immunized with a tryptic digest of *M. tuberculosis* have been shown to yield CD8⁺ CTLs specific for epitopes on hsp70. In addition, CD8⁺ CTLs recognizing *M. tuberculosis* hsp70 have been isolated from the pleural effusion of patients with tuberculosis. Human $\gamma\delta$ receptor-bearing T cells which recognize hsp60 have been isolated from the peripheral blood of individuals immunized with BCG.

In autoimmune disease

Because hsps are ubiquitous and highly conserved, and have been shown to be dominant antigens in a range of infections (see above), they have been proposed to provide a link between anti-infectious and autoimmune responses. Thus, antibodies and T cells elicited to hsps encoded by a pathogen might cross-

react with self-hsps. Indeed, peptides derived from endogenous (self) hsps have been isolated from the binding grooves of both MHC class I and class II molecules. Anti stress protein reactive T cells have been implicated in two experimentally induced animal models of autoimmune disease and also in rheumatoid arthritis.

Adjuvant arthritis Intradermal injection of heat-killed *M. tuberculosis* in rats induces a disease similar in many respects to rheumatoid arthritis. An autoimmune process involving T lymphocytes is responsible for the generation of the disease, and transfer of T cells from arthritic rats to irradiated recipients can cause a transient form of the disease in the latter. One arthritogenic T cell clone was shown to recognize a mycobacterial hsp60 epitope. Also, immunization of mice with mycobacterial hsp60 in immunostimulating complexes (ISCOMS) will induce CD8⁺ $\alpha\beta$ CTLs which cross-react with murine hsp60 and are therefore autoreactive.

Streptococcal cell wall induced arthritis (SCIA) Similar results have been obtained for a second polyarthritic disease in rats, SCIA, which can be induced by intraperitoneal injection of *Streptococcus pyogenes* cell walls. Streptococcal cell wall preparations contain an antigen recognized by antimycobacterial hsp60 antibodies and T cells. Again, the disease condition can be transferred with purified T cells.

Rheumatoid arthritis Results with adjuvant arthritis prompted investigators to ask whether T cells from rheumatoid arthritis patients can also recognize mycobacterial hsps. In some studies, mycobacterial hsp60 and hsp70 have been shown to be among the antigens recognized by polyclonal synovial T cells, and there is evidence that these can cross-react with human hsp70. $\gamma\delta$ T cells have also been cloned from rheumatoid synovia which respond to mycobacterial hsps. Moreover, elevated levels of IgG and IgA antibodies that bind mycobacterial hsp60 and hsp70 have been detected in some patients with rheumatoid arthritis. However, any role for mycobacteria (or indeed any other infectious agent) in the development of rheumatoid arthritis in humans remains highly speculative.

Stress proteins and other chaperones in antigen-presentation pathways

hsp70

The ER-resident member of the hsp70 family, BiP, has been shown to associate with newly synthesized

human (but not mouse) MHC class I molecules. It is unclear whether this association is important for the assembly of class I molecules, or whether the BiP:heavy chain complex is an intermediate on the way to heavy chain degradation in the ER. Similarly, MHC class II molecules synthesized in the absence of invariant chain associate with BiP prior to their intracellular degradation.

Antibodies raised to a unique, constitutively expressed member of the hsp70 family (PBP72/74) block MHC class II restricted antigen presentation. Although it is not clear how PBP72/74 is involved, the well-documented ability of hsp70 to bind peptides in an ATP-dependent way suggests that one way may be to protect or transport peptides prior to their association with MHC class II. A similar role has been suggested for cytosolic hsp70 in the chaperoning of peptides from their site of production (the proteasome) to the TAP transporter, although the evidence is extremely indirect and is based on the ability of hsp70-peptide complexes to induce peptide-specific CTLs.

hsp90

Both hsp90 and grp95 (as well as hsp70 – see above) purified from meth-A induced tumors can elicit MHC class I restricted CTLs which are specific for the tumors from which the hsps were purified. These CTLs actually recognize peptides which copurify with the hsps, in a class I restricted way, and this observation has led to the suggestion that hsp90 serves to chaperone these immunogenic peptides to an intracellular site where they can bind to class I. By extension, it has been suggested that grp90 may normally play a role in chaperoning peptides arriving in the ER from the TAP transporter to awaiting MHC class I molecules.

Ubiquitin

The proteolytic events involved in generating antigenic peptides in the cytosol for presentation with MHC class I molecules involve the proteasome. This multicatalytic complex is responsible for disposing of ubiquitin-tagged proteins (see above), and the requirement for ubiquitination of cytosolic proteins destined for the MHC class I processing pathways has been implicated in a number of instances. For example, a temperature-sensitive Chinese hamster ovary (CHO) cell mutant of one of the ubiquitinating enzymes was able to present cytosolic antigens to

MHC class I restricted CTLs at the permissive, but not the nonpermissive temperature.

Calnexin and calreticulin

Although the ER-resident chaperone proteins calnexin and calreticulin are not stress proteins, they are included here for the sake of completeness. They bind to newly synthesized MHC class I heavy chains as they assemble with β_2 -microglobulin and retain them in the ER until they are fully assembled with antigenic peptides supplied by the TAP heterodimer.

Class II specific molecular chaperones: DM and Ii

Similarly, two proteins involved in the biogenesis of MHC class II-peptide complexes are included here even though they are not stress-induced. Invariant chain (Ii) prevents MHC class II molecules from aggregating in the ER; hinders their association with peptides in the ER; and specifically targets newly synthesized MHC class II molecules to the endosomal compartment. There it is degraded, leaving an Ii-derived peptide called CLIP bound in the MHC class II peptide-binding groove. The removal of this peptide, and its replacement with an antigenic peptide is facilitated by the MHC-like molecule DM which is itself encoded within the MHC class II locus.

STROMAL CELLS

Richard L. Boyd, Department of Pathology and Immunology,
Monash Medical School, Prahran, Victoria, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

One of the distinguishing features of lymphoid development is that it involves blood-borne multipotential precursor cells seeding to a selective site where their differentiation to phenotypically and functionally distinct mature cells is induced. This is regulated by a population of sessile cells, collectively termed stromal cells, which form an interconnected network providing not only the structural integrity of the organ but also the specific inductive microenvironment responsible for the differentiation and maturation of the incoming precursor cells. As distinct from hemopoiesis, the complete spectrum of lymphocyte development, particularly that of T cells, cannot be induced by a combination of cytokines – cell:cell plasma interactions are a critical requirement. Identification of the non-MHC (major histocompatibility complex) surface molecules involved in this is a central focus of research into the lymphoid microenvironments. Given that there are as many as 8–10 steps in T and B cell development lineages, each definable by a combination of surface molecules rather than single stage-specific markers, a logical prediction would be that the stromal cells controlling these pathways are equally complex. Despite the wide acceptance of the term ‘stromal cells’, historically based on the lack of histologically distinct features between these cells, more sophisticated phenotypic analyses now make it clear the stromal cells and their organization are equally as complex as the cells whose development they regulate. The thymus as the primary lymphoid organ for T cell genesis is the best studied for stromal cells, its composition and structure serving as a valuable model for other tissues (Figure 1).

Thymic stromal cells

Basic thymic structure

Thymus stromal cell heterogeneity is no doubt a direct reflection of the input of all three germ layers. The thymus is bounded by a connective tissue capsule. Between this and the underlying epithelium is a subcapsular space which contains some vasculature and is the site of entry of blood-borne precursors and macromolecules. It is thus very likely that the thymus is bathed in plasma constituents, which has very important implications for self tolerance. Fibroblast- and type 1 collagen-rich trabeculae branch off from the capsule and penetrate the cortex, terminating at

the corticomedullary junction, thereby lobulating the thymus and providing a structural link between the subcapsule and the medulla. These trabeculae are well vascularized and innervated and contain predominantly fibroblasts and macrophages; there are also minor populations of adipocytes, eosinophils, neutrophils, plasma cells, mast cells and granulocytes. Towards the internal base of the trabeculae are the perivascular spaces which effectively constitute the blood–thymus barrier. These connective tissue-rich regions are actually external to the thymic parenchyma, being separated from it by type 1 epithelium (see below) and from the vascular endothelial cells by basal laminae. They contain multiple leukocytes, including neutrophils and mature T and B cells and even germinal centers. Although there is no formal barrier dividing the cortex from the medulla, both of these areas are readily definable by their desmosomal-linked epithelium which have been extensively classified ultrastructurally and phenotypically.

Epithelium

Subcapsular/subtrabecular/perivascular (type 1 epithelium) Immediately underlying the capsule and lining the internal face of the trabeculae and perivascular spaces is a continuous layer of flattened epithelium which rests on a basal lamina, effectively separating cells of the connective tissue compartment from the lymphoepithelial compartment. This is termed type 1 or lining epithelium. It completely encases the cortex at the interface with the trabeculae and the capsule, but it is discontinuous at the base of the trabeculae. This latter feature may have important implications for cellular migration from the vasculature into the thymus. Phenotypic similarity with neuroendocrine tissue suggests this epithelium has its neurogens from the neural crest. Many antigens expressed in the subcapsular epithelium are shared with the medullary epithelium, indicating a potential lineage relationship, but they also express region-specific molecules. This is best exemplified in the chicken, where the subcapsular type 1 epithelium is exclusively defined phenotypically. Furthermore there is ultrastructural and phenotypic heterogeneity within the type 1 epithelium. Being such a discrete region, its functional significance is difficult to investigate but its potential importance stems from the finding that there are

Figure 1 The thymic stromal architecture. (Reproduced by permission from *Immunology Today* 14: centrefold. The author is very grateful to D Godfrey for the provision of the figure.)

abnormalities in type 1 epithelium prior to the onset of autoimmune disease in genetically prone chickens. It is unlikely to involve abnormal selection to self peptides, however, because the type 1 epithelium is very poor, if not negative, in MHC class II expression. Given that this is the site of intrathymic precursor entry and subsequent localization and many of these are dividing, the working hypothesis for the role of the type 1 epithelium is that it attracts blood-borne precursor cells and induces their activation/proliferation, which may be subsequently coupled to TcR gene rearrangement and commitment to the T cell lineage.

Cortical epithelium Over 85% of thymocytes are localized within the cortex. The cortical epithelium consists of an interconnected network of stellate-shaped cells characterized by relatively small cell bodies and long cytoplasmic processes which surround the tightly packed thymocytes. There is a remarkable degree of elasticity in the cortical epithelium, as it is able to rapidly expand and contract

in response to shifts in the thymocyte pool, essentially keeping the desmosomal contacts intact. Although most monoclonal antibodies (mAbs) which react with cortical epithelium label the entire network, there is evidence at the ultrastructural level of heterogeneity. Types 2 and 3 epithelial cells are located in the outer cortex, have large nuclei, are metabolically active and often form thymic nurse cells (TNCs). Type 4 epithelial cells are 'dark', electron dense with more oval/spindle-shaped nuclei and located in the deeper cortex/medullary regions.

Of the many structural features of the thymus, TNCs are arguably the most interesting. They are multicellular complexes consisting of a cortical epithelial cell (type 2 or 3) which has physically encompassed surrounding thymocytes varying in number from <5 to over 100, depending on the species. These T cells are not within the cytoplasm but rather encompassed within vacuoles formed by the extensive plasma membrane processes of the epithelial cell. Whether TNCs are fully enclosed structures *in situ* is debatable but the intimate association between the

enclosed thymocytes and the epithelial plasma membrane is indicative of a major role in thymopoiesis. The epithelial cell expresses high levels of MHC class I and II. In fact these structures may be microcosms of T cell development because they contain CD3⁺CD4⁺CD8⁻ precursors, CD3⁺ or CD31⁺ CD4⁺CD8⁺ immature T cells and phenotypically and functionally mature CD3^{hi} CD4⁺CD8⁻ and CD3^{hi} CD4⁺CD8⁺ cells. The level of mature T cells in TNCs is increased in TcR transgenic mice. Hence TNCs may be the primary site of positive selection, given the current dogma that this is the domain of cortical epithelium. Consistent with this is the presence in TNCs of acidic organelles necessary for antigen processing and presentation. There is also evidence of apoptosis in TNCs, which may reflect negative selection or death of T cells with a nonproductive TcR or one which fails to recognize self MHC-peptide complexes. Although there are relatively few TNCs per thymus, they may represent the most extreme form of dynamic opening and closing pockets of thymopoiesis in the cortex.

Medullary epithelium Unlike the stellate network of the cortex interconnected by long cytoplasmic processes, the medullary epithelium is more compact. The medulla is clearly distinguished from the cortex phenotypically, which may reflect different germ-layer origins, although the subcapsule and medulla share antigens. This relationship between the subcapsule (type 1 epithelium) and medulla is still unresolved, but since the former also lines the trabeculae, which extend into the corticomedullary junction, there is a continuous physical link between the outer and inner thymus. Hence precursor cells entering the thymus at either the subcapsule or corticomedullary junction will encounter the same epithelial cells. The profound phenotypic differences between the cortex and medulla no doubt reflect functional differences but these are still speculative. Medullary epithelium is not necessary for positive selection but it may contribute; it does have a role in tolerance at the level of inducing anergy rather than deletion. Given that T cell migration is thought to occur from the medulla, the epithelium in this region might provide the necessary differentiation signals. In addition to the interconnecting epithelium network in the medulla, there are also small clusters of swirling keratinized epithelial cells termed Hassall's corpuscles, particularly in the human, which typify the thymus. They are likely to be end-stage epithelium and may also be a site of removal of dying medullary thymocytes.

Origins of epithelium Although still unresolved, it is likely that both ectoderm and endoderm contribute

to the thymic epithelium and mesoderm to the leukocyte component. Whether the cortex and medulla derive from separate precursors or are different maturation stages of a common lineage is also unresolved. Until recently, the dogma was that there is a putative epithelial stem cell expressing determinants of the cortex or medulla, which develops into either of these regions, depending on the inductive signals it receives. It now appears likely that both regions develop autonomously and their maturation and expansion, at least in part, are dependent on the T cells themselves – immature thymocytes regulating cortical epithelium and mature T cells of either $\alpha\beta$ - or $\gamma\delta$ -TcR type inducing medullary epithelium expansion. This highlights an important symbiotic developmental relationship between the thymocytes and the stromal cells.

Nonepithelium

Despite its primary role as the central organ for inducing T lymphocyte development, but consistent with the need to present immature T cells with a broad spectrum of self antigens, there is a surprising heterogeneity in the stromal cell compartment.

While the epithelial cells constitute the specific microenvironment, they do not act alone but rather in concert with a heterogeneous group of nonepithelial stromal cells. Of these, the most important are the dendritic cells, which are the subject of separate entries in this encyclopedia. There are two types of dendritic cells in the thymus – those of so-called lymphoid origin and those of myeloid origin. Their relative intrathymic localization is not clearly known but, as a population, dendritic cells are spread throughout the thymus, with preferential localization at the corticomedullary junction where they are thought to be the major mediators of negative selection through their specialized ability to trap, process and present antigen. In addition, MHC-class II negative macrophages are also present throughout the thymus, including within the trabeculae; their major role is in the removal of the vast number of thymocytes which die *in situ*. One of the more unusual stromal cells in the thymus are myoid cells which are present in the medulla. These contain contractile proteins reminiscent of striated muscle. Their role is unknown but they may influence T cell migration, and the presence of acetylcholine receptors on them is no doubt important for establishing tolerance to neuroendocrine molecules. In thymic hyperplasia, these acetylcholine receptors may be involved in the pathogenesis of myasthenia gravis. Fibroblasts and reticular fibroblasts are a major part of the trabeculae but they also surround the vasculature and are present scattered throughout the cortex in particular.

While they clearly have a structural role in the thymus, undergoing activation following thymic damage, the fibroblasts also provide the differentiation-inducing ligand for CD44, which is expressed on intrathymic precursors.

Given the obvious importance of vascular endothelium cell adhesion molecules and/or their ligands in mediating leukocyte extravasation at sites of inflammation, and lymphocyte trafficking through high endothelial venules in lymph nodes, it is highly likely that they also play an important role in thymocyte migration. It is unclear precisely how and where precursors enter the thymus and mature cells emigrate, although it is likely to be complex because E-cadherin – a member of the cadherin superfamily of adhesion molecules – apparently mediates migration of prethymic but not intrathymic precursors.

How does the thymic stroma influence thymopoiesis?

Despite the obvious functional importance of the thymic stroma, precisely how it mediates T cell development is unclear. MHC–peptide complexes are essential for selection and while most cells can mediate negative selection, the current dogma is that cortical epithelium would appear to be unique in its ability to induce positive selection. There appear to be differences in MHC class II expression, peptide processing and antigen presentation properties between cortical and medullary epithelial cells, which may facilitate their preferential roles in positive selection and self tolerance, respectively. It is feasible, however, that medullary epithelium is potentially capable of inducing positive selection but, because of the structural restraints of the thymic architecture, do not contact the appropriate target thymocytes. The identity of the plasma membrane molecule(s) responsible for positive selection is one of the major unsolved questions of thymus function. While much of thymic function is organ autonomous, it is very much under the influence of neuroendocrine molecules.

Thymic epithelial cells produce many cytokines, particularly interleukin 7 (IL-7), which promotes precursor survival and TcR gene rearrangement, and transforming growth factor β (TGF β), a product of subcapsular and cortical epithelial cells, which also regulates the differentiation of early thymocyte subsets. While cytokines obviously have important roles, no combination to date, alone or in conjunction with nonthymic stromal cells, has been able to recapitulate complete T cell differentiation from precursor through to mature T lymphocyte. Extracellular matrix proteins are important in cellular differentiation and function in many systems including the

thymus. A wide variety of extracellular matrix constituents have been described in the thymus, such as laminin, fibronectin, merosin and type I and IV collagens, each localizing to discrete regions. These may influence thymopoiesis either directly through provision of ligands for specific T cell surface receptors or indirectly by trapping cytokines by acting as a reservoir. They may also facilitate thymocyte migration through the stromal milieu. Multiple cell adhesion receptor–counter-receptor pairs, such as LFA-1/ICAM-1, -2, VLA-4/VCAM-1 and $\alpha_E\beta_7$ /E-cadherin, have been proposed to be involved in thymic stromal cell–T cell interactions, and, while none appear to be imperative for thymopoiesis, their combined effects and coordinated expression patterns could be major constituents of the specific thymic microenvironment.

Bone marrow

As the primary lymphoid organ in mammals generating B lymphocytes, and the major site of hemopoiesis, it is not surprising that stromal cells also play an important role in the microenvironment of the bone marrow. In contrast to the thymus, bone marrow stromal cells are almost all mesenchymal in origin. The cellular architecture of this tissue is obviously much more difficult to study than that of the thymus, and there has not been a concerted phenotypic analysis of these cells with specifically targeted mAbs. Electron microscopy and, in particular, numerous *in vitro* culture systems of bone marrow stromal cells, either as heterogeneous mixtures or long-term cell lines (LTBMCs) and clones, have provided some insight into the nature of the bone marrow stroma. It is clearly a complex three-dimensional matrix consisting primarily of cells broadly defined as: adventitial reticular cells which are localized around venous sinuses and regulate blood cell flow; fibroblastic reticular cells present in the marrow hemopoietic cord and in close proximity to foci of granulopoiesis; macrophages dispersed throughout the marrow including the central erythroblastic islands and surrounding the sinus endothelium, adipocytes which form the majority of the marrow cavity, and the vascular endothelium. All of these cells and their associated extracellular matrices are proposed to be involved in various phases of haemopoiesis and/or B cell genesis. Cell culture has provided one approach to resolving the cellular basis to bone marrow function. Following the original 'Dexter' long-term cultures of bone marrow stroma for hemopoiesis, various modifications have been described, notably that of Wittlock and Witte, which skew the cultures towards B cell genesis. The identity

of the stromal cell(s) mediating B cell genesis is unclear but similar activity has been reported for some non-bone marrow stromal cells, including the thymus and fetal liver.

A variety of cytokines are produced by bone marrow stroma including G-CSF, M-CSF, GM-CSF, IL-1, IL-6, IL-7, IL-8, IL-11, SCF, TGF β , TNF; these are released into the immediate environment but may also selectively bind to components of the extracellular matrix, forming foci of cytokines. Bone marrow stromal cells also express many of the cell adhesion molecules important for induction of lympho- and hemopoiesis and, together with the cytokines, for maintaining the structural integrity of the microenvironment.

Not only are the bone marrow stromal cells vitally important for normal blood cell development, there is also evidence that they may be of etiological significance in some forms of leukemia development, although leukemia-associated abnormalities in bone marrow stromal cells may be a consequence rather than cause of leukemia.

In conclusion, the specific inductive microenvironments of the primary lymphoid organs are clearly encompassed within the stromal components. These cells, however, may not only be exclusive to the thymus or bone marrow. Some may be present in other sites throughout the body, such as the spleen, gastrointestinal tract and fetal liver, but it is their structural organization and proximity to the cells whose development they induce and regulate that normally provides the capacity for highly efficient lympho- or hemopoiesis. As a corollary, abnormalities in these cells at the cellular, molecular or structural levels could be of etiological significance in development of disease states such as leukemia or immunodeficiencies. The generic term 'stromal cells' clearly belies their phenotypic and functional complexity. Identification of the specific stromal cell genes which regulate lymphopoiesis and the factors determining the structural organization of the lymphoid tissues remain the key areas of research in this field, the ultimate goal being to target stromal cell products as a rational approach to immunotherapy.

STRONGYLOIDIASIS

Robert M Genta, Department of Pathology, Medicine, and Microbiology and Immunology, Baylor College of Medicine, Center for Infectious Diseases, University of Texas, and Veterans Affairs Medical Center, Houston, Texas, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Strongyloidiasis is caused by infection with any member of *Strongyloides*, a parasitic genus comprising 38 named species collectively known as threadworms. Humans, dogs and cats are infected by *Strongyloides stercoralis*. *S. ratti* is a parasite of wild rodents which has a worldwide distribution and can be easily maintained in laboratory rats and mice. The relationship of these two species with their respective hosts' immune system has been investigated most extensively, but other species are of considerable clinical and economic importance. These include *S. fülleborni*, primarily a parasite of primates, but known to cause human infections in Africa and New Guinea; *S. ransomi* and *S. westeri*, which infect swine and equines, respectively, on the American continent; and *S. papillosus*, found in ungulates throughout Europe and North America.

Life cycle

The adult females of *S. stercoralis* reside in the lamina propria of the small intestine, just underneath the epithelial layer. Their eggs hatch locally and liberate rhabditoid larvae. These slow-moving, plump larvae reach the intestinal lumen and pass into the external environment with the feces. In the soil, they molt into slender, fast-moving filariform larvae, the infective forms able to penetrate the skin of suitable hosts. From the skin, filariform larvae follow poorly understood migratory pathways, molt several times along the way, become adults and settle in their small intestinal niche.

S. stercoralis has the ability to reproduce within a single host, a phenomenon referred to as autoinfection. This occurs as some rhabditiform larvae molt into the infective filariform larvae while still in the host's intestine, penetrate the colonic wall, complete their cycle and return to the small intestine as adult parasites. Otherwise healthy hosts may harbor asymptomatic infections for decades while the total worm burden appears to remain relatively constant. In compromised hosts, particularly those receiving corticosteroids, the host-parasite balance may be altered, with a resulting amplification of the autoinfectious cycle (hyperinfection) that rapidly leads to the widespread dissemination of filariform larvae throughout the body and death.

Humoral immune responses

More than 90% of immunocompetent patients with strongyloidiasis have detectable serum levels of immunoglobulins of the IgG, IgA and IgE classes specifically directed against the antigens of *S. stercoralis* filariform larvae. The most prominent humoral response directed against *S. stercoralis* filariform larvae is represented by the IgG4 subclass. More than 50 different antigens, most between 15 and 100 kDa, are recognized by IgG4, while less than 20 antigens are recognized by the other IgG subclasses. A 40 kDa protein identified as zinc endopeptidase and two other unidentified proteins (31 and 28 kDa) are among the antigens that elicit the most consistent and specific responses in infected patients. There is no evidence, however, that any of the circulating antibodies directed against *S. stercoralis* antigens have a role in protecting the host against dissemination. Many patients without detectable humoral responses against parasite antigens have apparently well-controlled, asymptomatic infections. High titers of parasite-specific antibodies may be found in the serum of immunocompromised patients with disseminated infection. Immunologic studies in primate and canine models of steroid-induced disseminated strongyloidiasis have failed to demonstrate a relationship between humoral responses and the course of the parasitosis. Partial protection against primary infection, however, has been demonstrated in rats actively and passively immunized against *S. ratti* larval antigens.

Cellular immune responses

In published reports of patients with disseminated strongyloidiasis, some unspecified impairment of the cell-mediated immunity is often cited as the cause of the dissemination of the parasite. Though plausible, this concept is not supported by experimental or clinical data. In canine and primate models no correlation has been demonstrated between decreased lymphocyte responsiveness to *S. stercoralis* antigens *in vitro* and behavior of the infection. Human studies have been few and inconclusive, in part because immunocompromised patients with disseminated infection are frequently on drug regimens that greatly and nonspecifically depress their cellular immune response.

An argument against a central regulatory function of cellular immunity in the protection against disseminated strongyloidiasis is provided by the fact that disseminated *S. stercoralis* infection has not emerged as an opportunistic infection in patients with the acquired immune deficiency syndrome (AIDS), even in areas such as Central Africa and Brazil where both strongyloidiasis and AIDS are highly endemic. Thus, the host factors that regulate the autoinfection may not be affected by the destruction of the effector branch of the immune system occurring in AIDS.

Hypothetical regulatory mechanisms

Investigations of the relationship between *S. stercoralis* and its hosts have resulted in the characterization of a number of immune responses, some of which (IgG and IgE) have been exploited to develop sensitive and specific serodiagnostic tests. However, the regulatory mechanisms that appear to control the parasite population in competent hosts and fail to operate in the presence of immunosuppression still elude explanation.

A recent theory suggests that glucocorticosteroids themselves (but not their immunosuppressive effects) could cause the dysregulation of the infection that may lead to hyperinfection. According to this hypothetical model, *S. stercoralis* maintains the optimal size of its parasitic population in the human duodenum by regulating larval molting through the production of ecdysteroids (molting hormones found in most invertebrates, including parasitic worms). The host develops specific humoral and cellular immune responses which, although insufficient to eradicate all the parasites, may exert an additional control over the size of the population. Their absence may

allow the development of larger parasitic populations, but does not cause total dysregulation because, to a large extent, worms regulate themselves. Similarly, the presence of these host responses is not sufficient to prevent dissemination should the parasitic population's own regulatory mechanisms fail. The administration of exogenous — and in some cases, even an excess of endogenous — glucocorticosteroids results in increased amounts of ecdysteroid-like substances in the host's tissues, including in the intestinal wall, where adult females reside. These substances may compete with ecdysteroid receptors and send molting signals to the existing rhabditiform larvae, which transform intraluminally into filariform larvae. Once a population has become very large it may continue to expand rapidly even at low molting rates, and the discontinuation of steroids may not be sufficient to arrest the relentless growth process. The population has been irreparably dysregulated and forced to do what parasites have learned to avoid: kill their host.

SUPERANTIGENS

Terje Kalland, Pharmacia & Upjohn, Nerviano, Italy

Mikael Dohlsten, **Per Antonsson** and **Morten Sögaard**, Pharmacia & Upjohn, Lund Research Center, Lund, Sweden

Superantigens (SAGs) are proteins produced by bacteria and viruses that are able to stimulate a large proportion of T lymphocytes via interaction with the variable domain of the β chain of the T cell antigen receptor (TCR-V β). To be presented to the TCR, SAGs must bind to the major histocompatibility complex (MHC) class II molecules. In contrast to con-

ventional peptide antigens which generally activate <0.01% T cells, SAGs have the ability to stimulate 2–30% of the T cell repertoire. SAGs are extensively used in studies of T cell biology in humans and rodents. SAG-mediated immune activation is likely to be responsible for some of the characteristic symptoms associated with infections with SAG-producing

microbes, such as the toxic shock syndrome and food poisoning caused by staphylococci.

The superantigen family of bacterial and viral proteins

Proteins with SAg property are produced by evolutionary divergent microorganisms, including gram-positive bacteria, gram-negative bacteria, mycoplasma, rhabdoviruses and retroviruses and it is likely that SAGs confer a biological advantage in terms of survival and persistence of the microorganisms in the host. Proteins reported to have SAG properties are listed in Table 1. The prototype bacterial SAGs are the *Staphylococcus aureus* entero-

toxins (SEs). The SEs are single-chain polypeptides with high intrinsic stability and molecular masses ranging from 22 to 28 kDa. The amino acid sequence homologies among different SEs varies from 20 to 80% identity. The structure of several SEs (SEA, SEB, SEC₂, SED and TSST-1) has been determined by X-ray crystallography which revealed a highly similar topology in their three-dimensional structures, indicating a strong evolutionary pressure to preserve the structural integrity of the proteins. In general, they are monomeric two-domain structures (Figure 1). The two domains are made up of two β sheets capped by an α helix (domain I) and a β sheet packed against a central helix (domain II).

Mouse mammary tumor viruses (MMTV) are the

The data has been collected from various reports. Some of the SAGs are not yet available in recombinant form and their classification as SAGs remains uncertain. Mtv, mouse mammary tumor virus; SE, staphylococcal enterotoxin; TSST-1, toxic shock syndrome toxin 1; ExF-T, exfoliative toxin; Spe, streptococcal pyrogenic toxin; SSA, streptococcal superantigen; MAM, mycoplasma arthritis mitogen.

Figure 1 Molscript model of SEA interacting with two MHC class II molecules. SEA is colored red, MHC class II and bound peptide blue and purple, respectively. On the left-hand side MHC class II β -chain contacts the SEA coordinated zinc ion (yellow) through a histidine residue on the MHC class II β chain (His81, illustrated as ball-and-chain). The right-hand side shows the interaction between MHC class II α chain and SEA. This point of interaction is centered around a phenylalanine residue in SEA (Phe47, illustrated as ball-and-chain) and a lysine residue in MHC class II α chain (Lys39, illustrated as ball-and-chain). The TCR binding interface is located at the top of the SEA molecule. (See also color Plate 9.)

best characterized viral SAGs. They were originally discovered because of their ability to stimulate a primary mixed lymphocyte reaction between MHC-identical mice (Mls antigens). MMTV SAGs are encoded within the 3' long terminal repeat of the virus genome, either by retroviral cDNA incorporated in the mouse genome or from B lymphocytes infected with MMTV. They are type II membrane proteins of approximately 320 amino acid residues. Most likely, the MMTV SAG is a proteolytic cleavage fragment of the full length protein. The products of the SAG genes of the MMTV affect the T cell repertoire by causing thymic deletion of T cells expressing TCR encoded by V β segments reactive with the MMTV SAG. Since these deletions affect large populations of T cells with receptors of heterogeneous specificity, they serve as an important model for the study of T cell development in normal mice. A similar role of endogenous SAGs has so far not been demonstrated in humans.

MHC class II binding

SAGs do not activate T cells in solution, but generally require multivalent presentation on MHC class II-antigen-presenting cells (APCs). SAGs differ from conventional peptide antigens in that they bind as unprocessed proteins with high affinity to MHC class II molecules on APCs. In this way, SAGs are able to subvert the T cell antigen presentation pathway for their own benefit. The binding of SAGs to MHC

class II is promiscuous and allows each SAG to bind to a large number of different MHC class II alleles and isotypes, although with variable affinity. The binding of SAGs to MHC class II generally occurs outside the conventional peptide-binding groove, but the affinity is to some extent influenced by the nature of bound peptides.

Structural and functional studies have shown that SEA and SEB share a common binding site located in the amino-terminal domain, interacting with the nonpolymorphic α chain of MHC class II. In addition SEA (as well as SED, SEE and probably SEH) have a second binding site located in the carboxyl-terminal domain, which is dependent on a zinc ion for interaction with the β chain of MHC class II (Figure 1). Biochemical studies of SEA have shown that three amino acids in domain 2, His187, His225 and Asp227, are crucial for zinc coordination and interaction with MHC class II (Figure 1). Structural models suggest that SEA cannot engage the α and β binding sites on a single MHC class II molecule and indicate that SEA may cross-link separate MHC class II molecules. Cross-linking of MHC class II by SEA induces the expression of inflammatory cytokines in monocytes. SEA mutants or natural SE variants lacking either the MHC class II α or β chain binding sites are unable to stimulate monocytes, implicating that cross-linking of separate MHC class II molecules is a biologically important feature allowing the release of inflammatory cytokines.

Recent studies have demonstrated that SAGs targeted to cell surfaces, by conjugation of the SAG with monoclonal antibodies to cell surface structures, activate some but not all SAG responding T cells in the absence of MHC class II. Moreover, SAGs are able to activate T cells in mice lacking MHC class II. This suggests that SAGs may engage TCRs in a functional manner in the complete absence of MHC class II. A direct interaction between SAGs and the TCR is supported by biochemical and structural data implicating a binding affinity in the μ M to mM range. MHC class II molecules are abundantly expressed on all types of APC. It is therefore possible that MHC class II molecules were favored during evolution as a SAG receptor to allow multivalent presentation on a broad variety of APC. In addition, for certain SAG-TCR combinations, MHC class II molecules contribute to create a high avidity due to the intrinsic affinity between MHC and TCR complexes.

TCR interaction

The ability of SAGs to activate such a substantial fraction of the T cell repertoire is mainly due to the interaction of SAGs with the V β domain in the TCR.

The contribution of the other five, D β , J β , V α , D α and J α , variable parts of the TCR $\alpha\beta$ complex is relatively limited. A particular SAg activates a distinct pattern of TCR-V β expressing T cells, allowing each individual SAg to give an almost unique immunological 'V β fingerprint' (Table 1).

The TCR binding region in the SE proteins is located in the vicinity of the shallow cavity formed between the two domains (Figure 1). Recent structural studies of SEC2 and SEC3 in complex with a TCR β chain indicate that the key points of interactions, in the V β chain, are located in the CDR1, CDR2 and HV4 loops.

The large family of MMTV SAgS, probably containing more than 50 different SAgS, seem to primarily differ in the outermost C-terminal part. This region has been assigned as the TCR binding domain because of a remarkable correlation with homology between different MMTV and the V β repertoire of activated T cells. MMTV interactions with TCR-V β has primarily been mapped to the HV4 loop.

Superantigens and T cell biology

T cells require two signals to be activated to proliferate and produce cytokines. SAgS essentially activate T cells in a manner similar to conventional peptide antigens. SAgS bound to MHC class II complexes on APCs provide the first signal by ligation of the TCR, while a second signal is delivered by costimulatory molecules on the APC, such as CD80 or CD86. Exposure to bacterial SAgS *in vivo* results within hours to secretion of T cell-derived cytokines, including interleukin 2 (IL-2), tumor necrosis factor α (TNF α) and interferon γ (IFN γ). This is followed within days by expansion of CD4 and CD8 T cells bearing the SAg reactive TCR-V β and development of cytotoxic T cells. IL-2 production resides predominantly in the CD4 subset, while IFN γ is produced by both subsets. Production of substantial amounts of TNF α is seen in T cells as well as monocytes, emphasizing that multiple immune cells are activated after SAg exposure *in vivo*. Activated CD8 cytotoxic T cells efficiently kill cells with SAgS bound to their MHC class II molecules, a mechanism termed SAg-dependent cell-mediated cytotoxicity (SDCC). SDCC represents a powerful mechanism for targeted T cell cytotoxicity against APCs. It has been suggested to serve as a mechanism to inactivate APCs and thereby downregulate specific immunity against the SAg-producing pathogen. Later in the activation phase, extensive T cell deletions and functional inactivation (anergy), particularly among CD4⁺ T cells, limit the size and function of the expanded T cells.

Superantigens in disease

Bacterial superantigens have been implicated as a causative agent in several acute pathological conditions, including food poisoning, toxic shock associated with staphylococcal sepsis, the toxic shock syndrome, scalded skin syndrome and scarlet fever. A common feature of these diseases is massive systemic immunoactivation, as reflected by high serum levels of TNF α , IL-1, IL-6 and IFN γ . Associated toxic shock is likely, at least in part, to be due to excessive release of cytokines.

SAgS are believed to be involved in the pathogenesis of some viruses. The MMTV retrovirus is secreted in the milk of infected mice and infects B cells of lactating pups. MMTV SAgS presented on infected B cells induce V β -specific T cell activation. The T-B cell interactions support proliferation of infected B cells, facilitating perpetuation and spreading of the virus. The involvement of similar SAg encoding retroviruses in human disease remains to be shown. SAgS are also implicated in the pathogenesis of rabies virus. This is supported by the fact that T cells expressing TCR-V β 6 are expanded in rabies-infected mice, and mice lacking V β 6 T cells are difficult to infect. The immunostimulatory properties of SAgS may lead to a breakdown of tolerance and favor development of autoimmune responses. In Kawasaki syndrome, a cause of acquired heart disease in children, general immunoactivation with expansion of T cells expressing TCR-V β 2 and 8 and high systemic levels of IFN γ is frequently observed. IFN γ induces expression of MHC class II molecules on aortic endothelial cells, which is believed to facilitate SAg-dependent destruction of these cells. Staphylococcus strains producing TSST-1 have been implicated as a major causative agent. In a number of autoimmune diseases, including rheumatoid arthritis, multiple sclerosis, Sjögren's syndrome, autoimmune thyroiditis and psoriasis, a skewed pattern of V β usage has been observed. Moreover, it has been shown that SEs and possibly *Mycoplasma arthritidis* mitogen induce and exacerbate autoimmune disease in various experimental models. This has suggested to a number of investigators that SAgS may be involved in modulating human autoimmune disease. However, no firm evidence is present to support a role for SAg in the initiation or perpetuation of chronic inflammatory diseases.

The potent immunostimulating properties of SAgS have recently been exploited for immunotherapy of cancer. Recombinant fusion proteins between tumor reactive monoclonal antibody fragments and SAgS mutated to reduce MHC class II binding have been used successfully to treat experimental tumors. Such

tumor-specific SAgS localized to the tumor and were able to induce massive infiltration in tumors of T cells actively producing TNF α and IFN γ , and resulted in apparent cure of animals in the absence of systemic toxicity.

SUPPRESSOR T LYMPHOCYTES

David R Webb, Cadus Pharmaceutical Corporation, Tarrytown, New York, USA

Bruce H Devens, Targeted Genetics Corporation, Seattle, Washington, USA

From almost the beginning of immunology as a research discipline, there has been the realization that the immune system must have some way of controlling or preventing antiself (autoimmune) responses. Related to this issue is the question of how the immune response is turned off once a response to antigenic challenge is initiated. In the early 1970s, Gershon, among others, made a remarkable suggestion that there existed cells in the immune system whose purpose was to inhibit the capacity to mount an immune response. These cells he termed 'suppressor cells'. He hypothesized that such cells could explain many of the phenomena that immunologists had observed earlier, such as infectious tolerance, i.e. the ability of T cells tolerant to antigen A to transfer tolerance to antigen A from one host to another without affecting the response to antigen B. For the past 20 years a large number of researchers have been attempting to unravel the complexities of immune regulation and to try to determine whether the ingenious but nonetheless controversial proposal of Gershon, namely the existence of a specific subset of T suppressor (T_S) cells, is valid.

Historical background

In the late 1960s it was found that mice made tolerant to either a hapten or protein antigen contained

lymphocytes in the spleen and lymph nodes that could specifically transfer the tolerance to a recipient animal. Conversely, fresh T lymphocytes (antigen primed or unprimed) transferred into a tolerant recipient were unable to break the tolerant state and also became tolerant. These results had two consequences: first, it was demonstrated that tolerance could be both antigen specific and dependent on the presence of a specific population of lymphocytes, namely T cells; secondly, it laid to rest the notion that the shutdown or negative control of an immune response was solely the result of antibody-dependent feedback mechanisms. Other workers, at the same time, using syngeneic murine tumor models were demonstrating that tumor-bearing animals possessed fully immunocompetent antitumor cells. Nonetheless, these mice not only failed to respond to the tumor, but contained T cells that prevented the host from making an antitumor response. Yet another converging line of studies came from experiments using strains of mice that spontaneously developed autoimmune syndromes such as the NZB/NZW F1. It was shown that T cells from young NZB/NZW F1 that had not yet developed autoimmune disease were capable of delaying the full expression of the autoimmune syndrome when transferred to older mice already beginning to show clear signs of disease.

While these studies provided the phenomenological background for the emerging hypothesis concerning the existence of specific suppressor cell mechanisms, other lines of experimentation were developing that gave the concept a more mechanistic foundation. It had been noticed in the late 1960s that certain strains of guinea pigs and mice injected with synthetic homopolymers of selected amino acids (polylysine or polyglutamic acid) failed to mount an immune response to these molecules. In subsequent exhaustive studies of this phenomenon, particularly in the mouse, it was discovered that such nonresponsiveness to synthetic polypeptide antigens was directly linked to class II genes in the major histocompatibility complex (MHC). Furthermore, it was found that at the cellular level this lack of responsiveness was not due to lack of specific B cells or T helper cells but rather was because of the preferential activation of populations of antigen-specific suppressor T cells. These studies for the first time linked the phenomenon of suppression to specific sets of genes and it was assumed that from experiments such as these eventually would come complete genetic and molecular understanding of suppressor T cell biology and biochemistry.

Further support for the role of antigen-specific T_s cells in immune regulation came from studies that showed that cell extracts or supernatants obtained from cultures of such cells contained antigen-specific suppressor molecules that could substitute for the suppressor T cells. Such studies were in keeping with the emerging concept that all aspects of immune regulation were dependent on the production of soluble cytokines that served as growth and differentiation factors as well as inhibitors of immunity. Thus it was that antigen-specific suppressor cells were noted as being different from helper T cells or macrophages in their apparent capacity to down-regulate immune responses via soluble suppressor mediators rather than augmenting them.

Lastly, the soluble mediators of suppression were unique from most of the cytokines then being studied in that they showed exquisite antigen specificity. However, it is important to note that it has now been shown that much of what was taken as evidence of cell-mediated suppression in fact represents the interaction of specific populations of T cells termed T_{H1} and T_{H2} , each of which make unique sets of cytokines that have the capacity to suppress the activity of the reciprocal cell. These observations have now been broadened into the concept of type I and type II cytokine-producing cells in the immune system since it has been found that both $CD4^+$ and $CD8^+$ T cells as well as mast cells exhibit the capacity to

express either the type I or the type II cytokine phenotype.

Finally, although T_s cells could be distinguished functionally from other regulatory T cell subsets they were indistinguishable phenotypically from T cells involved in cytotoxicity (e.g. $CD8^+$) until several workers serologically defined an apparent new locus within the MHC class II region which they termed I-J. Alloantisera specific for this locus reacted with both T_s cells and T suppressor factors (as well as with a few $CD4^+$ T cells) and thus provided what was, at that time, the only reagent that could be used to generally distinguish T_s cells phenotypically from other $CD8^+$ T cells. Within the last couple of years, new serological markers have emerged that distinguish T suppressor cells in mice and humans from other T cells. In at least one case, the serological marker in mice has been biochemically defined and monoclonal antibodies specific for this structure made available.

Cell and molecular biological studies of suppressor cells

The studies mentioned above plus numerous others clearly established that the concept of cell-based negative regulation had merit. Furthermore, the phenomenology of suppression could be demonstrated in virtually all types of immune responses. The challenge became to establish the physiological, biochemical and molecular genetic basis of suppression. The major questions that required study were as follows: 1) Does there exist a phenotypically and biologically distinct population of lymphocytes whose sole function is to specifically suppress immune responses (i.e. 'professional' T_s cells)? 2) What is the precise role of such cells in immunity (e.g. do they play a role in tolerance, autoimmunity, regulation of normal immune responses and tumor immunity) and what is the interplay between T_s cells and other regulatory elements? 3) What is the biochemical and molecular basis of T_s cell function? 4) What is the nature of the antigen receptor on T_s cells and how is it related to the antigen-specific suppressor factors?

Initially, at least, the question of a phenotypically distinct population of T_s cells did not seem a major concern since the anti-I-J antisera seemed to preferentially distinguish T_s cells from other $CD8^+$ T cells. Then, it was discovered that in the region where I-J mapped genetically (between I-A and I-E), there was no I-J gene. Furthermore, when the two strains of congenic mice that were originally used to define the I-J gene location were examined, no difference was found at the DNA level in the region where genetic

mapping had placed I-J. Thus, researchers were found in the awkward position of having antibodies to an undefined cell surface determinant present on many T_S cells that had no known genetic origin, let alone a known function. This picture has been further complicated by the observations that interferon γ ($IFN\gamma$) produced by T_H1 cells can inhibit the differentiation and cytokine production by T_H2 cells (which make interleukins 4, 5 and 10). Conversely T_H2 cell-specific cytokines can block the activity of T_H1 cells. In certain *in vitro* and *in vivo* assays such activities read out as suppression and the cytokine-producing cells have been misrepresented as suppressor cells. It is also clear that both IL-10 and $IFN\gamma$ are capable of inducing monocytes, macrophages and B cells to produce additional cytokines that can negatively regulate immune responses. This has increased our sophistication in terms of understanding immune regulation but has only partially resolved the issue of antigen-specific suppression. Researchers working in both human and murine systems have also defined cell surface markers that denote specific subpopulations of $CD8^+$ T cells that act exclusively as suppressor cells. In the mouse these have been most clearly defined by a monoclonal antibody termed 984D4.6.2 which recognizes an $\alpha 2,6$ sialic acid-lined carbohydrate defined as LSTc, a carbohydrate moiety originally detected in human milk.

Finally, several laboratories have shown that T_S cells seem to be capable of recognizing nominal antigen in the absence of antigen-presenting cells; in fact, T_S cells could be shown to bind to immobilized antigens and selected much like B cells.

An additional challenge is that until recently T_S cells could not be cloned by growth on feeder layers in the presence of antigen and growth factors such as IL-2. Although T_S hybridomas could be constructed, such lines frequently exhibit both unstable phenotypic markers (e.g. variable expression of I-J or CD8) and a variable ability to produce antigen-specific suppressor factors. There has been a continuing effort to prepare stable T_S lines that has finally met with success. Several groups now report the preparation of both human and murine T_S clones that are antigen specific, bear the T cell receptor (TCR) complex and, in some cases, secrete or release antigen-specific T suppressor factors (TSF).

In terms of the precise role for suppressor cells in normal and pathological immune responses, evidence has continued to grow suggesting that the phenomenon of suppression is an important aspect of the homeostatic control mechanism in the immune system. As mentioned earlier, T_S cells could be demonstrated in MHC-controlled immune responses to

synthetic polypeptides, in response to protein and erythrocyte antigens, in contact sensitivity reactions, in delayed-type hypersensitivity, in antitumor immunity, autoimmune disease and in transplantation immunity. The common features of such studies were the existence of some type of inducer cell that produced an antigen-specific, non-MHC-restricted TSF, and effector T_S cells that produced either an antigen-specific, MHC-restricted TSF or a non-specific TSF (probably a cytokine) that blocked T helper function.

Indirect evidence suggests that for the most part, antigen-specific T_S cells act at the level of T helper cells. Thus, recent studies show a decrease in the production of T cell-specific cytokines (e.g. IL-2 or IL-4) following activation of T_S cells. Cloned T_S cells have now been shown directly to be capable of inhibiting the production of cytokines by T helper cells, providing the first biochemical evidence for a mechanism by which T_S cells regulate immune responses. This has been perhaps best studied in models of cellular immunity involving the response to alloantigen in mice and in humans.

Recently, it has become clear that many other cells besides the putative antigen-specific T_S cells can, at times, negatively regulate immunocompetent cell function. The interaction of T_H1 and T_H2 cells is one example cited earlier. The capability of T cells to respond to closely related peptides or proteins is directly linked to the expression of an appropriate MHC class II molecule and a given clone of T cells could fail to respond to an antigen due to failure to recognize that antigen in the context of an inappropriate class II protein. Experiments have shown that a given antigen-specific T cell clone can be rendered unresponsive to antigen if it is paralyzed by an antigen overdose. T cells that have not previously been exposed to antigen may also be rendered nonresponsive if they are presented with their cognate antigen by an inappropriate antigen-presenting cell such as a B cell. Related to this is the fact that immunocompetent cells exposed to other, nonimmune cells in the body could be rendered nonresponsive by such cells (veto cells) under certain circumstances, thus preventing a potential autoimmune response. Thus, immunologists have discovered several situations in which clear-cut evidence of unresponsiveness could be demonstrated not to be dependent on the presence of antigen-specific suppressor T cells.

Over the last few years it has become clear that T cell repertoire selection takes place in the thymus and is critically dependent on the expression of the T cell receptor and associated molecules such as CD4 and CD8. Thus, many potentially autoreactive T cells are eliminated before they ever leave the thymus. Like-

wise, T cells that are not self-responsive are selected in the thymus for migration out to the peripheral tissues. It has also been discovered that B cells can be rendered nonresponsive directly via mechanisms that are T cell independent.

The picture that is emerging suggests that the initial regulation of the immune system takes place in the thymus where positive and negative selection mechanisms operate. Despite the powerful selection processes that exist in the thymus, it has been repeatedly shown that autoreactive T cells and B cells exist in the periphery. The regulation of such cells to prevent their activation has been shown to involve T_S cells. There are now data to suggest that possibly this type of T_S cell-based regulation involves a subset of T cells that can recognize T cell antigen receptor idiotypes.

The issue that has most perplexed immunologists that study T_S cells has been the inability to understand the molecular basis of T_S cell antigen specificity and the nature of the antigen-specific TSF molecules. At the beginning of the 1980s, before the discovery of the molecular nature of the T cell antigen receptor, it was known that at least one form of TSF consisted of a disulfide-linked heterodimer, one chain of which was capable of binding to its inducing antigen and one chain of which contained the restriction element or serological determinant for MHC class II (e.g. I-J). By the mid-1980s, evidence had mounted that there were probably two major classes of TSF, one was the heterodimer and the other most likely a homodimer that is expressed by suppressor inducer cells.

All of the evidence concerning the structure of the TSFs came from experiments done using culture fluids or extracts of T_S cell hybridomas. While such experiments worked well at the protein level, the critical question about the nature of TSF genes remained elusive. With the discovery of the T cell receptor genes it became possible to analyze any T cell line for the presence of appropriately rearranged genes. Initially, there was some confusion about whether T_S cell hybridomas expressed normal T cell antigen receptors. That issue has now been resolved and a number of experiments have been performed at the cellular and molecular level to explore the role of T cell antigen receptor genes and proteins in antigen-specific suppression.

Taken as a whole, the experiments indicate that the TCR α chain protein forms the antigen recognition component of soluble TSF. In some T_S cells and lines it appears that the TCR β chain protein is also involved; however in most T_S cell lines studied the molecular and genetic character of the second chain of the TSF has not been unambiguously

defined. One exception is the recent study in immediate-type hypersensitivity which suggests that the non-antigen-binding chain of the TSF is a molecule termed 'glycosylation inhibitory factor'. This molecule has been cloned and characterized as being the biologically active component of a TSF that blocks the development of immediate-type hypersensitivity in tissue culture and *in vivo*. Suffice to say this area of research remains the most controversial aspect of suppressor cell biology and in the minds of most immunologists still remains to be fully explained.

Current prospects

At the phenomenological level (e.g. in tissue culture models and *in vivo*) antigen-specific suppression of immune responses mediated by specific subpopulations of T cells can be unequivocally demonstrated using monoclonal antibodies that recognize T_S cell-specific cell surface proteins. Such proteins have also been found on putative T_S cell hybridomas and more recently on T_S cell clones. Based on the use of monoclonal antibodies and experimental data from many laboratories, it is possible to construct a hypothetical scheme (see Figure 1) in which both nonspecific and antigen-specific T_S cells play a role in the regulation of immune responses. This scheme attempts to tie the activation and regulation of T_S cells with other cells

Figure 1 Hypothetical scheme of nonspecific and antigen-specific suppressor T cell regulation of immunity. The scheme attempts to integrate cytokine-mediated regulation by T helper cells (T_{H1} and T_{H2}) with regulation mediated by nonspecific and antigen-specific suppressor T cells. DTH, delayed-type hypersensitivity; APC, antigen-presenting cell; Ag, antigen; M, macrophage; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; TNF, tumor necrosis factor; LT, lymphotoxin; IFN γ , interferon γ ; SIRS, soluble immune response suppressor; SIRS $_{ox}$, oxidized soluble immune response suppressor; T_{S1} , T suppressor inducer; TSF-1, suppressor inducer factor; T_{S2} , T suppressor effector; TSF-2, suppressor effector factor.

and cytokines. For example, it is proposed that interferon γ plays a key role in activating antigen-specific T_S cells via a mechanism similar to that involving induction of MHC class II expression. Other cytokines, such as IL-2, also play important roles in the growth and regulation of T_S cells of all types. With the relevant monoclonal antibodies, it is possible to test the validity of the scheme, at least in tissue culture models. Such antibodies also offer the chance along with appropriate cell lines to answer the fundamental questions posed earlier concerning the nature of the T cell antigen receptor on such cells and its relationship to the soluble factors produced by these cells. Only when the characterization of T_S cells and mediators at the molecular level takes place will immunologists be completely convinced that discrete antigen-specific T_S cells exist. Without such characterization, the phenomenon of antigen-specific T_S cells will remain to puzzle and perplex us.

SURFACE PLASMON RESONANCE

George Panayotou, Ludwig Institute for Cancer Research, London, UK

The use of biosensors in biomedical research has increased substantially in recent years. Many different types of biosensor have been developed, including electrochemical (amperometric, potentiometric or conductimetric), calorimetric, acoustic and

optical. Advances in the development of optical biosensors have been particularly fast and have resulted in the appearance of several commercially available instruments that are now used widely in academic, clinical and industrial laboratories. The

most commonly employed instruments have a detection system based on the phenomenon of surface plasmon resonance (SPR), which can be exploited to measure interactions between macromolecules in real time. This detection system essentially measures changes in the refractive index of the medium surrounding a 'receptor' immobilized on a solid support, which occur when a 'ligand' is allowed to bind. SPR has been particularly successful in the analysis of antibody-antigen interactions and can be used to obtain kinetic parameters (association and dissociation rate constants) and equilibrium binding constants, as well as measure concentrations, perform epitope mapping and determine antibody isotypes with experimental procedures that can be substantially more accurate, sensitive and reliable compared to conventional methodologies.

What is SPR?

When light traveling within an optically dense medium reaches the interface with a medium of lower refractive index it can be partially reflected or refracted depending on two parameters: the ratio of the refractive indices of the two media and the angle at which the incident light reaches the interface. Therefore, for a given refractive index ratio, there is a critical value for the angle of the incoming light above which total internal reflection occurs. Under these conditions, and even though the light is totally reflected, an electromagnetic field component, called the evanescent wave, penetrates the interface between the two media. As its name suggests, the evanescent wave is very weak and can only travel for approximately one wavelength within the medium of lower optical density. If the light is monochromatic and p-polarized (that is its electrical vector component is parallel to the plane of incidence) and the interface is coated with a thin layer of a metal, such as gold, then a resonance can occur between the evanescent wave and the delocalized surface of electrons (or plasmons) of the metal layer. This phenomenon, called SPR, results in amplification of the evanescent wave, taking up a considerable amount of the energy of the incident light and thus causing a measurable loss in the intensity of the reflected light. SPR only occurs at a distinct angle of the incident light, which in turn depends on the ratio of the refractive indices of the two media, the wavelength of the light and various physical properties of the metal surface. These latter parameters, as well as the refractive index of one medium can be kept constant and therefore by measuring the angle at which SPR occurs it is possible to monitor changes in the refractive index of the other medium. Since an increase in the amount

of a macromolecule causes a corresponding increase in the refractive index of a solution, SPR can be used to detect changes in mass close to a surface. For example, if an antibody is immobilized on that surface, binding of an antigen will cause an increase in the refractive index which can be measured by SPR.

SPR-based biosensors

Several optical biosensors are commercially available, all exploiting the evanescent wave and using SPR or other, wave-guiding techniques for detection. They include the BIAcore (Biacore AB, Uppsala, Sweden), IASYS (Affinity Sensors, Cambridge, UK), IBIS (Intersens Instruments, Utrecht, Netherlands) and BIOS-1 (Artificial Sensing Instruments, Zurich, Switzerland). The vast majority of published applications have used several different models of the BIAcore system and therefore the following descriptions are based on these instruments.

The BIAcore has a light source that produces a wedge of monochromatic light in order to provide a wide range of incident angles, all above the critical value for total internal reflection. The light passes through a prism and is focused on a small area (1.4×0.16 mm) on the surface of a disposable 'sensorchip'. The latter consists of a glass support on to which a thin gold film is attached. For most applications, a carboxymethylated dextran layer (100 nm thick) is fixed on to the gold surface in order to provide a hydrophilic environment for immobilization of one of the interacting components (such as an antibody, peptide or any other macromolecule). The sensorship is sealed against a micro-fluidic delivery cartridge, so that the dextran layer is present within a flowcell of precise dimensions (60 nl volume), through which solutions can be passed under conditions of constant flow and temperature. Several methods are available for immobilizing molecules on the dextran layer; the most commonly employed uses standard succinimide chemistry for the covalent immobilization of proteins through free amino groups. Indirect methods may also be used, such as immobilizing streptavidin to capture biotinylated molecules.

The principle of detection is demonstrated in **Figure 1** (as an example, antibody molecules are shown immobilized on the dextran layer). With buffer flowing through the flowcell, the medium close to the sensorchip surface has a certain refractive index which depends on the amount and size of the immobilized antibody and the composition of the buffer. SPR occurs at a certain angle, θ_1 , of incident light and is detected as an intensity 'dip' in the reflected light by

Figure 1 Schematic outline of the principle of SPR measurements using the BIAcore biosensor (not in scale). See text for further details.

a position-sensitive diode array detector (A). When antigen is injected through the flowcell, it interacts with the immobilized antibody, thus increasing the refractive index. Because of the very short distance the evanescent wave penetrates into the medium, only binding events very close to the sensorship surface are registered and the bulk of the protein solution contributes insignificantly to the signal (a 'bulk' effect can be seen at high concentrations and is constant throughout a protein injection). Upon binding, the angle of incident light at which SPR occurs changes (θ_2) and this is again registered by the detector (B). The changes in angle (C) are converted by the instrument's software into arbitrary resonance units which are plotted versus time to provide a binding curve called a sensorgram (D). The sampling rate can be set by the user and can be as high as 10 points per second, providing a real-time response. Quantitative analysis of the binding data is performed by suitable software.

Figure 2 shows examples of antigen binding to a panel of different monoclonal antibodies which are immobilized on the sensorchip. Following injection of the antigen, buffer flow is introduced resulting in dissociation of bound material and a corresponding drop in the signal. This part of the sensorgram can be used to measure the dissociation rate constant of an interaction, whereas the 'on' phase can be analyzed for quantitation of the association rate constant. Figure 2 demonstrates that different antibodies

Figure 2 An example of antibody-antigen interaction measured by SPR. The same antigen was injected separately over three immobilized monoclonal antibodies. The arrows point to the beginning and the end of the antigen injection, which is followed by buffer flow. Note the differences between the antibodies in the association and dissociation rates. (Data kindly provided by Dr R. Karlsson, Biacore AB.)

have distinct on and off rates for the same antigen. The equilibrium binding constant of an interaction can also be determined by injecting a series of concentrations and allowing the reaction to proceed to equilibrium. The response can then be plotted versus the concentration and suitable fitting algorithms can be used for quantitation.

Advantages and limitations

The main advantage of SPR-based biosensor measurements is that macromolecular interactions can be monitored in real-time, providing a large number of high-quality data for analysis. There is no need to label one of the interacting components (with radioactive or other labels) and, most importantly, it is not necessary to devise experimental conditions for separating free from bound ligands, as is the case in many alternative techniques. This is particularly useful for interactions with fast dissociation rates. These factors have allowed the quantitation of interactions in a large number of different applications.

Apart from the high cost of the instruments, the most important limitation of SPR biosensors derives from the need to immobilize one of the interacting components. The immobilization process itself may alter the properties of the ligand, necessitating the development of indirect coupling methods. Moreover, the immobilized ligand must be stable to regeneration conditions which are commonly employed in order to remove bound analytes and thus prepare the ligand for subsequent experiments. Additionally, if the amount of immobilized material is not carefully controlled, mass transport limited interactions may occur which make impossible the correct quantitative analysis of the binding curves. A further limitation regards the size of the analyte which is allowed to interact with an immobilized ligand: Since SPR measures changes in refractive index, molecules with a small mass (up to 5 kDa) will give weak signals which may not be suitable for accurate analysis.

Applications

Recent years have seen an exponential growth in the number of studies that have employed SPR to address a plethora of biological questions, too numerous to list here. Applications relevant to immunology have been particularly successful due to the high affinity, large size and stability of antibodies. Approximate ranges for the various parameters that can be measured include binding constants of 10^4 – 10^{12} M⁻¹, association and dissociation rate constants of 10^3 – 10^7 M⁻¹/s and 10^{-5} – 10^{-1} s⁻¹, respectively and concentration measures of 10^{-3} – 10^{-11} M. The estimation of kinetic parameters has allowed very precise 'ranking' of panels of antibodies. Epitope mapping has also been successfully undertaken with SPR, especially using instruments with automated injection systems that allow unattended operation for a large number of cycles. The

same is true for determining the isotype of different antibodies, using specifically developed kits.

SYSTEMIC LUPUS ERYTHEMATOSUS, ANIMAL MODELS

Argyrios N Theofilopoulos, Immunology Department, Research Institute of Scripps Clinic, La Jolla, California, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

As in any disease entity, animal models with spontaneous incidence of systemic autoimmunity have been sought, and a few have been identified. Of these models, the inbred murine strains of lupus are the best suited for study because their serologic, cellular and histopathologic characteristics closely match the corresponding human disorder.

There are three main types of mice with lupus predisposition (Table 1). The New Zealand (NZ) mice (NZB, NZW and their F1 hybrid), the BXSB mouse and the MRL mouse. Crosses of SWR with NZB also develop a lupus-like disease, as do certain F1 mice undergoing a graft-versus-host reaction upon injection of parental lymphoid cells, and mice with the motheaten (*me*) mutation. The NZB (H-2^d) and the NZW (H-2^z) mice are of unknown background, the BXSB mouse (H-2^b) was derived from crosses of C57BL/6 females with SB/Le males, and the MRL mouse has a complex genome composed of LG/J (75%), AKR (12.6%), C3H (12.1%) and C57BL/6 (0.3%). For (NZB × W)F1 mice, the females develop disease earlier than males, but, in contrast, BXSB males are much more severely affected. During inbreeding, some of the MRL offspring developed massive lymph node enlargement, splenomegaly and early-life severe lupus, while others remained free of this lymphoid cell accumulation and developed a mild, late-life, lupus disease, thereby creating the MRL-*lpr/lpr* (lymphoproliferation) and the MRL-*+/+* sublines, respectively. The incidence and severity of disease is almost equal for both MRL-*lpr* sexes. The *lpr* mutation is inherited as a single autosomal recessive gene. Since its original description, the *lpr*

mutation has been transferred to a number of other standard inbred strains. These normal background *lpr* homozygous mice similarly develop various grades of lymphadenopathy and autoantibodies but, in contrast to lupus-background *lpr* homozygous mice, exhibit minimal histopathologic manifestations, thereby indicating the requirement of additional genes for lupus pathology.

Two additional single autosomal recessive mutations, termed *gld* (generalized lymphoproliferative disease) and *lpr^{cg}* (*lpr*-complementing gene) have been described. Normal background mice with these mutations also develop early-onset humoral autoimmune responses and lymphoid hyperplasia, but histopathologic manifestations such as nephritis and vasculitis are minimal. The *lpr* mutation (mapped on chromosome 19) and the *gld* mutation (mapped on chromosome 1) are nonallelic and non-complementary, while the *lpr^{cg}* mutation is complementary to both the *lpr* and the *gld* mutation.

Histologic and serologic manifestations

Lupus disease-manifesting mice develop severe glomerulonephritis and early-life thymic atrophy. Lymphoid hyperplasia is minor in (NZB × W)F1, moderate in BXSB, and severe in MRL-*lpr* mice. Arteritis and arthritis are uniquely present in MRL-*lpr* mice, while degenerative vascular disease and myocardial infarcts characterize all these types of mice. The incidence of myocardial infarcts is greatly enhanced in crosses of BSXB males with NZB or NZW female mice. Lymphoid infiltrates in several

Table 1 Derivation, H-2, accelerating factors and survival rate of lupus mice

Strains	Derivation	H-2	Accelerators	50% Survival
NZB	Unknown	d	—	15 months
NZW	Unknown	z	—	22 months
(NZB × W)F1		d/z	Female hormones	Females, 9 months Males, 13 months
MRL	LG (75%) AKR (12.6%) C3H (12.1%) C57BL/6 (0.3%)	k	<i>lpr</i> gene	<i>lpr/lpr</i> , 4–5 months +/+, 16–18 months
BXSB	SB/Le (50%) C57BL/6 (50%)	b	Y chromosome-associated	Males, 5 months Females, 21 months

organs, including salivary and lacrimal glands, are observed, particularly in MRL-*lpr* mice.

Serologically, all of the above systemic autoimmunity-prone mice develop hypergammaglobulinemia, a variety of anticellular autoantibodies (predominantly antibodies to chromatin components), and antibodies against retroviral glycoproteins, but some strain-specific responses are noted. For example, anti-Sm autoantibodies appear only in MRL (both *+/+* and *lpr/lpr*) mice, and high titers of IgM and IgG rheumatoid factors are present primarily in the *lpr* homozygous mice, while anti-erythrocyte and antithymocyte autoantibodies mainly characterize the NZB and (NZB $\times$ W)F1, and antiplatelet autoantibodies are found in BXSB mice.

Cellular abnormalities

Transplantation experiments have documented that the genetic defects of lupus are associated with the lymphoid cell compartment. An increased number of activated/memory phenotype T cells is observed in all lupus strains, B1 (Ly-1⁻) cells are elevated in NZ mice, and there is a dramatic increase with age in BXSB of atypical monocytes. In *lpr* and *gld* homozygous mice, there is a massive accumulation of a CD3⁺, CD4⁻, B220⁺ T cell subset that appears to originate from the CD8⁺ compartment. The T cells of all lupus mice manifest defective responses to *in vitro* activation signals, perhaps as a reflection of their previous activation *in vivo*. Several disturbances in cytokine production have been observed, particularly low production and response to interleukin 2 (IL-2), and increased production of interferon γ (IFN γ) and IL-10.

Major histocompatibility complex (MHC) genes

Although lupus susceptibility is not restricted to a single MHC haplotype (Table 1), the major contribution of certain MHC alleles to lupus susceptibility has been clearly demonstrated. In BXSB mice there is a dominant role for H-2^b, while for NZ mice, heterozygosity of the MHC (H-2^{d/z}) appears to confer higher susceptibility. Yet, H-2^{d/z} heterozygosity is not the only factor contributing to accelerated autoimmunity in the F1 hybrid, as crosses of NZB with SWR (H-2^a) or BXSB (H-2^b) also develop a disease similar to that of (NZB $\times$ W)F1 and crosses of NZB with congenic BALB/c.H-2^e are devoid of disease. Additional studies of H-2 congenic NZB mice revealed that the H-2^{bm12} haplotype predisposes to early onset lupus similar in severity to that in (NZB

$\times$ W)F1, whereas the H-2^b haplotype, which differs from the H-2^{bm12} I-A β gene only in three amino acids in the peptide-binding groove, predisposes to a mild autoimmune phenotype similar to that of the wild-type NZB (H-2^d). This finding, together with the absence of lupus in MRL-*lpr* mice in which the class II MHC genes have been deleted by homologous recombination, strongly implies that the class II genes are responsible for MHC-associated lupus susceptibility. Overall, however, a predisposing MHC in itself is insufficient, and additional genes are required for disease susceptibility.

Apoptosis genes

Apoptosis, a major form of programmed cell death, refers to an active, gene-directed process associated with internucleosomal degradation. Recent advances in the molecular definition of apoptosis have indicated its regulation by a complex web of genes, some of which promote and others that inhibit this process. Apoptosis is the major mechanism by which self-reactive cells are eliminated centrally or peripherally.

The *lpr* mutation has been shown to be associated with an intronic insertion of an early retroviral transposon between exons 2 and 3 of the apoptosis-promoting Fas gene, leading to abnormal splicing and termination of transcription. The *lpr*^{ca} mutation is caused by a single point mutation within the intracytoplasmic domain of the Fas gene that modifies an amino acid essential for signal transduction and function. The *gld* mutation is a single point mutation in the C-terminal extracellular domain of the gene for Fas ligand (FasL), which abolishes its binding to Fas.

Despite these findings, *lpr* and *gld* mice do not exhibit defects in central (intrathymic) deletions of T cells recognizing endogenous superantigens or conventional peptide antigens. Nevertheless, in such mice, defects in peripheral mature T cell deletions have been observed, consistent with the primary role of Fas and FasL in activation-induced apoptosis. Activation-induced cell death is initiated by antigen receptor engagement, which upregulates Fas and induces FasL primarily in CD8⁺ cells and the T_H0 and T_H1 CD4⁺ subsets. B cells from *lpr* and *gld* mice also exhibit resistance to apoptosis. Although the discovery of the Fas/FasL gene defect is of major importance, these defects obviously do not provide a universal explanation for murine lupus. Moreover, no defects in the structure, expression and function of the Fas gene have been uncovered in the vast majority of lupus patients, although rare human correlates to the mouse *lpr* disease have been described.

Overall, however, identification of the Fas/FasL defects strongly suggests that lupus pathogenesis may be related to other abnormalities within the apoptosis machinery.

The Y-chromosome accelerator of autoimmunity

In contrast to the female predilection for lupus found in humans and most susceptible mouse strains, male BXSB mice develop a much more accelerated and severe disease than females. This striking sexual dimorphism is not hormonally-mediated, but results from a Y-chromosome autoimmune-accelerating (*Yaa*) gene that has not yet been cloned. The genetic contribution of *Yaa* to lupus susceptibility has been shown to be additive and dependent on other background genes. Non-autoimmune strains remain largely unaffected by the *Yaa* gene, whereas all lupus-susceptible strains develop an earlier and more severe disease that generally maintains the clinical characteristics of the background strain. For example, male NZW.*Yaa* congenics develop accelerated renal and cardiac disease and early death, while male NZB.*Yaa* mice primarily show enhanced anti-red blood cell autoantibody production. Regarding the mechanisms responsible for the *Yaa* phenotype, double bone marrow chimera experiments using a mixture of *Yaa*⁺ and *Yaa*⁻ cells of different Igh allotypes revealed selective production of antibodies to DNA by *Yaa*⁺ B cells. These and other findings have led to the postulation that the *Yaa* gene acts to increase expression of an 'intracellular adhesion molecule' on B cells, thereby promoting low-avidity T helper-B cell interactions.

Motheaten mice and the protein tyrosine phosphatase gene

Mice homozygous for the recessive allele 'motheaten' (*me*), and its milder variant 'viable motheaten' (*me*^v) express multiple hematopoietic and immunologic abnormalities, including developmental or functional defects in macrophages, granulocytes, T cells, B cells and natural killer (NK) cells. These mice develop systemic autoimmunity with hypergammaglobulinemia and antinuclear autoantibodies, and the majority of B cells are of the B1 type (Ly-1⁺). The *me* mutation was initially mapped to the distal end of chromosome 6. Subsequent linkage analysis positioned the *me* locus at the same site on chromosome 6 to which the protein tyrosine phosphatase 1C (PTP1C) gene (hematopoietic cell protein tyrosine phosphatase (Hcph) gene) had been previously mapped. Cloning and sequencing of the PTP1C gene from *me*^v mice

revealed two types of transcripts that differed from the wild-type catalytic domain by a 15 bp in-frame deletion or a 69 bp in-frame insertion. In contrast, the PTP1C catalytic domains from *me* and wild-type mice were identical in sequence. On the other hand, the majority of *me* PTP1C transcripts have a 101 bp frameshift deletion within the signal transducing SH2 (src homology 2) domain. There is also a second, minor transcript that instead has a single C nucleotide deletion in the SH2 domain. In contrast, no abnormalities were detected in the SH2 domain of the *me*^v PTP1C transcripts. These transcript changes, the result of single-point mutations and modification in the splicing process, lead to absence of PTP1C expression in the more clinically-severe *me* mutation (but not the less severe *me*^v mutation) and reduced catalytic activity in both mutations. How these hematopoiesis-affecting PTP1C mutations lead to autoantibody production is not clear. Recently, however, PTP1C was found to associate with FcγRIIB1 and CD22 and to inhibit B cell receptor (BCR) signaling. Thus, the lack of PTP1C could, upon BCR engagement, result in the uninhibited activation of Lyn and Syk kinases. B cell activation would be promoted, resulting in hypergammaglobulinemia and apoptosis primarily of B1 cells (Ly-1⁺) because of the normally poor response of B1 cells to BCR signaling.

Lupus susceptibility loci

A new avenue of inquiry for broadly defining the genetic defects of lupus is that of genome-wide searches using dense chromosomal maps derived from polymorphic microsatellite markers. Microsatellites or simple-sequence length polymorphisms (SSLP) are repeats of usually dinucleotides that exhibit a high degree of polymorphism in the number of repeats at a given chromosomal site.

Studies of the interspecific MRL-*lpr* and *Mus castaneus* (CAST/EI)F1 hybrid backcrossed to MRL-*lpr* identified two loci associated with renal disease, termed *Lrdm1* and *Lrdm2*. *Lrdm1* is located at the centromeric end of chromosome 7 and *Lrdm2* in the middle of chromosome 12.

Several groups have used microsatellite markers to identify susceptibility loci contributing to disease in the (NZB × W)F1 cross (Table 2). A study of (NZB × W)F1 × NZW backcross mice identified a single dominant locus (termed *nba1*) on chromosome 4 associated with proteinuria and early mortality. In another study, backcrosses of a new NZB × W recombinant strain (NZM/Aeg 2410) to the F1 with C57BL/6, was analyzed and four major loci linked to glomerulonephritis (GN) were identified, includ-

ing the MHC and three loci designated *Sle1*, *Sle2* and *Sle3* on chromosomes 1, 4 and 7, respectively. The incidence of GN increased with the number of susceptibility alleles inherited regardless of the combination, suggesting a threshold liability model of inheritance with a simple additive contribution from each locus. Finally, a third study with (NZB × W)F₂ intercrosses identified eight susceptibility loci, designated *Lbw1* to *Lbw8* on chromosomes 17, 4, 5, 6, 7, 18, 1 and 11, respectively, and two loci that predisposed to splenomegaly (designated *Sbw1* and *Sbw2*) were mapped to chromosomes 1 and 4. Production of antibodies to chromatin was linked to three loci (*Lbw1*, 7 and 8). GN was linked to three loci (*Lbw1*, 2 and 6), all of which were also linked to mortality, consistent with GN being the major contributing factor to early mortality. The two non-MHC loci had no linkage to autoantibody production, suggesting that their contribution to GN involves a stage(s) after autoantibody production. Six loci, *Lbw1* to *Lbw6*, were linked to early mortality, but, of these, three were not linked to GN and presumably contributed to other pathologic manifestations that adversely affect mortality (vascular disease, neoplasia). The *Lbw2* locus showed strong epistasis with other loci and appeared to be required

for early mortality. Further mapping has revealed that the *Sbw1* and *Sbw2* loci map to the same regions as *Lbw7* and *Lbw2*, respectively, and are probably pleiotropic alleles, therefore the *Sbw* designations have been dropped.

Based on the overall findings to date, it can be concluded that the genetics of murine lupus follow a multiplicative model of inheritance in which specific combinations of genes acting additively are required for phenotype expression. Moreover, it appears that each susceptibility locus contributes to specific stages of lupus immunopathology, suggesting that separate thresholds for each stage are influenced by different sets of susceptibility genes. With loci predisposing to murine lupus susceptibility already mapped, the next step, identification and characterization of the actual predisposing genes will undoubtedly be forthcoming in the foreseeable future.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE), HUMAN

David A Isenberg, Bloombury Rheumatology Unit, Arthur Stanley House, London, UK

It seems likely that the condition described by Hippocrates as herpes esthiomenos was a synonym for what is now known as systemic lupus erythematosus (SLE). In modern times this was first described by Cazenave and Clausit in 1852. In 1875 Hebra and Kaposi differentiated discoid lupus from the systemic form. By the beginning of the present century, Sir William Osler and others had comprehensively described many of the clinical features of the disease including involvement of the joints, kidney and central nervous system. The involvement of the heart in SLE was first recognized by Libman and Sachs in 1923 who described a classic form of endocarditis. In the mid-1930s Baehr, Klemperer and Schiffrin stressed the structural changes in the glomeruli of lupus patients. In 1948 Hargreaves first identified the so-called LE cell but the modern era of antinuclear antibody detection was ushered in by Friou and colleagues when using immunofluorescence in 1957–1958. The first mouse model of human lupus was described in the New Zealand black mouse in 1959.

Clinical features

As the name implies, systemic lupus is characterized by a very broad range of clinical manifestations. It is principally a disease affecting women during the child-bearing years. Invariably arthralgia or arthritis is involved (90%) but myalgia (50%) and tenosynovitis (20%) are also common features in the musculoskeletal system. Involvement of the heart and lungs is also common with shortness of breath, pleurisy and pleural effusions being present in at least a quarter of the patients. Current pulmonary function tests will detect abnormalities in up to 85% of lupus patients. Skin involvement is common in systemic lupus and up to 30% of patients have the so-called butterfly rash (Figure 1), essentially a vasculitis over the malar bones and bridge of the nose. A wide variety of other dermatological manifestations may be observed including alopecia, livedo reticularis, an erythematous maculopapular eruption and discoid lupus.

Involvement of the central nervous system (CNS)

Figure 1 The 'butterfly rash' seen in up to 40% of SLE patients. (See also color **Plate 10**.)

can manifest as an enormous range of features from single migraines or depression to frank psychosis, hemiplegia, or seizures. Recently a variety of CNS manifestations, together with a predisposition for venous or arterial thrombosis and spontaneous abortions has been recognized. These features are often linked to the presence of antiphospholipid antibodies.

Kidney involvement is the most important feature of lupus, especially as significant kidney damage is

the major threat to long-term survival. Whilst proteinuria is found in some 60% of patients overall, probably less than one-third of patients actually have serious renal disease. This may take a variety of forms ranging from minimal or mesangial involvement to severe diffuse proliferative glomerulonephritis. Gastrointestinal involvement is relatively uncommon. Anorexia occurs at some time in up to 40% of the patients and vague abdominal pains occur in approximately one-third but these often settle spontaneously.

Nonspecific but very troublesome features of lupus include lymphadenopathy (which may on occasion be severe enough to warrant biopsy to exclude an accompanying malignancy), weight loss and fatigue. Fatigue is frequently a major problem for patients with lupus. It is important to recognize that with time the cumulative clinical features in adult and childhood onset cases varies, as is shown in **Table 1**. There are also differences amongst different ethnic groups; for example, black patients are more likely to have renal and central nervous system problems.

Investigations

Hematological abnormalities

A normochromic normocytic anemia is a frequent feature of lupus. Hemolytic anemia, as evidenced by a positive Coombs' test, is rarely found but iron-deficiency anemia may be induced by the non-steroidal anti-inflammatory drugs sometimes prescribed. Thrombocytopenia occurs in three main forms: acute, chronic or antecedent. In this last case patients may initially be diagnosed as having idiopathic thrombocytopenia but within months or years other features evolve making it clear that the thrombocytopenia was merely the first sign of SLE. Persistent and sometimes profound leukopenia ($<4.0 \times 10^9 \text{ l}^{-1}$), often accompanied by lymphopenia ($<1.5 \times 10^9 \text{ l}^{-1}$), is frequently found.

Table 1 Cumulative clinical features in adult and childhood onset groups (as percentages)

	By 2 years		By 5 years		By 10 years

Serological abnormalities

Antinuclear antibodies, as detected using rat liver or human epithelial cell substrates, are present in over 95% of lupus patients. Antigens within the nucleus which these antibodies recognize include double-stranded DNA (40–90%) single-stranded DNA (up to 70%) poly (ADP ribose) (up to 70%) RNP (35%) and Sm (30% in the USA, 5% in Europe). Antibodies to double-stranded DNA, notably of the immunoglobulin G (IgG) isotype in high titers, are essentially disease specific as are antibodies to Sm. In addition, antibodies to cytoplasmic antigens notably Ro (up to 35%) and La (15%) as well as those binding to cell surfaces of red cells, white cells and platelets are frequently found. Antiphospholipid antibodies, notably anticardiolipin, have been identified in up to half of the patients with lupus, whilst the so-called 'lupus anticoagulant' is probably present in about 20%. Apart from anti-DNA antibodies and those binding poly (ADP) ribose, the remainder seem to fluctuate relatively little with disease activity.

Natural history of SLE

The prevalence of lupus varies according to ethnic group. Amongst black females it is approximately 1 in 250, amongst Chinese approximately 1 in 1000, amongst Caucasian about 1 in 4000. The female-to-male ratio in lupus is approximately 9:1 though some studies have indicated that there are families in which the disease occurs in mainly males and is transmitted through the fathers.

SLE in pregnancy

Pregnancy for the lupus patient entails far more danger for the offspring than the mother. Generally speaking patients with very severe active lupus will not become pregnant and the risk of developing a major relapse during pregnancy seems to be mild to modest at worst. In contrast, the fetus is threatened by an increased predisposition to spontaneous abortion (which is associated with anticardiolipin antibodies) and prematurity which may be due to vasculitis affecting the placental blood supply.

Approximately 1 in 20 of lupus mothers who have the anti-Ro or anti-La antibodies will give birth to children with a transient rash or a potentially permanent cardiac conduction defect – the neonatal lupus syndrome. It has recently been speculated that the target of the antibodies in the fetal heart may be laminin.

SLE in children

Children as young as 2 years old have been described as having lupus. As Table 1 indicates, cardiopulmonary disease is more uncommon in children with lupus, but major hematological manifestations are more common. In addition, anti-DNA, anti-Sm, anti-RNP and low C3 have also been reported more frequently in younger patients. Lupus in children may be particularly severe.

Outcome

There is a 10-year survival in SLE patients of around 90–95% but when the disease is associated with major renal involvement this falls to around 60%. Fifteen years survival has been estimated recently at around 70%.

Drug-induced lupus

Approximately 10% of patients with SLE are thought to have a variant induced by drugs. These patients resemble idiopathic lupus with respect to the musculoskeletal and dermatological features, but it is generally a milder condition with the kidneys and CNS very rarely if ever involved. In addition, antibodies to double-stranded DNA are most unusual, whereas antibodies to histones and single-stranded DNA are almost universally found. The commonest drugs giving rise to this condition are hydralazine, procainamide, a variety of β -blockers and anti-convulsants.

Genetic factors and etiological considerations

The contribution of HLA to relative risk for developing lupus depends upon the ethnic groups studied. It appears for example that HLA A1 B8 DR3 is associated with lupus in Caucasians though it has been postulated that this haplotype is in linkage disequilibrium with a C4 null allele. In contrast, lupus amongst other ethnic groups, including the Japanese, seems common amongst patients who carry the HLA-DR2 haplotype. Inherited complement deficiencies also predispose to lupus. Thus the majority of individuals who are homozygous for C1q, C1r, C1s, C2 or C4 deficiency develop lupus or a lupus-like syndrome. IgA deficiency also appears to predispose towards systemic lupus.

Family studies have indicated that amongst monozygotic twins the concordance rate for lupus is around 25% but amongst dizygotic twins it is around 3%. Where more than one case of lupus occurs in the family (around 3%) it is usually present in a sister.

Immunopathology

The immunopathology of SLE is complex, involving a network of multiple cellular defects associated with the overproduction of a range of autoantibodies.

Immune complexes

For many years it was thought that the presence of circulating immune complexes (CICs) comprising in part DNA and anti-DNA antibodies in the sera of lupus patients was an important immunopathological characteristic of lupus. More recently several authors have provided evidence that antibodies binding the nucleosome (DNA and histone) could bind directly to targets in the kidney, hence forming local immune complexes *in situ*. Immune complexes, whether deposited from the circulation or formed *in situ*, are likely to be involved in the damage caused to the kidneys, skin, choroid plexus of the brain and other tissues. From these sites they initiate a number of inflammatory mechanisms including 'bystander lysis' whereby tissues surrounding the deposited complexes are damaged by complement after it has been fixed to the complexes and also by the recruitment of inflammatory cells.

Because immune complex formation is part of the normal immunophysiological process directed at eliminating foreign antigens, their presence even in 'healthy' subjects is not unusual. Their pathogenicity in SLE may be due to a number of physicochemical and biological factors including the size of the complex, the class, subclass, valency and affinity of the antibody and the composition and size of the antigen.

Based on the observation that New Zealand lupus-prone mice have largely low-affinity antibodies to DNA, it has been suggested that such animals are particularly susceptible to immune complex disease as they have a genetic predisposition to produce low-affinity antibody. As a result, antigen is not complexed and eliminated in an efficient manner, and this favors the persistence of antigen excess immune complexes. Binding affinities of serum anti-DNA antibodies in lupus patients with and without renal lupus have been measured and it was found that those with nephritis had lower affinity autoantibodies. However, the anti-DNA antibodies obtained from glomerular eluates were of uniformly high affinity. It may be that the antibody that is bound in CICs differs from those deposited in tissues.

It also remains possible that antibodies in the circulation merely happen to cross-react with DNA and are deposited in the kidney when they recognize other cross-reactive epitopes.

Complement

The complement system is involved in the sequence of inflammatory events that occur in SLE. Numerous studies have demonstrated that complement is fixed or consumed by immune complexes and localized in the tissues, particularly the kidney. The cleavage fragments C3a and C5a cause the release of vasoactive amines from mast cells. Furthermore, vascular permeability can be increased by fragments of C2 with kinin-like activity. This allows localization of immune complexes as well as causing acute inflammation *per se*.

Low complement levels in the serum are associated with active lupus. Not only is the overall hemolytic ability (as usually measured by the CH₅₀ test) of the complement system decreased, but levels of C3 and C4 are also reduced. Breakdown products of complement, notably C3d and C4d, have been reported to reflect disease activity even better than the total C3 and C4 levels.

Cellular aspects

It is now clear that numerous other cellular defects exist in SLE which can be seen in the T, B and accessory cell compartments. The major cellular defects described in lupus are depicted in Figure 2.

T cells Evidence suggesting that the immunological imbalance seen in lupus can be partly attributed to malfunctioning suppressor cells is now considerable. B cells from the blood of patients spontaneously secrete larger amounts of immunoglobulin *in vitro* than cells from normal subjects. In addition, the ability of lymphocytes from patients with SLE to develop suppressor activity following con A or adenosine activation is restricted. Further evidence for a suppressor cell defect comes from other studies with mitogens. It is well recognized that the T cell mitogens (Con A or phytohemagglutinin (PHA)) will elicit a greater stimulation in lymphocyte cultures if added after 24 h. This effect is thought to be due to the loss of a population of short-lived suppressor cells. However, when lymphocytes from lupus patients have been utilized, there is little or no enhancement of the response which suggests that the short-lived population of suppressor cells is absent in these individuals.

Cytokines It is also evident that in SLE patients there is a defect in the production and response to interleukin 2 (IL-2). Perturbed IL-2 regulation seems to play a key role in the immunological imbalance of lupus-prone mice and in patients with lupus and other autoimmune rheumatic diseases. *In vitro*, the

Figure 2 A summary of the major cellular defects in SLE. *T cell compartment:* (i) Defective thymic processing, decreased production of thymic factors. (ii) Decreased numbers and dysfunction of post-thymic precursor cells (Tp). (iii) Defective suppressor T cells (Ts) fail to regulate the B lymphocyte compartment, although induction of antibody production continues owing to impaired function of helper T cells (Th). (iv) Impaired interleukin 2 (IL-2) secretion and unresponsiveness causes further imbalances in the T cell populations. *B cell compartment:* (v) A primary B cell defect exists. (vi) Secretion of antilymphocyte or natural thymocytotoxic antibody (NTA) amplifies regulatory disorder. (vii) Immune complexes may further impair suppressor T cell function, as well as causing tissue damage. *Accessory cells:* (viii) Macrophages may contribute to the autoimmune process; various unusual characteristics have been observed (ix).

immunostimulatory agent isoprinosine increased PHA-induced IL-2 production by mononuclear cells, although it failed to stimulate IL-2 responsiveness.

Elevated serum levels of interferon γ (IFN γ) have been noted in patients with SLE, although others have reported that the production of both IFN γ and IFN α is decreased. Interestingly the IFN found in lupus is an unusual form in that it is acid-labile, a hallmark of IFN γ , but is neutralized with anti-IFN α antiserum.

Amongst other cytokine abnormalities it has been reported that IL-10 is increased in lupus patients. IL-10 has been shown to have a particular propensity for stimulating B cells to produce autoantibodies.

B cells Although B cell hyperresponsiveness has largely been attributed to lack of T cell regulation, there is now evidence to suggest that there is a B cell defect *per se* in lupus. Thus B cells from SLE patients have an intrinsic fault manifested by their inability to produce anti-influenza antibodies when sensitized *in vitro*. The antibodies produced by the B lymphocytes in lupus patients frequently carry common

idiotypes. It is evident that switching of both antibody isotype and idiotypes may be involved in the immunopathology of lupus. Thus IgG autoantibodies are evidently more pathogenic than IgM and certain idiotypes (e.g. Id 16/6) have been found in the serum of the majority of lupus patients and in many renal biopsies.

Accessory cells Dysregulated function of accessory cells may not be the most crucial immunological lesion in the SLE disease process, but nevertheless can amplify the inflammation in several ways.

Deficiencies in the reticuloendothelial system may influence the deposition of immune complexes. An *in vitro* test showing a neutrophil defect has been described in SLE.

Natural killer (NK) cells are normally associated with the killing of virus-infected or tumor cells and function in combination with interferon. Although the role of the NK population in SLE has yet to be fully determined, various abnormalities have been reported including reduced numbers and functional

immaturity and reduced killing capacity and insensitivity to interferon.

Apoptosis With the description of a transgenic mouse overproducing the proto-oncogene bcl-2 developing a lupus-like disease, anti-DNA and anti-Sm antibodies and an immune complex glomerulonephritis, much interest has focused on apoptosis in relation to SLE. Amongst a variety of hypotheses it has been suggested that some cells in lupus patients may undergo increased apoptosis, thus yielding a surfeit of nucleosomal material, but that other cells, notably the B cells, have a lower rate of apoptosis, the consequence of which is that they live longer and produce more autoantibodies. There has been considerable interest in the Fas molecule, a 43 kDa glycoprotein which is involved in inducing apoptosis in both B and T cells. In the MRL/lpr model, the lymphoproliferation mutation results in defective transcription of the gene that codes for Fas protein. However, an initial claim that 60% of lupus patients have elevated levels of the soluble Fas protein in their serum has not been confirmed by other studies and the role of this molecule in human lupus remains uncertain.

Treatment

The arthralgia, malaise and skin rashes of lupus can be treated with nonsteroidal anti-inflammatory drugs and a variety of antimalarial preparations. Patients with these problems alone rarely, if ever, need to go on any more major medication. When lupus involves the heart or lungs, modest doses of prednisolone, perhaps 30 mg a day initially, are invariably required. Profound hemolytic anemia or thrombocytopenia require large doses of prednisolone, perhaps 60–80 mg per day, often supplemented by another immunosuppressive drug such as azathio-

prine. Similar medication is required for severe renal and cerebral disease though studies from the National Institutes of Health in the USA have strongly supported the concept of intravenous monthly pulses of cyclophosphamide.

The use of plasma exchange in systemic lupus remains somewhat controversial though there is general agreement that it has no part to play in the treatment of mild or moderately severe disease. It may be of some value to patients with severe renal or CNS involvement.

Lymph node irradiation has not generally been adopted as a method of treatment in lupus. Dietary manipulation, notably reducing the total saturated fat content of the diet and increasing the level of fish oils, whilst simple and attractive, is unlikely to make a major impact on the disease.

T

TARGETING OF IMMUNOLOGICAL AGENTS

Although T cells represent the pinnacle of the host defense against cellular antigens, they can threaten the continued survival of a host. For example, T cells recognizing foreign or self antigens expressed on host tissues can cause autoimmune disease, reject donor organ grafts or, when infused into an allogeneic recipient, cause multiorgan system destruction termed graft-versus-host disease (GVHD). To combat the adverse effects of T cells in these situations, pharmacological reagents have been used to inhibit T cell responses and biological reagents have been synthesized to modify or eliminate T cells with undesired immune capabilities. GVHD will be used as the paradigm for discussion.

Pharmacological agents

Antiproliferative agents such as methotrexate and azathioprine, in combination with lympholytic agents such as glucocorticoids, have been used as the mainstay for GVHD prevention and therapy. Antiproliferative agents are broadly reactive because of their interference with basic cellular functions required for DNA synthesis, resulting in a wide range of toxicities, especially to organs with rapid turnover rates. Cyclosporine and FK506, agents commonly employed to suppress T cell responses for solid organ or bone marrow transplants, inhibit T cell activation earlier in the cell cycle than the antiproliferative agents. Although each binds to distinct intracellular proteins, they share common mechanisms of action by interfering with T cell receptor (TCR)-associated signaling events, leading to diminished cytokine synthesis which is required for productive T cell expansion. Rapamycin, structurally similar to FK506, inhibits lymphokine responses, and has been shown to prolong organ graft survival and inhibit GVH responses. Cyclosporine and rapamycin, used together, are additive or synergistic in suppressing T cell (including GVH) responses by inhibiting lymphokine production and responsiveness.

Antibody-directed approaches

The infusion of monoclonal antibodies (mAbs) with defined specificities offered high hopes that aberrant T cells could be eliminated and T cell-mediated disease processes subdued. Anti-CD3 (OKT3)-directed mAbs have been given to bone marrow transplant (BMT) patients with GVHD. However, because anti-CD3 mAbs are typically mitogenic, side-effects due to T cell activation are relatively common and may obscure the beneficial properties of this approach. Other problems for the use of mAbs in the BMT setting have included the need to administer large quantities, increasing the risk of allergic response and the fact that the recipient post-BMT may have an intact ability to remove mAb-coated T cells. Alternatively, drugs and radionuclides have been linked to antibodies, but drugs are mostly limited by their lack of potency and radionuclides have a notable cross-fire effect that affects adjoining tissue. Another solution is to use catalytic toxins from plants (ricin, abrin, ribosome inhibitory proteins) or bacteria (diphtheria toxin (DT), *Pseudomonas* exotoxin a) which are catalytic enzymes. These molecules share in common the fact that a single molecule in the cytosol destroys a cell by inhibiting protein synthesis in the 60S ribosome. First-generation immunotoxins (IT) were made by biochemically linking mAbs to toxins. Although *in vitro* they are highly potent in nanomolar concentrations, their *in vivo* efficacy is limited by instability and nonspecific side-effects due to localization in nontarget tissue. By constructing molecular ITs, the mAb or toxin moiety can be genetically engineered to reduce these undesired IT properties.

An example of these next-generation ITs are scFv (single-chain Fv) fusion immunotoxins. The scFv fragment consists of a single variable heavy (V_H) and a single variable light (V_L) domain (Figure 1) connected by a flexible linker. DNA elements from an scFv can be spliced to toxin cDNA such as truncated DT resulting in a protein that is small, configured in a single chain and produced in large quantities in bacteria. Such agents have been shown to give significant

Figure 1 The DT₃₉₀anti-CD3sFv construct. Left to right (N-terminus to C-terminus): truncated diphtheria toxin, ASGGPE connector, V_L, flexible linker, and V_H. Below is a diagram of the folded protein with a function monovalent binding site.

antitumor and anti-GVHD effects in *in vivo* animal models.

The future of IT conjugates for *in vivo* use will depend upon solving the toxic side-effects of these potent reagents without hindering their biological efficacy.

Blockade of T cell costimulation

Additional T cell signals (termed costimulation), other than those delivered by CD3/TCR complex stimulation, are required to drive T cell expansion. A state of nonresponsiveness termed anergy is induced in T cells that have received signaling via their CD3/TCR complex in the absence of adequate costimulation. T Cells not receiving CD3/TCR complex signaling are unaffected. In theory, GVHD can be inhibited by temporarily precluding T cell costimulation during initial alloantigen exposure, leaving intact the majority of T cells to mediate leukemia- and viral-specific T cell responses upon antigen exposure later in the post-BMT course. Costimulator molecules include members of the immunoglobulin supergene family (e.g. CD28:B7), tumor necrosis factor/nerve growth factor receptor families (e.g. CD40 ligand: CD40, 4-1BB:4-1BB ligand; OX40:OX40 ligand), and adhesion molecules (e.g. LFA-1:ICAM-1, CD2:CD48). Balancing these positive signals are negative regulators which downregulate immune responses primarily by inducing cell death, compete for the same substrates as the positive regulators, or provide negative regulatory signals. The net balance of positive and negative regulators of T cell activation and expansion determine whether donor alloreactive T cells can reach the critical threshold number and stage of activation neces-

sary to cause GVHD lethality in a recipient. As an example of the requirement for costimulation, the CD28/B7 pathway, the most well-studied interaction, will be highlighted. CD28 is constitutively expressed on all murine T cells and its natural ligands, B7-1 or B7-2, are predominantly found on activated antigen-presenting cells. The infusion of CTLA4-Ig, a protein consisting of the high avidity B7 ligand-binding extracellular domain of CTLA-4 fused to the C_γ1 moiety of immunoglobulin, has been noted to suppress sheep red blood cell responses, xenogeneic islet cell and cardiac allograft rejection, immune responses to self antigens, and GVHD responses. The infusion of anti-B7 mAbs post-BMT allowed survival rates of $\geq 94\%$ in allogeneic recipients of either CD4⁺ or CD8⁺ T cells, in contrast to no survival of controls. In a human mixed lymphocyte reaction (MLR) system, blockade of CD28/B7 interaction was found to induce donor antihost alloantigen specific hyporesponsiveness. Thus, it may be possible to render donor T cells anergic to alloantigens *in vitro* prior to *in vivo* transfer into BMT recipients.

Cytokine regulation

CD4 T cells are distinguished as either T helper type 1 (T_H1) or T helper type 2 (T_H2) cells, based on the particular cytokines that are produced upon activation. Interferon γ is produced by T_H1 cells and is involved in cellular responses, whereas interleukin 4 (IL-4) is produced by T_H2 cells and is critical to humoral responses. T_H1 and T_H2 cells are cross-regulatory, and the balance of these cells determines the outcome of the immune response. T_H1-like inflammatory processes appear to be involved in the development of GVHD. T_H2 cytokines have been used during the GVHD induction phase to try to skew the CD4⁺ T cell response away from the deleterious T_H pathway. For example, T_H2-type alloreactive T cells can be generated *in vitro* or *in vivo* by coinubation of cells in the presence of IL-4 and antigen and the transfer of T_H2 cells can downregulate the GVHD potential of naive donor T cells. Interleukin 10 (IL-10: cytokine synthesis inhibitory factor) is a product of T_H2 clones and is an ideal candidate cytokine for inhibiting the acute GVHD response because it inhibits the MLR, downregulates major histocompatibility complex (MHC) class II expression, inhibits the production of inflammatory cytokines and nitric oxide synthesis from activated monocytes and macrophages which have been shown to be involved in acute GVHD generation, and downregulates B7 expression on accessory cells. High endogenous production of IL-10 has been

found to be associated with skin and cardiac allograft acceptance, the induction of neonatal tolerance and high endogenous levels of IL-10 mRNA were detected in circulating cells obtained from long-term BMT chimeric patients tolerant to host alloantigens *in vivo*. The addition of exogenous IL-10 to an MLR culture was shown to induce alloantigen-specific nonresponsiveness. Human CD4⁺ T cells activated by allogeneic monocytes specifically failed to proliferate after restimulation with the same alloantigens. The IL-10-induced anergic state was long-lasting, and could not be reversed upon restimulation of the cells through the CD3/TCR complex. Biochemical and cellular studies have shown that IL-10-induced anergy induction is distinct from that obtained by costimulation blockade as well as the immune regulatory approach achieved with manipulation of the T_H1/T_H2 balance.

CD4 immunotherapeutics

The CD4 molecule functions as a coreceptor for T cell receptor–antigen interactions and contributes to the intracellular signaling pathways required for CD4⁺ T cell activation. CD4⁺ cells are involved in the pathogenesis of several autoimmune diseases, e.g. multiple sclerosis, and participate in transplantation reactions. Over the last few years, several approaches have been developed to inhibit the responses of CD4⁺ T cells, including the use of mAbs and peptides which compete for the presentation of antigens, yet these may have broad effects on all CD4⁺ T cells. Recently, synthetic peptides that mimic structural features of the CD4 molecule itself have been designed to block the functional role of CD4 during antigen-specific T cell activation. It is thought that this approach can achieve inhibition of the CD4⁺ T cells that participate in autoimmunity or transplantation reactions, without impairing the ability of other T cells from later responding to other antigenic challenges.

Initially, a peptide was generated from the CDR3 region of the first immunoglobulin domain of the murine CD4 molecule, by computer-assisted structure-based design approaches. This CD4-CDR3 cyclized peptide was 13 amino acids long and was nonimmunogenic. The peptide was a potent inhibitor of CD4⁺ T cell responses in a murine autoimmune model and could prolong survival of MHC class II disparate skin allografts. It also inhibited the development of CD4⁺ T cell-mediated GVHD. Although equivalent human analogs of the CD4-CDR3 site were effective *in vitro*, their practical application was limited by the inability to reduce their size below 13 residues. As an alternative, computer analysis of the structural surface features of the first domain of

human CD4 revealed a potential pocket for intermolecular binding, formed between the CDR3 and the CC' loops. A heptameric cyclized peptide was generated to mimic the CC' loop and it was found to inhibit both human T cell proliferation and murine models for skin allograft rejection and GVHD. Computational analysis has recently been used to screen organic chemical libraries for potential compounds which can block the putative CD4-binding pocket formed between the CDR3 and CC' loops. Two small compounds (mol. wt <300) have been found in this way and have displayed specific inhibition of CD4⁺ T cells. Their application to the prevention of GVHD and autoimmunity is under current investigation. Although studies are needed to determine the precise mechanism of action of these compounds, it is clear that the computer screening approach will be an important tool for future drug discovery.

T CELL RECEPTOR, $\alpha\beta$

Tak W Mak, The Ontario Cancer Institute, Toronto, Ontario, Canada

The importance of thymus-derived lymphocytes (T cells) in mediating the cellular basis of the immune response was recognized in the early 1960s. Independently, J. F. A. P. Miller, R. A. Good and B. Waksman and their colleagues observed that neonatal thymectomy of mice, or thymoma development in humans, led to a reduced ability to synthesize antibodies, reject grafts, and develop delayed-type hypersensitivity.

During the late 1960s and 1970s, many investigators built a vast body of evidence supporting the role of T cells in helping B lymphocytes to generate antibody responses (T–B cell cooperation). Certain T cells also provided similar helper–effector cell assistance to a different subset of T cells responsible for cell-mediated responses. The first population of T cells is known as the helper T lymphocytes (T_H) while the latter subset of T effectors are the cytotoxic (or killer) T lymphocytes (CTLs). It is now known that there are distinct subpopulations of helper T cells that can secrete specialized panels of cytokines.

The specificity of the helper and effector functions, as well as the finding that only a very few T lymphocytes could react to a given antigen, led to the conclusion that these thymus-derived cells (like their B lymphocyte counterparts) also carried antigen-specific receptors. The cell-bound antigen recognition structure on T lymphocytes is the T cell receptor (TCR). Upon specific interaction of the T cell receptor with its ligand(s), signals are transduced through the plasma membrane. This transduction results in activation of the lymphocyte, followed either by the initiation of cell division and the secretion of cytokines (T_H), or by lysis of the target cell (CTLs).

Thus, the specific recognition of antigens by the T cell receptor controls the activation and suppression of the specific immunity compartment. However, despite its importance, the identification of the genes for the T cell receptor, the elucidation of its molecular structure, and an understanding of the mechanism by which T cells generate their diversity, remained elusive throughout the 1970s and early 1980s.

Structure of the T cell receptor

Both helper and cytotoxic T cells recognize antigens in a specific manner and occur in diverse, clonally distributed repertoires. Unlike B cells, whose receptors (BCRs) are immunoglobulins (Igs) capable of interacting with free antigens, T lymphocytes only recognize antigens on the cell surface, and only in association with major histocompatibility complex (MHC) products, a phenomenon known as MHC restriction. Antigens recognized by T cells are now known to be oligopeptides bound to the grooves of the MHC class I or class II gene products. Most T_H recognize peptides associated with class II MHC products while the majority of TCRs of CTLs recognize peptides associated with class I MHC molecules. This MHC I/II discrimination is facilitated in part by the coreceptors CD4 and CD8, found principally on T_H and CTLs, respectively. It is the MHC restriction that enables T cells to survey the universe of antigens and to distinguish ‘self’ and ‘foreign’ molecules, aiding in the selection of thymocytes and the regulation of extrathymic responses against foreign antigens.

The specific recognition of these antigen–MHC

complexes is mediated by the T cell receptor. An understanding of the structure of the T cell receptor and the mechanism by which its diversity is generated was not reached until 1983, when the problem was resolved using two different approaches. First, several groups (Allison; Kappler and Marrack; Reinherz; Schwartz; and Trowbridge) reported that surface structures on T lymphocytes consisting of disulfide-linked heterodimers of an acidic α chain and a more basic β chain could be detected using monoclonal antibodies specific for individual T cell clones. Using the techniques of molecular biology, two groups (Davis; Mak) independently cloned the gene coding for the β chain of the TCR, thus defining its molecular structure. The deduced protein sequence of this message revealed a large extracellular portion linked to a short cytoplasmic tail by a transmembrane section. Like the immunoglobulin chains, the extracellular domain of the β chain is composed of variable (V) and constant (C) regions, linked by diversity (D) and joining (J) gene segments. Subsequently, several investigators isolated cDNAs encoding the α chain of the TCR. This polypeptide is similar to the β chain, being comprised of extracellular variable and constant domains, a transmembrane region and a cytoplasmic tail. Both the α and β chains of TCR are members of the immunoglobulin gene superfamily.

The greater portions of TCR chains are extracellular and form the antigen recognition structure. The extracellular portion of each TCR chain is composed of two domains. Each domain has an immunoglobulin-like structure of approximately 110 amino acids, with a central internal disulfide bond that spans approximately 65 amino acids. Several conserved residues are thought to be structurally important. The constant domain is essentially invariant, while the variable domains are distinct on different T cells. These variable domains are responsible for repertoire diversity and the recognition of peptide antigens in the context of either class I (for CTLs) or class II (for T_H) MHC gene products. This contention was directly supported by the finding that transfection of TCR α and TCR β chain coding sequences conferred the antigenic and MHC specificities of transferred receptors to recipient cells.

The transmembrane portions of the TCR anchor the receptor in the cell membrane as part of a large complex with the CD3 proteins that are believed to play a role in membrane transduction of the recognition signal. It has been proposed that, based on the conserved positively charged arginine and lysine residues in the transmembrane portion of the TCR α and β chains, and the negatively charged glutamic and aspartic acid residues in the CD3 δ , ϵ and γ

chains, interactions between these charged amino acids may be important for the association of TCR and CD3 in a multimeric structure.

X-ray crystallographic studies of fragments of the TCR α and β chains have confirmed that these T cell recognition proteins resemble the BCR immunoglobulin domains. However, the constant region of the C α and the interdomain pairing of C α with C β also show differences. In addition, it is likely that the complementarity-determining regions CDR1 and CDR2 of the TCR are less variable than their B cell counterparts. Crystallographic studies of a TCR-MHC-superantigen complex indicate that interaction of these proteins involves nonpolymorphic regions of TCR-V β .

The crystal structure of the TCR with peptide-MHC molecules indicates a flat combining site of the TCR except for a deep hydrophobic cavity between the CDR3 of the α and β chains. For this TCR, CDR1 and 2 of V α contacts the N-terminus of the peptide while CDR1 and 2 of V β binds the C-terminal region. CDR3 of V α and V β are positioned over the peptide between the helices at the middle region of the peptide.

Genomic organization

The diversity required for T cell recognition depends on the variable domain sequences, produced via somatic recombination of different noncontiguous variable (V), joining (J), and diversity (D) gene segments. Individual V, D and J segments used in a particular somatic recombination are believed to be chosen more or less at random. The genomic organization of the sequences encoding the TCR chains is similar to that of immunoglobulin gene clusters, in that multiple copies of V gene segments are located upstream of the segments encoding D, J and constant region sequences. However, the fine structures of the TCR α , TCR β and BCR gene clusters differ greatly in arrangement and number of gene segments, as well as in the size and complexity of the clusters as a whole (Figure 1).

β chain genes

The TCR β gene cluster, which spans several hundred kilobases of DNA (Figure 1) and includes two highly homologous C regions, is located on chromosome 7 in humans and chromosome 6 in mice. It has been estimated that there are approximately 23 TCR-V β gene segments in mice and about 47 in humans (Figure 2). Rearrangement studies with particular TCR-V β genes have indicated that many are located upstream of the two TCR-C β genes. At least one TCR-V β in the murine system is located about 10 kb

Figure 1 Genomic organizations of the T cell receptor $\alpha\delta$ and β chain genes. V, D and J denote variable, diversity and joining gene segments, respectively. C denotes constant region genes.

Figure 2 The T cell receptor $\alpha\beta$ heterodimer. The number of gene segments encoded within the germ line of human and mouse (in parenthesis where they differ) is illustrated. V, D and J denote variable, diversity and joining gene segments, respectively. C denotes constant region genes.

3' to the 3' TCR- C_β gene in an inverted transcriptional orientation. This TCR- V_β segment has been shown to be used in a functional T cell. Downstream of the TCR- V_β gene segments are two clonally related gene segment clusters. Each cluster consists of a TCR- D_β gene segment and six (in mice) and seven (in TCR- $J_\beta 2$ in humans) functional TCR- J_β gene segments (Figure 1) and is contained within a large stretch of several hundred kilobases of DNA (Figure 1).

Recombinant signals, similar to those in BCR genes, flank the TCR- V_β , TCR- D_β and TCR- J_β genes. Immediately proximal to the coding segment is a highly conserved heptamer, followed by a nonconserved spacer sequence, and then an A/T-rich nonamer. The spaces can be either long (23 nt) or short

(12 nt), with long spacers located 3' to the TCR- V_β and TCR- D_β segments, and short spacers located 5' to the TCR- D_β and TCR- J_β segments. This arrangement of recombinational signals precludes the direct recombination of TCR- V_β and TCR- J_β gene segments without the inclusion of TCR- D_β .

α chain genes

The organization of the TCR α chain locus stands in striking contrast to that of the TCR β chain and BCR loci. Large numbers of TCR- V_α gene segments have been identified in both human (42) and mouse (75), occupying several hundred kilobases on chromosome 14 in both species. The coding sequences of the TCR- J_α regions are several codons longer than those of BCR and TCR β chains and are also more numerous, spanning a distance of about 80 kb. The TCR- J_α genes are separated on average by 1 kb, with the first being located about 4 kb upstream of the single constant region. No TCR- D_α segment has been identified to date. Nested within the TCR α locus are the TCR δ genes. The products of these genes, TCR δ chains, are known to associate with the TCR γ chains to form the $\gamma\delta$ TCR heterodimers. Although TCR δ chains use their own TCR- D_δ and TCR- J_δ gene segments, some of the TCR- V_δ segments are shared with the TCR α chain genes.

Recombination signals, homologous to those of BCR and TCR β chains, are found flanking the TCR α chain segments, with long (23 nt) spacers 3' to the TCR- V_α genes and short (12 nt) ones 5' to the TCR- J_α gene segments. Since it has been shown that signals with short spacers only recombine with those with long spacers, it is possible for the TCR- V_α and TCR- J_α genes to join directly together without the inclusion of a D segment.

The majority of TCR rearrangement patterns can be explained by the looping/excision model, although patterns inconsistent with this model have also been described. In the case of the murine TCR- V_β segment situated 3' of the TCR- C_β region, functional rearrangement would require an inversion mechanism. The mechanism of allelic exclusion, in which the lymphocyte limits itself to one functionally expressed gene, has also been demonstrated in the TCR β chain locus. However, this phenomenon does not appear to be applied rigidly in the TCR α loci. Thus, multiple mechanisms, including gene inversion

and sister chromatoid exchange, may be used in the production of TCR genes.

TCR diversity

T lymphocytes, like their B cell counterparts, must handle a huge number of foreign antigens. Elegant mechanisms have evolved to generate a vast diversity while refraining from overburdening the genome with too many different sequences. An estimate of the total potential of TCR diversity before thymic selection of T cells is summarized in Table 1. For TCR α and TCR β chain genes, diversity is created in two key ways: through the germ line and through junctional and N-region diversity. Germline diversity is the summation of all the possible combinatorial joinings between the V, D and J gene segments of each gene locus, as well as the association between the products of the TCR α and TCR β genes. Junction diversity is the result of an imprecise joining between the V, D and J gene segments, leading to codon changes at the junctions. N-region diversity is generated by the addition of nucleotides (that are not coded by rearranging germline segments) to the V-D-J junctions during the rearrangement process. Assuming the insertion of three different codons at each junction, this process yields a potential 10^4 ($20 \times 20 \times 20$) different combinations of N-region diversity.

Both these processes substantially increase the repertoire of TCR sequences, but also produce a large number of nonfunctional genes by shifting the reading frame. Somatic hypermutation, which generates point mutations throughout the variable regions of BCR molecules, does not appear to occur in either the TCR α or TCR β genes, although there has been a single report that hypermutation occurs in TCR. One hypothesis is that, while somatic hypermutation can occur in T cells, it is a rare event because of the lack of selection pressure *in vivo* for the expansion of hypermutated cells. Such cells might exhibit a lower

dependence on affinity for the antigen/MHC complex for T cell activation than is the case for BCR affinity for antigen in B cells. Alternatively, somatic hypermutation may be prevented in T cells because it would allow the generation of potentially harmful (self) specificities. T cells undergo a rigorous selection procedure in the thymus that results in T cell recognition of antigen in the context of self MHC. The development of new, unselected specificities after thymic export could result in potentially dangerous autoreactive T cell clones.

Specificity of T cell receptors

The functional specificities of T cells is attributed mainly to the TCRs because the recognition of the antigenic peptides and MHC polypeptides ultimately depends on the final conformation and folding of the $\alpha\beta$ TCR heterodimer. Thus, a direct and simple structure–functional relationship between T cell specificity and primary TCR α and TCR β chain structure would be unexpected in most cases. Surprisingly, however, there are many examples in which a direct relationship exists between the specificity of the antigen and the primary sequence of the TCR. This correlation of structure and function breaks down into two categories: one including standard antigenic peptide–MHC complexes, and the other including ‘superantigens’, a class of antigens covering bacterial products (e.g. enterotoxins), minor lymphocyte-stimulating antigens MIs (e.g. endogenous retroviral products) and certain MHC products (e.g. I-E).

The most striking examples for the first category are the use of particular TCR-V α segments to recognize certain cytochrome *c* peptides in association with I-E products, and the use of specific TCR-V α J α , TCR-V β J β combinations to recognize a peptide from the myelin basic protein in association with I-A^b products. For superantigens, the correlation is often to a particular V gene (especially TCR-V β segments), with little structural contribution by the D and J gene segments or junctional sequences. It is likely that the conformation of these V gene segments possesses intrinsic affinity for these superantigens.

At this time, it is not known precisely how $\alpha\beta$ TCR heterodimers interact with their ligands (antigenic peptide–MHC product complexes). One hypothesis suggests that the V gene segments may recognize the MHC polypeptides while the V-D-J junctions make contact with the antigenic peptides. An understanding of the mechanism of this dual recognition may be gained when the three-dimensional conformational interactions between the $\alpha\beta$ TCR heterodimers and the peptide–MHC complex are defined.

Table 1 Estimate of human TCR repertoire

Gene segment	α chain	β chain
V	42	47
D	—	2
J	61	13
V $\times$ D $\times$ J	3×10^3	10^3
N-sequences	10^4	10^4
Total α or β	3×10^7	10^7
Total $\alpha\beta$ combinations	10^{14}	

Thymic selection of TCR $\alpha\beta$

Because the T cell receptor $\alpha\beta$ heterodimer is ultimately responsible for the specificity of the individual mature T cell, the development of functional TCRs providing an effective defense against infection by viruses, bacteria and parasites is essential. At the same time, these receptors must also be able to distinguish between 'self' and 'foreign' antigens, so as not to produce TCR reactivities against self antigens. Positive and negative selection and the participation of the coreceptors CD4 and CD8 are integral components of the thymic selection process.

It is believed that TCR $\alpha\beta$ combinations are generated randomly in the thymus by the association of the V, D and J gene segments, as well as by insertion of N-region sequences. Many of these TCRs will lack affinity for their own MHC molecules, and thymocytes bearing these TCRs die in the thymus during positive selection. Those TCRs with strong reactivities against self antigens (such as antigenic self peptide-MHC complexes, superantigen Mls or certain MHC) will also be clonally deleted (negative selection), thereby establishing central tolerance. Thus, only mature T cells which possess receptors having a weak affinity to self MHC products will be allowed to emerge from the thymus, resulting in a repertoire skewed towards the recognition of self MHC molecules in the presence of a foreign peptide.

TCR genes in malignancies

TCR and BCR genes provide useful tools for the evaluation of tissues from patients with lymphoproliferative disorders. Rearrangements of the TCR and BCR genes establish clonality of malignant cells in leukemia or lymphoma patients at the time of presentation or relapse, and are useful for establishing T or

B cell lineage, respectively. Chromosomal translocations involving the TCR genes are often found in T cell tumors. Using the genes of the TCR, several putative proto-oncogenes that may play a role in malignant transformation of T cells have been identified.

T CELL RECEPTOR, $\gamma\delta$

Adrian Hayday and **William Pao**, Department of Molecular Cell and Developmental Biology, and Section of Immunology, Yale University, Connecticut, USA

There is growing evidence that by comparison to cells bearing an $\alpha\beta$ T cell receptor (TCR), cells that bear a $\gamma\delta$ TCR recognize a broad and distinct spectrum of antigens, and contribute in unique ways to immune responses to pathogens, and to the development of autoimmunity.

The γ and δ chains can each be subdivided into variable (V) and constant (C) regions, the bodies of which comprise 'immunoglobulin (Ig)-like domains'.

As for other antigen receptors, the V regions of γ and δ chains are each encoded by genes assembled somatically from V, D (in the case of δ), and J gene segments that are noncontiguous in the germ line. Gene rearrangement is mediated between characteristic 'heptamer-nonamer' motifs that flank V, D and J, and depends on the recombinase-activating gene (RAG)-1 and -2 products. γ chain genes were first isolated in 1984 and were proposed to encode TCR

chains based on their capacity to rearrange like Ig genes, their organizational similarity to both Ig and TCR β chain genes, and their T cell-specific expression. δ genes were discovered 3 years later, during study of the TCR α chain locus, within which they are located. Between these two events, in 1986, human T cells were described that expressed a form of the TCR other than TCR $\alpha\beta$.

It now appears that $\gamma\delta$ cells, like B cells and $\alpha\beta$ T cells, are highly conserved components of vertebrate immune systems. Nonetheless, features of the $\gamma\delta$ repertoire can vary greatly among species. For example, $\gamma\delta$ cells in some species but not others are strikingly prominent within epithelia. Divergence of the γ chain genes may be one of the underlying causes of such differences.

γ gene families

Human γ chain genes are on chromosome 7, while the murine genes are on chromosome 13. Various nomenclatures have been adopted for γ genes. Table 1 lists two commonly used nomenclatures, adjacent to an official designation proposed in 1995 by a WHO-IUIS subcommittee. In BALB/c mice, there are seven potentially functional V_γ gene segments, three functional J_γ gene segments, and three functional C_γ gene segments. A fourth J_γ is a pseudo-(ψ) gene, as a result of which the proximal V_γ segment (GV5S3 ($V_{\gamma 3}/V_{\gamma 1.3}$), Table 1) is essentially unused. There are slight departures from the BALB/c γ gene organization in other strains of mice, but in all cases there seem to be six functionally employed V_γ genes, far

less than the ~ 23 V_β genes or ~ 75 V_α genes. Humans also have only $\sim$ six functional V_γ genes compared to ~ 47 V_β genes and ~ 42 V_α genes. However, V_γ gene divergence is such that it is difficult to establish human/mouse counterparts. Indeed, there are different genetic bases for the small size of the V_γ gene families in mice and humans. In mice, there are no overt $V_\gamma \psi$ -genes, whereas in humans, at least eight of ≥ 14 V_γ gene segments are ψ -genes (Figure 1). Table 2 compares commonly used human V_γ gene designations with the proposed designation.

δ gene families

TCR δ chain genes in mice and in humans are on the respective chromosomes 14. Like IgH and TCR β loci, TCR δ chain loci include D gene segments. The organization of the heptamer–nonamer motifs is such that D_δ segments may join to each other, and whereas V_δ - D_δ 2- J_δ is the most frequent rearrangement in murine fetal $\gamma\delta$ cells, most δ rearrangements in adult mice are V_δ - D_δ 1- D_δ 2- J_δ . Likewise, whereas early human fetal rearrangements join V_δ to J_δ via a single, J-proximal D (D_δ 3), rearrangements late in gestation include two or three D segments.

The sizes of the human and mouse δ gene families are difficult to assess, because V_δ gene segments are interspersed among V_α gene segments (Figure 1), and some V segments can be used as V_δ or V_α . For example, human V_δ 4, V_δ 5 and V_δ 6 have each been found rearranged to D_δ or J_α , as a result of which they are referred to by the new nomenclature as ADV6, ADV21 and ADV17, respectively (ADV denoting variable gene segments for both the alpha and delta loci). In the mouse, $\geq$ four murine V genes are transcribed as either V_δ or V_α mRNAs, and thus denoted ADV7S1, ADV7S2, ADV11SS5 and ADV17S2. Nonetheless, there are characteristic features of V segments commonly used in TCR δ chains (see below). As a result, it has been possible to estimate that there are ≥ 16 mouse V_δ genes. Of these, six are highly homologous members of a single (DV7/ADV7) family, reducing to 11 the number of distinct mouse V_δ segments, compared to $\sim$ eight distinct human V_δ genes. Although V_γ genes are highly diverged, it is possible to identify human/mouse counterparts, e.g. mouse V_δ 1 and human V_δ 2, that are more closely related to each other than they are to other Vs in the same species.

Gene structure

γ and δ chain genes comprise five and six exons, respectively. As in Ig genes, exon 1 of functionally rearranged $\gamma\delta$ genes encodes all but the last four

Table 1 Proposed official nomenclature for murine V_γ gene segments compared to two commonly used designations

Official designation ^a	Heilig and Tonegawa (1986) ^b	Garman et al (1986) ^c
GV1S1	$V_{\gamma 5}$	$V_{\gamma 3}$
GV2S1	$V_{\gamma 6}$	$V_{\gamma 4}$
GV3S1	$V_{\gamma 4}$	$V_{\gamma 2}$
GV4S1	$V_{\gamma 7}$	$V_{\gamma 5}$
GV5S1	$V_{\gamma 1}$	$V_{\gamma 1.1}$
GV5S2	$V_{\gamma 2}$	$V_{\gamma 1.2}$
GV5S3	$V_{\gamma 3}$	$V_{\gamma 1.3}$

In the proposed designation, G refers to γ ; V to variable; 1 to the allocated number for the particular V region family (in this case, numbers 1–4 are based on increasing distance from J_γ); S to the designation of a V segment as a member of a family of highly homologous V gene segments. GV1–V4 are not strongly homologous to any other V segments, thus they only have one member sets. By contrast, there are three closely related members (S1–S3) of the V5 family.

See footnote to **Table 1** for basis of designation, with the added use of: A1/A2 to denote alleles at a single locus; P, pseudogene; N, sequence substitutions that conserve the encoded polypeptide; T, allelic variants that are currently tentative.

amino acids of a hydrophobic leader. Exon 2 mostly encodes the Ig-like domain of the V region, fully formed by the somatic recombination of V, [D(δ)], and J. All murine J_γ segments are unusual in lacking 'glycine-X-glycine', a motif common to other Ig and TCR J regions. Exon 3 encodes the Ig-like domain of the C_γ/C_δ regions. Both V and C region Ig-like domains contain cysteine codons appropriately spaced to facilitate intradomain disulfide bonding, an important component of Ig-like structure.

In IgH genes, exon 4 encodes a protein hinge. Like that exon, the fourth murine and human δ gene exons are short and encode several prolines. But, proline codons are largely absent from the fourth γ gene exons, which are also noticeably diverged one from another: in murine $C_\gamma 1$, 2 and 3 genes, exon 4 encodes 10, 15 and 33 amino acids respectively; in human $C_\gamma 1$ it encodes 16 amino acids, while in $C_\gamma 2$, it is reiterated 2–3 times, depending on genotype. The short fourth exons can also encode Cys residues that mediate interchain $\gamma\delta$ disulfide bonding. For human $C_\gamma 2$, none of the reiterated copies contains a Cys codon, and $\gamma\delta$ TCRs encoded by $C_\gamma 2$ lack a $\gamma\delta$ interchain disulfide bond.

Exon 5 in all $\gamma\delta$ genes encodes a putative trans-membrane domain of uncharged, mostly hydrophobic amino acids. As in all TCR genes, these exons of $\gamma\delta$ genes each encode a basic (lysine) residue that may interact with a negatively charged residue in the

transmembrane domains of CD3. In mouse and human δ (and in TCR α and β) there is a potentially charged arginine, five residues N-terminal to the lysine. The coding potential of the γ genes ends in a hydrophilic, 12 amino acid, putative cytoplasmic tail, with a high charge density. In δ the putative cytoplasmic tail is very short (4–5 amino acids) and not highly charged. In δ genes, the 3' untranslated sequences and polyadenylation signals are within a sixth exon.

TCR $\gamma\delta$ protein

The sequence relatedness of $\gamma\delta$ genes to each other and to Ig genes is low. A γ cDNA is ~18–23% (depending on the regions being compared) similar to either TCR β cDNA or IgH cDNA; δ genes are only ~10–20% similar to other TCR and Ig genes, although parts of C_δ are claimed to be over 30% similar to IgG C regions. Despite these limited sequence similarities, the antigen receptor genes share high organizational similarities. Hence, based on the observation that within multigene families, protein folding is better conserved than primary amino acid sequence, TCR and Ig sequences have been intensively compared, in order to assess the likely resemblance of TCR protein structures to Ig structures that have been resolved by X-ray crystallography. The data suggest that $\gamma\delta$ TCR V and C regions can assume the characteristic structure of an Ig domain, termed the 'Ig fold' – seven β strands arranged in two antiparallel β sheets packed face to face. Furthermore, the Ig folds of V_γ and V_δ should associate, presenting at their surface a rather flat antigen-combining surface, perhaps of similar geometry to that of Ig.

When sequence data are used to create 'divergence trees', the human ADV regions (i.e. those rearranged as either V_α or V_δ genes) differ from other V_α regions in occupying their own branch, one that in mouse is occupied solely by V_δ regions. Such comparisons pinpoint structural signatures of TCR $\gamma\delta$, particularly in regions implicated in $\gamma\delta$ chain-pairing and in the putative complementarity-determining regions (CDR1, CDR2 and CDR3) that most likely bind antigen. For example, in all human and mouse V_α , residue 14 is glutamic acid, and residue 37 is glutamine, whereas neither is the case in any mouse or human V_δ . Residue 37 may be critical in restricting chain-pairing of V_α with V_β , and V_δ with V_γ . Indeed, residue 37 in human DV102 ($V_\delta 2$) is positively charged, while the only γ chain that is negatively charged in the equivalent position is GV2 ($V_\gamma 2/V_\gamma 9$) with which DV102 pairs almost exclusively.

Compared to most V_α regions, DV102 ($V_\delta 2$) is two

amino acids longer in CDR1, while DV103 ($V_\delta 3$) is two amino acids longer in CDR2. Likewise, the ADV genes have longer N-terminal sequences, that may extend the exposed, antigen-binding face occupied by the CDR loops. Interestingly, V_γ and V_δ chain genes are similar in many respects (e.g. both have CDR2 regions four amino acids larger than V_α), but compared to V_β , GV2 is two amino acids longer in CDR1, just as DV102, the δ chain commonly paired with GV2, is longer in CDR1. Similarly, GV1 has a two amino acid extension in CDR2, as does DV103, with which it commonly pairs.

CDR3 regions largely comprise amino acids encoded at the V(D)J join. Their diversity stems from variability in the joins and is heightened by the capacity of TCR D segments to be read in all three reading frames. CDR3 lengths are predicted to profoundly affect CDR shape and hence ligand specificity. Comparison of many sequences showed that murine and human CDR3 δ lengths are both highly variable and commonly longer than those in other TCR or Ig chains. This is in part because of D_δ – D_δ joining. CDR3 γ lengths are shorter, but more variable than CDR3 α or CDR3 β . The constraint on CDR3 α and CDR3 β may be imposed by the requirement of TCR $\alpha\beta$ to 'fit' on to major histocompatibility complex (MHC) molecules. Conversely, the IgH-like variability in CDR3 δ , and the imbalance between CDR3 γ and CDR3 δ (akin to that between IgH and IgL) indicates that $\gamma\delta$ TCRs are not restricted to recognition of a single class of antigen presentation molecule (e.g. MHC), and may recognize diverse antigens, as does Ig. Consistent with this is the high divergence of $\gamma\delta$ V gene segments. For example, two murine γ genes <1 kb apart are only ~30% similar. Hence, CDR1 and CDR2 would be very different in $\gamma\delta$ TCRs using these two V_γ s, predicting that the TCRs might bind dissimilar antigens.

Nonetheless, there are constraints on TCR $\gamma\delta$. Unlike Ig, there is no evidence that diversity is increased by somatic hypermutation, and the small size of $\gamma\delta$ gene families limits combinatorial diversity, obtained by recombination of any one of many V segments with any one of many D and/or J segments. There is also limited chain-pairing, and remarkably, certain epithelial $\gamma\delta$ populations show virtually no diversity; e.g. a single TCR ($V_\gamma 5$ – $J_\gamma 1$: $V_\delta 1$ – $D_\delta 2$ – $J_\delta 1$ (GV1–GJ1:DV101–DD2–DJ1)) is expressed by >95% of murine skin T cells; another TCR ($V_\gamma 6$ – $J_\gamma 1$: $V_\delta 1$ – $D_\delta 2$ – $J_\delta 1$ (GV2–GJ1:DV101–DD2–DJ1)) is expressed by most murine uterine T cells. Taken together, the data suggest that $\gamma\delta$ T cell repertoires may recognize a small number of highly diverse antigens.

Antigen specificity

Table 3 lists many of the antigen specificities reported for $\gamma\delta$ cells. Specificity is broad, and includes proteinaceous and nonproteinaceous ligands. By two criteria, TCR $\gamma\delta$ specificity can be distinguished from most TCR $\alpha\beta$ specificity. First, there is conspicuously little data for the recognition of peptides presented by conventional MHC (Table 3A). Second, recognition by TCR $\gamma\delta$ can be of native antigens, e.g. class II MHC (Table 3B), or herpes simplex virus glycoprotein I (Table 3I), without requirement for either antigen processing or presentation of the antigen on cells.

Tables 3C and 3D indicate that some $\gamma\delta$ cells may resemble a poorly understood set of $\alpha\beta$ T cells that can recognize murine nonclassical MHC and human CD1, molecules that may be functional analogs. Again, the direct target of $\gamma\delta$ cell recognition may be the molecules themselves, or bound antigens that can include lipids, glycolipids or hydrophobic peptides. Different CD1 and nonclassical MHC molecules show tissue-specific expression, perhaps compatible with the association of particular $\gamma\delta$ TCRs with certain tissues. CD1 responses may be a subset of those that participate in the immune response to mycobacteria: $\gamma\delta$ cells have been identified that react to mycobacterial antigens (Table 3E), that may be proteinaceous (Table 3E2) but that may not require presenting cells (Table 3E1, E2). Human $\gamma\delta$ cells can also react to low molecular weight phosphorylated, nonproteinaceous mycobacterial antigens (Table 3E3): currently no mouse $\gamma\delta$ cells have shown such specificity. Other specificities include less well-defined bacterial or protozoan antigens (Table 3F), staphylococcal enterotoxins in the absence of class II MHC (Table 3G), and cell-bound LPS (Table 3J). Although the specificities listed in Table 3 are highly diverse, it is not clear that $\gamma\delta$ cells *in vivo* can react to myriad foreign antigens in the same way that $\alpha\beta$ cells or B cells can. Thus, specific responses to challenging antigen are difficult to elicit in $\alpha\beta$ cell-deficient mice (see below).

Autoreactivity and selection

$\gamma\delta$ Cells recognizing mycobacterial heat shock protein (hsp) (Table 3E2) are cross-reactive to autologous hsp, provoking the idea that $\gamma\delta$ cells are primarily autoreactive. There are human $\gamma\delta$ cells that recognize Ig (Table 3H), possibly presented by hsp. Self-reactivity, e.g. to stress or activation antigens, may underlie $\gamma\delta$ cell reactivity to tumor cells or activated autologous cells of many types, in the absence of foreign antigen (Table 4). Likewise murine intra-

epithelial $\gamma\delta$ repertoires are commonly established in fetal/perinatal animals prior to foreign antigen exposure, and unlike $\alpha\beta$ repertoires, seem essentially constant in specific pathogen-free animals.

Several results suggest that the maturation of $\gamma\delta$ cells includes an interaction of the $\gamma\delta$ TCR with a stromal ligand, an equivalent of positive selection for $\alpha\beta$ cells. Since positive selection for $\alpha\beta$ cells may differ from negative selection that purges the repertoire of strongly autoreactive cells largely by a difference in affinity of the TCR for the ligand, one wonders whether autoreactive $\gamma\delta$ cells are similarly purged by high-affinity interactions with the stroma. This is suggested by studies of mice transgenic for an MHC-reactive $\gamma\delta$ TCR, but currently no data pertain to naturally arising $\gamma\delta$ cells.

Lymphoid and epithelial $\gamma\delta$ cells

The anatomical representation of $\gamma\delta$ cells varies strikingly. In adult mice, $\gamma\delta$ cells account for ~1–3% of T cells in spleen and lymph nodes, 10–50% of intestinal intraepithelial T cells, the majority of reproductive epithelial T cells, and $\geq 95\%$ of resident epidermal T cells. In humans, $\gamma\delta$ cells usually account for from 0.5% to 15% of T cells in peripheral blood, are variably represented in the gut epithelium, but are not obviously present in the skin. In chickens, $\gamma\delta$ cells frequently comprise 30% of peripheral T cells, and can constitute the majority of gut intraepithelial T cells. In ruminants, 30–80% of blood T cells are $\gamma\delta$ cells.

A high proportion of $\gamma\delta$ cells are double negative (lack surface CD4 and CD8) (see Tables 3 and 4), reflecting the fact that $\gamma\delta$ cells generally do not pass through positive selection by class I or class II MHC. Many gut $\gamma\delta$ cells are CD8⁺, but express the CD8 $\alpha\alpha$ homodimer that may be unrelated to recognition of class I MHC.

Murine epidermal $\gamma\delta$ cells can recognize keratinocytes, and gut $\gamma\delta$ cells may recognize gut epithelial cells. Epithelial cells acting as antigen-presenting cells would be relatively immobile, providing for few encounters with T cells. Thus, if the T cells are to be activated, those few encounters must have high chance of presenting a $\gamma\delta$ TCR ligand. This concept provoked the idea that intraepithelial $\gamma\delta$ T cells would have limited antigen specificity, strikingly borne out in the murine skin and reproductive epithelia.

Ontogeny of $\gamma\delta$ T cells

Considerable interest has been aroused by the ontogeny of $\gamma\delta$ cells. In mice and chickens, $\gamma\delta$ TCR

Table 3 $\gamma\delta$ T cell specificity: antigens

Origin	CD4/CD8	TCR usage	Antigen	Restriction element	Reference
A. MHC-restricted antigens

n.d., not defined; α -CI I, antibody against MHC class I; α -CI II, antibody against MHC class II.

is the first TCR expressed in the fetal thymus. Early fetal rearrangements are simple, using single D δ elements and no N nucleotides. Consecutive waves of early murine $\gamma\delta$ cells express successively V δ 1 (DV101) + V γ 5 (GV1) and V δ 1 + V γ 6 (GV2), and populate successively the skin, and reproductive tract. The schedule of V γ gene usage seems in part due to differential gene activation, although it is likely that important interactions occur between the expressed $\gamma\delta$ TCRs and ligands expressed by the thymic stroma in a developmentally programmed fashion (the intrathymic development of skin and uterine $\gamma\delta$ cells requires a fetal thymus). At later times, gut and lymphoid $\gamma\delta$ cells mature, expressing successively V δ 6 (ADV7)⁺ and V δ 5⁺TCRs with high junctional diversity.

Because humans lack obvious $\gamma\delta$ repertoires in skin or reproductive epithelia, it might have been predicted that there would be no equivalent of the murine early fetal thymic waves of V δ 1⁺ cells. Instead, the human thymus appears to produce similar waves of $\gamma\delta$ cells characterized by specific V δ expression. V δ 2 (DV102), the V gene most closely related to murine V δ 1 (early fetal), appears before V δ 1 (DV101), that most closely resembles mouse V δ 6 (neonatal), that appears prior to DV3, that resembles

mouse V δ 5 (postnatal). By contrast, the V γ chains paired with these V δ s are not as obviously related: for example there is no clear human equivalent of V γ 5 (GV1) that pairs with V δ 1 (DV101) in cells of the first thymic wave which populate the skin. Perhaps V γ divergence contributes to differences in ligand specificity (Table 3) and anatomical location between murine and human $\gamma\delta$ cells.

At least some cells that attempt and fail $\gamma\delta$ gene rearrangements can become $\alpha\beta$ cells, indicating a late common thymic precursor. Nonetheless, there may be multiple origins of $\gamma\delta$ cells: some epithelial $\gamma\delta$ cells may develop extrathymically, and the establishment of murine epithelial, but not lymphoid, $\gamma\delta$ populations, requires the syk tyrosine kinase, which may be involved in signal transduction from the TCR.

Functions of $\gamma\delta$ T cells

Although $\gamma\delta$ cells are probably heterogeneous in their functional capabilities, they can together seemingly perform all functions ascribed to $\alpha\beta$ cells. Thus, some protection against pathogens can be provided by $\gamma\delta$ cells in $\alpha\beta$ T cell-deficient mice, and $\gamma\delta$ cells can drive the production of autoantibodies,

thereby contributing to autoimmune disease. Both these effects may stem from generic interactions of $\gamma\delta$ cells with other lymphoid effector cells. However, most evidence suggests that antigen-specific responses cannot be efficiently induced in $\alpha\beta$ T cell-deficient mice, which are therefore highly immunocompromised toward most pathogens. Several non-exclusive reasons for this can be considered. $\gamma\delta$ Cells may not recognize a sufficient spectrum of foreign antigens. Thus, when TCR $\beta^{-/-}$ mice were repeatedly challenged with coccidia, $\gamma\delta$ B cell help was induced, but was not obviously directed at the pathogen. Nonetheless, given the reactivity of many $\gamma\delta$ cells to mycobacteria, it is difficult to understand how limited antigen specificity alone explains the immunodeficiency of TCR $\alpha/\beta^{-/-}$ mice toward mycobacteria. Alternatively, there may be inherent differences in the ways that $\alpha\beta$ cells and $\gamma\delta$ cells respond to antigen, even though $\gamma\delta$ cells reportedly can produce essentially all known effector molecules. Third, $\gamma\delta$ cells may be unable to interact efficiently and antigen specifically with professional antigen-presenting cells (APCs), and thereby coordinate a protective immune response. This inefficiency may be due to a failure of $\gamma\delta$ cells to recognize foreign antigens presented as peptides on MHC molecules possibly compounded by a failure of $\gamma\delta$ cells to express the surface and intracellular molecules that facilitate the efficient interaction of $\alpha\beta$ cells and APCs. The latter differences might underlie differences in the susceptibility of $\gamma\delta$ cells and $\alpha\beta$ cells to selection during development. They may also explain the lack of evidence for $\gamma\delta$ cells converting functionally to memory cells in response to foreign antigen.

A significant role for immunoregulation by $\gamma\delta$ cells is indicated by reports that $\gamma\delta$ cell-deficient mice show exaggerated lymphoid responses, both to pathogens (TCR $\delta^{-/-}$ mice show heightened immunopathology), and to self (TCR $\delta^{-/-}$ mice on particular

genetic backgrounds show increased autoimmune disease). This may again reflect recognition of activated effector cells, including $\alpha\beta$ cells, as indicated in several studies (Table 4).

In summary, there is overwhelming evidence that $\gamma\delta$ T cells have a distinct set of antigen specificities, facilitating their response to a variety of conditions. An important result of this in the healthy individual may be immunoregulation. In the immunocompromised, $\alpha\beta$ T cell-deficient individual, such as an AIDS (acquired immune deficiency syndrome) patient, $\gamma\delta$ T cells may activate other lymphoid effectors, such as B cells, but the targets of this combined action may more commonly be self than the challenging pathogen. Hence $\gamma\delta$ cells both contribute to and regulate immune responses to pathogens and to self.

T CELL RECEPTOR, EVOLUTION OF

Lee Rowen, Department of Molecular Biotechnology, University of Washington, Seattle, Washington, USA

T cell receptors (TCRs) comprise a subset of the vast immunoglobulin gene superfamily. Genes coding for four TCR polypeptides, designed α , β , γ and δ , have been well characterized in human and mouse. Transcripts for one or more of these polypeptides have been identified in numerous other vertebrates, including shark, salamander, chicken, sheep, cow, pig, rat and chimpanzee. It is believed that the TCR evolved during the origin of the vertebrate evolutionary lines, perhaps in conjunction with the major histocompatibility (MHC) locus. TCRs initiate the cellular immune response by responding to foreign antigens presented on the surface of antigen-presenting cells. Presented antigens take the form of small peptides nestled in the groove of receptors coded by the class I or class II genes located in the MHC locus. The repertoire of TCR α/β or γ/δ combinations is highly diverse, as required for an adaptive immune system. Diversity in the TCR repertoire of an individual organism is generated by a sophisticated immune cell-specific somatic recombination machinery that conjoins distantly-spaced DNA sequences in the chromosomes of T cells. An additional source of diversity from an evolutionary perspective is the expansion and contraction of gene segment numbers by nonhomologous recombination.

Generation of the T cell receptor repertoire in an individual

Two types of T cells are distinguished in humans and mice, according to their constituent TCR subunits – α/β or γ/δ . The predominant T cell type in humans and mice is the α/β form. The protein subunits, α , β , γ , δ , each contain a membrane-bound constant region and a variable region that recognizes the antigen–MHC complex. T cells originate in the thymus, where positive and negative selection ensures survival of only those T cells whose receptors can effectively recognize foreign antigens. Because thymic selection is tailored specifically to an individual's

MHC haplotypes, only a fraction of the potential diversity of the TCR repertoire is actually used.

Diversity in an individual's TCR repertoire is primarily generated as a result of two unique activities of the immune cell-specific recombination machinery: 1) rearrangement of chromosomal DNA so as to bring distantly spaced gene segments into conjunction (recombination), and 2) modification of DNA sequence at the junctions of gene segments by exonuclease nibbling and non-template-directed nucleotide addition (N-region addition). Polymorphism in variable gene segments contributes only a minor source of diversity to an individual's TCR repertoire, in contrast to the MHC. Diversity engendered by recombination is a function of the number of variable (V), diversity (D) and joining (J) gene segments in the germline TCR loci. Our current understanding of the organization of the TCR loci for human and mouse is schematized in Figure 1, and the relationship between a TCR gene, its transcript, and the polypeptide produced from the transcript is illustrated for the TCR β subunit in Figure 2. The α and γ loci each rearrange one V gene segment to one J gene segment; the β locus undergoes D–J, then V–DJ recombination; and the δ loci can rearrange V to DJ or V to DDJ. Several of the $V\alpha$ genes in human and mouse can rearrange to either a DJ segment of the δ locus or a J segment of the α locus. Once rearrangement of the TCR loci has occurred, permanently altering the chromosomal DNA of the T cell, a TCR of either the α/β or γ/δ subunits is produced from the mRNAs generated by transcription and splicing of the rearranged gene segments. Generally, only one α/β or γ/δ combination is allowed per T cell. Thus, the immune cell-specific recombination machinery ensures TCR uniqueness at the level of individual T cells and their descendants, and diversity in the TCR repertoire as a whole.

TCR loci differ from subunit to subunit and species to species in the number of germline gene segments capable of undergoing rearrangement. For

Figure 1 Genomic organization of the human and mouse TCR loci. Arrows indicate gene segments whose transcriptional orientation is inverted with respect to the other gene segments in the locus. kb, kilobases.

Figure 2 The TCR β subunit, from the perspective of gene, transcript and polypeptide. Genes for the TCR loci contain features not found in the transcript. The enhancer, promoter and other regulatory elements allow gene expression. Recombination signal sequences, indicated by a circle, facilitate alteration of the TCR chromosomal DNA through recombination and N-region addition, as described in the text. After transcription, introns are spliced to generate a mature transcript, which is translated into the polypeptide subunit. The VNDNJ region of the transcript provides the coding information for the third hypervariable region of the protein receptor, responsible for antigen-MHC recognition.

example, the human TCR β locus has twice the number of V gene segments as the mouse, whereas the converse is true for the α locus. The germline repertoire of γ/δ gene segments is more limited than that of α/β in human and mouse, but not necessarily so in other species, for example, chicken.

Diversity in the TCR repertoire is not, however, solely a function of the number of V, D and J gene segments in the loci. Indeed the most variable portion of the TCR transcript lies in the VJ or VDJ junctions. Codons from this region (VNJ or VNDNJ) translate into the third hypervariable region of the protein, which plays a key role in MHC-antigen recognition (Figure 2). During recombination, exonucleolytic nibbling of the 3' end of the V gene segment, both ends of the D segment, and the 5' end of the J segment is followed by the addition of an average of three to five nucleotides (N) in each junction, prior to the covalent joining of the gene segments. Due to nibbling and random N region addition, TCRs that share the same V, D, J and C gene segments can nonetheless differ in the length and amino acid sequence in the third hypervariable region. Thus, N region addition gives added value to the diversity potential inherent in the germline V, D and J gene segments.

Generation of the T cell receptor repertoire in a species

The number and overall organization of the V, D, J and C gene segments within the TCR loci are the result of evolutionary processes that lead to very different germline combinations in different species. In outbred populations within a species, there are variations in the TCR loci due to base substitution and insertion-deletion polymorphisms. These polymorphic variations provide the source material for potential evolutionary changes.

Across species, the organization of the TCR loci can differ greatly, even though the loci evolved from common ancestral TCR gene families. For a given TCR locus, species vary in 1) order of V, D, J and C gene segments, 2) number of V, J, D and C gene segments, 3) number of distinct subfamilies of V gene segments (V gene segments with sequence similarity less than 75% are in different subfamilies), and 4) the number of gene segments in each V subfamily. While most of the mapping and sequencing data come from the human and mouse TCR loci, some information, mostly in the form of cDNA sequences, has been obtained from other primates, other rodents, rabbit, artiodactyls, chicken, salamander, rainbow trout and shark. From the available data, inferences about mechanisms at work in the evolution of the TCR loci can be made.

Movement of large units of DNA

The complete DNA sequence of the human TCR β locus confirmed an organizational feature of the TCR loci that had been intimated by the physical maps, namely, the existence of multiple copies of locus-specific DNA sequence repeats. Most of the multimembered families of β variable gene segments are embedded in six repeats ranging in length from 0.8 to 31 kilobases. The number of copies of these repeats ranges from two to ten, indicating extensive duplication of some of the subfamilies. Blocks of repeated DNA sequence, or homology units, can be arranged in a tandem, dispersed or inverted orientation. Tandem arrays are particularly subject to increases or decreases in copy number due to recombination through unequal crossover. Tandem arrays can become dispersed, and thereby less subject to modification in copy number, by the intrusion of genome-wide interspersed repeats such as retroviral elements or LINE sequences. A comparison of the human and mouse γ loci illustrates how the movement of blocks of DNA can bring about differences in the organization of TCR gene segments between species (Figure 1). The mouse γ locus contains four copies of a 30–40 kilobase V–J–C homology unit, one of which is in an inverted orientation with respect to the other three. The human γ locus, by way of contrast, is organized along the lines of the β locus, with the V segments all 5' of the J–C elements.

Evolution within a species can take odd turns. For example, humans and closely related primates have two copies of a ~100 kilobase portion of the β locus containing several V gene segments, a functional copy on human chromosome 7 and a nonfunctional copy on chromosome 9. Presumably, a one-time duplication and translocation event occurred in the germline of a primate ancestor and subsequently became fixed in the population, but not necessarily because the duplication conferred a selective advantage. As a second example, humans today have a prevalent 20 kilobase insertion-deletion polymorphism involving three V β gene segments, two of which are functional, suggesting that the evolution of the β locus remains dynamic in our species.

Conservation of ancestral DNA units

A comparison of the physical maps and cDNA sequence data for the mouse and human TCR β loci shows that the order of orthologous gene segments is largely preserved for the single-membered subfamilies, suggesting the preservation of ancestral units of DNA containing several V gene segments. Sequences similar to some of these orthologous genes have been identified in artiodactyls and salamander, but the

maps for these species are not known. By way of contrast, chicken appears to have only two subfamilies of V β segments, each of which has been duplicated several times. The most striking example of preservation of an ancestral unit was obtained from a sequence comparison of 95 kilobases extending from the 3' most J δ to the 3' most V α in human and mouse (Figure 1). Not only was the order of the orthologous gene segments preserved in the two species, but much of the sequence was as well, exhibiting an overall 71% similarity, even in the noncoding regions. Interestingly, 32 J α segments have been identified in rainbow trout, suggesting that a large number of J α segments might have arisen early in vertebrate evolution. It would be fascinating to know how much sequence conservation, if any, has remained across the large evolutionary distance between fish and mammals.

Gene conversion

Gene conversion is a unidirectional exchange of sequence information between similar sequences, wherein one stretch of sequence is used as a template to 'repair' or 'correct' another stretch of sequence. Because the TCR loci are multigene families, with many regions of similar sequence due to duplications, gene conversion is likely to be common. Depending on the length of the converted region, which can vary from a few bases to many kilobases, gene conversion can be either a diversifying or a homogenizing force in evolution. The homogenizing effect of gene conversion has occurred independently in the constant gene segments of the β locus in several species (e.g. human, mouse and salamander). Although the D-J-C duplication in the β locus probably occurred early in tetrapod evolution (chicken lacks this duplication), the constant gene segments in each species investigated bear more intraspecies similarity than interspecies similarity. This suggests that there are species-specific constraints, such as a need to bind to accessory proteins, that exert selective pressure on the C β genes, leading to their concerted evolution.

Mutation

During DNA replication or recombination, DNA sequences can be altered by base substitution, insertion or deletion. Alterations in sequence can also occur by insertion of transposable elements. Because of mutation, functional gene segments can evolve into pseudogenes due to damage to the promoter, recombination signals, splice sites or coding sequence (frameshift, premature termination or deleterious amino acid substitution). Presumably, mildly damaged pseudogenes can evolve into functional genes

as well, through mutation or gene conversion. Badly damaged pseudogenes evolve into relics, gene segments identifiable primarily by sequence similarity rather than functional features. In the human TCR β locus, there are 45 or 46 functional genes, 19 or 20 pseudogenes and 22 relics. All but possibly one of the functional V β gene segments had been identified by sequencing cDNAs prior to the public release of the genomic sequence. Because pseudogenes are vastly underrepresented in cDNA libraries, genomic sequencing of other TCR loci will reveal heretofore unidentified pseudogenes and relics and will thus contribute to our understanding of the evolutionary dynamics of the TCR loci.

Because of their complexity, the TCR loci present a fascinating system for the study of molecular evolution. As the complete genomic sequences of TCR loci in different species become available, a detailed cross-species comparison of promoter and regulatory regions, recombination signal sequences and NDN and NJ diversity, will lead to a more complete understanding of this key component of the vertebrate immune system.

T CELL RECEPTOR, RECOGNITION BY

Arthur W Boylston, Department of Pathology, University of Leeds, Leeds, UK

Unlike antibodies, T lymphocytes do not recognize antigens in solution. Instead, they recognize antigens on intact cells in the context of surface molecules encoded by the major histocompatibility complex (MHC). How cells could recognize both a foreign antigen and MHC proteins was the central problem in immunobiology for many years. The answers to this problem have come from elucidation of the structure of the T cell antigen receptor (TCR) and MHC molecules, and appreciation of the phenomenon of antigen processing by antigen-presenting cells (APCs).

Usually, T lymphocytes do not respond to intact protein antigens, but rather to peptide fragments. APCs such as macrophages or B lymphocytes take up intact antigen and process it into fragments which are recognized in the context of MHC molecules. This process also occurs for normal cellular constituents as well as viruses so that 'self' proteins are also processed and presented.

MHC molecules have a surface consisting of two parallel α helices supported on a β pleated sheet. A groove or pocket is formed which has an α helix on each side and the β pleated sheet as its floor. The T cell 'sees' antigenic peptides which are bound into this groove in the MHC molecule. From the T cell's perspective, the MHC and the central peptide probably form an undulating surface, the exact contours of which will be determined by the amino acid sequence of the MHC and the enfolded peptide.

There are two classes of TCR, sometimes referred to as TCR1 and TCR2 in view of their appearance during ontogeny. TCR1 is a heterodimer composed of polypeptides called γ and δ chains, which appears

at about day 14 in the mouse embryo. The TCR2 heterodimer is composed of polypeptides called α and β chains, and appears at about day 17 in the mouse embryo. At birth, TCR2 is the predominant form and 90–99% of T cells in the blood and lymphoid organs of mice and humans express this class of receptor. TCR2 mediates conventional MHC-restricted antigen recognition by T cells. The nature of the antigen recognized by TCR1 is not yet clear.

Both TCR2 α and β chain gene complexes encode variable (V), joining (J) and constant (C) region segments and, in addition, the β chain gene contains diversity (D) segments. Further heterogeneity at the V–J or V–D–J functions can result from junctional flexibility and the loss or addition of nucleotides during the process of recombination (N region diversity). Comparison of the structure of V gene sequences for TCR and Ig suggests that TCR V genes, like Ig V genes, encode two regions of 'hyper-variability' known as complementarity-determining regions (CDR1 and CDR2); these, together with CDR3, form the surface which interacts with the antigen. In both TCR and Ig the third hypervariable or complementarity-determining region (CDR3) is encoded by the extreme 3' end of the V gene, together with (D and) J gene segments. It appears that the TCR α and β chain V regions form two wing-like surfaces with CDR1 and CDR2 regions on the outside and the two CDR3 regions adjacent to each other in the middle. Modeling this structure on to the MHC–peptide complex described above suggests that the V region CDR1 and CDR2 loops interact with the α helices of the MHC molecule, while the CDR3 segment interacts with the peptide. TCR

CDR3 diversity would allow recognition of an exceedingly large array of antigenic peptides. Theoretical calculations suggest that there are at least 10^{14} TCR2 combinations.

X-ray crystallography of MHC-peptide-TCR complexes has revealed that two or three amino acids on the peptide are exposed for potential TCR interaction, with the rest of the amino acids buried in the MHC groove. While the broad prediction of CDR3 interaction with the peptide has been confirmed the model is more complicated than expected. In one complex the β chain only makes contact through 2 or 3 amino acids in CDR3, and the CDR1 and CDR2 loops appear to have no contact with antigen. Thus there appears to be considerable variability in the way the TCR can bind to the relevant antigens. No definitive model can be deduced until many complexes have been analysed.

Analysis of the interaction between TCR2 and MHC-peptide complexes reveals low-affinity binding, largely due to a tendency for the complex to dissociate rapidly. This implies that the interaction between T cell and APC is mediated by non-TCR adhesion molecules and the TCR itself functions only to detect the presence or absence of specific antigens. Quantitative studies of TCR occupancy suggest that the T cell 'counts' each interaction with specific antigen so that the cell is triggered to respond when a particular predetermined threshold is passed.

Structural studies of TCR2 suggest an important difference from Ig molecules in the way that the V and C regions interact. In Ig molecules the hinge between V and C allows V region interaction with antigen without altering the conformation of the C region. In TCR molecules V-C interaction is rigid and therefore TCR-antigen recognition can lead to signal transduction through an altered conformation of the C region.

Subtle differences in TCR-antigen interaction can have profound effects on TCR responses. Changing a single amino acid in the antigenic peptide can change the effect from agonist to antagonist. Single mutations in important viral antigens can lead to T cell inactivation instead of lysis. Other changes may produce partial agonist effects which result in altered patterns of cytokine secretion. Finally, some changes induce anergy.

Recent X-ray crystallography indicates that class II MHC molecules probably occur as dimers on the APC surface. Interaction between TCR dimerized MHC and CD4 molecules could lead to the formation of recognition zones where multiple recognition events occur simultaneously in close proximity.

TCR1 ($\gamma\delta$) have considerably less V region diversity than TCR2 but at least as much CDR3 diversity.

Some $\gamma\delta$ T cells recognize antigens in the context of nonclassical MHC-like molecules such as CD1. Further, $\gamma\delta$ cells specific for nonprotein lipid-like determinants appear to be an important component of the response to *Mycobacterium tuberculosis* infections. Important differences in the location of $\gamma\delta$ T cells exist between humans and mice where defined populations of $\gamma\delta$ cells are found in specific epithelial sites. Overall the data suggest that $\gamma\delta$ cells may recognize unconventional antigens associated with cell surface molecules that do not show the exceptional polymorphism found in MHC molecules. The antigen binding groove of CD1 is much deeper and lined with hydrophobic amino acids when compared with conventional MHC molecules. It appears to be adapted to binding lipid antigens and presenting lipid-derived moieties to both $\gamma\delta$ and $\alpha\beta$ TCR. The TCR probably recognizes exposed carbohydrate structures linked to the embedded lipid. $\gamma\delta$ cells may be an important early pathway to recognition of organisms which are capable of evading conventional immune responses. However, unlike TCR2 deletion of the TCR1 receptor does not lead to rapid death from infection.

Both TCR1 and TCR2 have a hydrophobic transmembrane segment and short cytoplasmic tails. Both are physically associated with the CD3 complex of proteins. Following recognition of antigen by TCR, the CD3 complex probably acts as a transducing element converting recognition into a signal which induces cytokine and receptor expression. Ultimately, this signal leads to cell replication or expression of effector functions such as cytotoxicity.

T CELL VACCINATION

Irun R Cohen, Department of Immunology, The Weizmann Institute of Science, Rehovot, Israel

T cell vaccination (TCV) is a term describing a method for modulating immune responses in which T cells are administered as immunogenic agents. Typically, an autoimmune response is the subject for modulation and the vaccine consists of T cells specifically reactive to the target autoantigen. The first example of TCV in an autoimmune disease was reported in 1981 by Ben-Nun, Wekerle and Cohen who treated Lewis rats with a line of Lewis rat CD4⁺8⁺ T cells specifically reactive to the dominant epitope of myelin basic protein (MBP). The anti-MBP T cells, which served as the vaccine, were irradiated (1500 R) to prevent them from attacking the recipients and producing experimental autoimmune encephalomyelitis (EAE). Vaccination with the attenuated anti-MBP T cells led to resistance to later attempts to induce EAE by active immunization to MBP in adjuvant. Subsequently it was shown that TCV could also induce resistance to EAE adoptively transferred by virulent anti-MBP T cells.

T cell vaccination was extended to other disease models (adjuvant arthritis (AA), collagen-induced arthritis, experimental autoimmune neuritis, experimental autoimmune thyroiditis and insulin-dependent diabetes mellitus (IDDM)). Moreover, TCV was found to abort established autoimmune disease (AA, IDDM) and spontaneous autoimmune disease (IDDM) and so can be viewed as therapy as well as prevention.

The term TCV was coined to describe manipulation of autoimmune responses using autoimmune T cell vaccines; however, in principle and in practice the procedure may be applied to modify undesirable T cell responses central to allograft rejection or to allergy.

The concept of vaccination was introduced by Jenner about two centuries ago to describe the use

of cowpox to induce immunity to smallpox. A century later, Pasteur extended the word to encompass the concept of using an attenuated infectious agent of disease to induce resistance (now understood to be immunological) to virulent forms of the agent. TCV represents a further extension of Pasteur's vaccination concept to include the individual's own lymphocytes as perpetrators of disease from which vaccines might be made.

T cell vaccination may be analyzed conveniently by dividing the subject into three parts: the T cell vaccine, the regulatory response to the vaccine, and the lymphocyte networks linking these T cells.

T cell vaccines

It seems that T cells do not perform well as vaccines unless the cells have been activated. To be activated, the T cells are incubated for a minimum of about 6–8 h with their specific antigen, or with a T cell mitogen together with antigen-presenting cells. The molecular changes induced by activation that are critical for TCV have not been identified, but their effect is marked. Treatment of whole T cells with chemical cross-linkers can also enhance the effectiveness of some but not all T cell vaccines.

T cell receptor TCV

The T cell receptor (TCR) is clearly an important actor in TCV. Peptides of two different domains of the TCR have been found to mimic some of the effects of whole T cells as vaccines: TCR V region peptides and TCR joining region peptides. The joining regions of the TCR (VDJβ and VJα) determine the epitopes that can be recognized by the particular TCR; the joining regions also create the T cell idotype. Thus, the response to vaccination with a TCR joining region peptide is an anti-idiotypic

response, by definition. Indeed, TCV using whole T cells was found to activate anti-idiotypic T cells of both CD4⁺ and CD8⁺ phenotypes specific for the vaccine. In contrast to TCR joining region peptides, TCR V region peptides are not idiotypic by definition because a given V gene segment can be common to different T cell clones. Thus, TCV using a TCR V region peptide should be viewed as a kind of class-specific stimulus, and not as an anti-idiotypic immunization. Nevertheless, TCV with V region peptides is effective, at least in rodents, possibly due to restrictions in the TCR V regions deployed in the dominant T cell clones that mediate autoimmune diseases. Recently, it has been shown that naked DNA vaccination using DNA encoding a V gene segment relevant to mouse EAE can vaccinate against the disease.

Ergotypic TCV Partial resistance to experimental autoimmune diseases has been induced using attenuated, activated T cells lacking a specific TCR relevant to the particular disease. TCR-independent TCV seems to be induced by cell membrane factors expressed by T cells primarily in the activated state. The term *ergotype* was coined to designate the molecules associated with T cell activation that were proposed to function in the T-T interaction between effector T cells and anti-ergotypic regulatory T cells. It is possible that anti-ergotypic T cells synergize with anti-idiotypic T cells in the T-T interactions involved in TCV. Indeed, the requirement for activation of the T cells for effective TCV may be explained by the augmenting effect of the resulting anti-ergotypic response.

Mechanisms of regulation

An open question is how the anti-idiotypic and anti-ergotypic regulatory cells arrest the autoimmune disease process. Specific autoimmune T cells persist in TCV-treated animals, suggesting that effective regulation of disease does not depend on total deletion of the autoimmune effector cells. Indeed, TCV was found to suppress inflammation without inhibiting the production of autoantibodies. The divergent effects of TCV on tissue damage and antibody production may be explained by the T_H1-T_H2 dichotomy. TCV has been found to enhance a switch from a proinflammatory T_H1-type cytokine response to an anti-inflammatory T_H2-type cytokine response. Following TCV, the treated animals still respond to the target self antigen; however, instead of producing large amounts of interferon γ and interleukin 2 (IL-2), the responding T cells produce low amounts of these cytokines and high amounts of IL-4, IL-10 and

transforming growth factor β (TGF β). The shift in cytokine profile induced by TCV leads, in mice, to the production of immunoglobulin G1 (IgG1) isotype antibodies to the target self antigens. This shift has been observed both in naked DNA TCV against mouse EAE and in TCR peptide (VDJ β) vaccination against spontaneous diabetes in the NOD mouse. It remains to be determined whether TCV works by inducing existent T_H1 clones to change their cytokine output, or by activating dormant clones of T_H2 T cells to suppress the pathogenic T_H1 clones. In either case, these findings call attention to the influence of T-T interactions on the cytokine profile of the immune response.

Lymphocyte networks

Study of the physiological basis of TCV suggests that its effectiveness in regulating autoimmune disease owes much to natural lymphocyte networks that already exist before intervention by TCV. Vaccination with autoimmune T cells is effective in controlling an autoimmune disease because the anti-idiotypic regulatory T cells are present and await activation. According to this view, TCV merely strengthens a natural network; it does not initiate a new response.

The evidence for the existence of natural lymphocyte networks is discussed at length in several reviews cited at the end of this article. In brief, such anti-idiotypic networks can be observed in animals responding to particularly dominant autoantigens such as MBP, heat shock protein 60 (hsp60) and insulin. The uniformity of T cell receptor genes and the dominance of the major autoantigens is another expression of these lymphocyte networks. For example, MBP is a dominant neuroantigen because a pre-existing network of T lymphocytes anticipates MBP. The dominance of MBP is encoded in the anti-idiotypic helper T cells that drive the response of the anti-MBP idiotypes. It is quite possible that these anti-idiotypic T cells select, and thereby restrict, the T cell receptor gene products used for recognizing MBP. EAE is expressed clinically when natural anti-idiotypic regulation is inadequate to control the vigor of the anti-MBP T cells; TCV induces resistance to MBP by strengthening the regulatory networks. Likewise, TCV seems to arrest the development of diabetes in the NOD mouse by enhancing the regulation of a critical autoimmune response to hsp60.

Generalizing from the networks revealed in EAE and diabetes, it is quite possible that the limited number of autoimmune diseases and the uniformity of autoantigens recognized in these diseases is the

product of a limited number of networks that focus the immune response to selected autoantigens.

Elsewhere I have defined the lymphocyte networks responsible for the dominance of certain self antigens as an immunological homunculus, the immune system's preformed picture of the body. The homunculus operationally determines the dominance of particular self antigens and regulates the immune response to these antigens so that overt disease is rare. Disease emerges when the regulatory T cells of the network falter. TCV aborts disease by augmenting natural regulation. One expression of network regulation would seem to be the cytokine profile of the autoimmune response.

Clinical applications

Specific TCV has been used clinically in patients suffering from relapsing multiple sclerosis. The vaccines were prepared using autologous clones of attenuated T cells responsive to MBP. Similar to the results in experimental models, the patients with multiple sclerosis were found to develop anti-idiotypic T cells whose appearance was associated with a sharp decline in the frequency of anti-MBP T cells in the peripheral blood, as detected by T cell proliferation. More patients and more time will be required to learn whether TCV can influence the long-term course of disease. In any case, the immunology of TCV staged in experimental animals is reflected in clinical trials of TCV in natural human disease.

THEILERIOSIS

Subhash P Morzaria, International Livestock Research Institute, Nairobi, Kenya

Theileria species are tick-transmitted intracellular protozoan parasites of domestic ruminants and wild Bovidae and the diseases they cause are collectively referred to as theileriosis. Of the several *Theileria* species infecting domestic ruminants (Table 1), the two most economically important are *T. parva* and *T. annulata*. There are approximately 250 million cattle at risk from these two parasites, which together are responsible for inhibiting livestock development in many parts of the world (Figure 1). The distribution of *T. parva* is limited to eastern,

central and southern Africa where it is predominantly transmitted by the tick *Rhipicephalus appendiculatus*. *Theileria annulata*, transmitted by several species of *Hyalomma* ticks, is more widely distributed, extending from northern Sudan and the Mediterranean countries to the Middle East, India, southern Asia and China.

Theileriosis is mainly controlled by the application of acaricides to domestic ruminants. Apart from being expensive, these chemicals are toxic and hazardous to humans and the environment. Ticks also

rapidly develop resistance to acaricides. Therefore, alternative methods of controlling theileriosis are sought, mainly focused towards the development of vaccines.

Characteristics of *Theileria* and their antigens

Sporozoites injected during tick feeding are the infective stage; these then invade the host mononuclear

leukocytes (see Figure 2). The target cells for *T. parva* sporozoites are mainly bovine T cells, while those for *T. annulata* are B lymphocytes and macrophages. The target cell types for other *Theileria* species have not been defined. Following entry, sporozoites differentiate into multinucleate schizonts. The

Figure 1 Distribution of the two most economically important *Theileria* species, *T. parva* and *T. annulata*. The distribution of the tick vectors is wider than these parasites and hence the potential for spread is high.

Figure 2 Life cycle of *Theileria parva*. Sexual cycle is obligatory and occurs in the tick. Transformation and clonal expansion of infected cells has only been described in *T. parva*, *T. annulata*, *T. taurotragi* and *T. hirci*. All stages except zygotes and kinetes are haploid. The transmission is trans-stadial, thus larvae and nymphs of three host ticks become infected when feeding on an infected host and the resultant nymphs and adults transmit the parasite.

schizonts of *T. parva*, *T. annulata*, *T. taurotragi* and *T. hirci* induce the host cells to transform and proliferate. Casein kinase II in the host cell and the parasite may be involved in the signaling of this proliferation. During host cell division schizonts associate closely with the mitotic spindle and divide synchronously with the cell, resulting in clonal expansion of infected cells. Between 3 and 4 days after infection, some schizonts undergo merogony to produce large numbers of merozoites. These escape following the rupture of the host cells and invade erythrocytes, where they develop into piroplasms.

Ticks become infected when taking a blood meal from infected animals. Within the ticks the parasites undergo a complicated development, including a sexual cycle, to produce motile kinetes, which migrate to the salivary glands where they undergo a process of maturation to produce infective sporozoites.

The clinical signs of theileriosis are predominantly associated with the schizont stage. Infected animals develop pyrexia and enlarged lymph nodes, coinciding with the appearance of intracellular schizonts. Infected cells rapidly spread to other lymphoid tissues causing generalized lymphadenopathy. With the emergence of host killer cells and rupture of infected cells a lymphodestructive phase follows

which results in severe leukopenia. The animals quickly lose condition, develop respiratory distress and frequently die within 10–15 days with massive pulmonary edema and severe gastroenteritis. Anemia, associated with erythrocytic merogony is an additional feature in animals infected with *T. annulata* and *T. hirci*.

A number of *Theileria*-specific antigens have been identified and characterized (Table 2). An antigen referred to as the polymorphic immunodominant molecule (PIM) of *T. parva* is present in all the stages of the parasite and varies considerably in size among the different stocks. The PIM gene shows highly conserved terminal sequences flanking a central variable region. Some antibodies specific for the PIM antigen neutralize sporozoite infectivity for lymphocytes *in vitro*. However, cattle immunized with recombinant PIM are not protected against *T. parva* challenge. The role of PIM in the induction of cell-mediated immune responses is currently being evaluated.

The 67 kDa antigen of *T. parva* is localized on the surface of sporozoites. The gene coding for this antigen has been sequenced and characterized. It is present as a single copy, has a small 29 bp intron and is highly conserved among different stocks of cattle-derived *T. parva*. Murine monoclonal antibodies

Table 2 Antigens of different *Theileria* species

Species	Molecular weight (kDa)	Method of identification	Localization	Identified function	Application
<i>T. parva</i>	104	Recovered sera/immunoblot	Sporozoites	Rhoptry associated	None
	85 (PIM)	Recovered sera/immunoblot	Sporozoites, schizonts, piroplasms	None	Diagnostic antigen for ELISA
	67	Recovered sera/immunoblot	Sporozoites	Role in sporozoite entry	Candidate vaccine antigen
	32	Recovered sera/immunoblot	Sporozoites, schizonts, piroplasms	Merogony	None
<i>T. annulata</i>	43, 12 and 4.2	T helper cells	Schizonts	None	None
	85, 72, 63, 54 family	mAb/immunoblot/immunoprecipitation	Sporozoites	Role in sporozoite entry	Candidate vaccine antigen
	99, 116, 125 family	Immunoprecipitation	Surface of schizont-infected cells	None	None
	32	mAb, immunoprecipitation	Sporozoites, schizonts, piroplasms	Merogony	Diagnostic antigen for ELISA
<i>T. mutans</i>	117	mAb	Schizonts, merozoites	Merogony	None
	32	Recovered sera/immunoblot	Piroplasms	None	Diagnostic antigen for ELISA
<i>T. sergenti/orientalis/buffeli</i>	32	Recovered sera/immunoblot	Piroplasms	None	Diagnostic antigen for ELISA

(mAb) and rat polyclonal sera raised against different stocks of *T. parva* and bovine sera from ECF-endemic areas neutralize the infectivity of sporozoites *in vitro*. The potential of this antigen as a subunit vaccine is currently being explored (see below).

In *T. annulata* a family of related proteins (85, 72, 63 and 56 kDa) referred to as SPAG1, and expressed on the surface of sporozoites, has been identified by a mAb. This mAb and bovine infection sera block sporozoite entry into leukocytes *in vitro*. The SPAG1 gene has a high degree of homology with the C-terminus of the 67 kDa gene of *T. parva*. The protective capacity of SPAG1 has yet to be fully evaluated.

Infection-specific proteins (95–120 kDa) on the surface of *T. annulata* schizont-infected cells have been identified and mAbs against these proteins mediate complement lysis of the infected cells. However, it is not clear if these proteins are parasite or host specific.

A family of 32 kDa antigens has been found in all *Theileria* species so far examined. This antigen has been more extensively characterized in *T. annulata*. It is expressed at low levels in the schizont stage but is upregulated during merogony and is localized on the surface of merozoites. The gene encoding the polypeptide has been sequenced and shows a high degree of homology with the 32 kDa merozoite genes of *T. parva*, *T. mutans*, *T. taurotragi* and *T. sergenti/orientalis/buffeli* complex. The recombinant forms of the Asian *Theileria* complex induce high levels of specific antibody in cattle but do not confer protection.

During the acute phases of infection, schizonts and piroplasms can be identified in Giemsa-stained smears of lymph nodes and blood, respectively. Immunofluorescence tests have low sensitivity and specificity. Improved antibody detection ELISAs based on recombinant antigens such as PIM for *T. parva* and p32 for other *Theileria* species are currently being validated. DNA probes and mAbs are available for the characterization of stocks and strains of *T. parva*, and polymerase chain reaction (PCR)-based tests have been developed for differentiation of *Theileria* species.

Hydroxynaphthoquinones parvaquone and buparvaquone, and halofuginone are highly effective anti-theilerial drugs but are relatively expensive and have to be administered early in the infection to be effective.

Immune responses of the host

The immune responses in cattle to *T. parva* and *T. annulata* have been more extensively characterized than for other *Theileria* species. Cattle exposed to

challenge in the field exhibit variation in severity of disease, which is largely dependent on the dose of sporozoites inoculated. Animals that recover are resistant to homologous challenge and in the absence of further challenge the immunity lasts between 3 and 5 years. Cattle immunized using live parasites (see below) may also exhibit a similar duration of immunity.

Cell-mediated immune responses play an important role in protection. The transfer of CD8⁺ lymphocytes from a *T. parva* immune calf to its naive twin protect the recipient against a homologous challenge. Parasite-specific major histocompatibility complex (MHC) class I restricted cytotoxic T cells (CTLs) directed against schizont-infected cells are the major effectors of protective responses in both *T. parva* and *T. annulata* infections.

Humoral responses directed against schizonts and piroplasms are unimportant in the generation of natural protective immunity. Sera from immune animals with high levels of schizont and piroplasm antibodies do not confer protection when passively transferred into naive cattle. In addition, animals that are immunized using lysates of schizonts or piroplasms are fully susceptible to infection with sporozoite challenge. Thus, infection with sporozoites and the development of schizonts appear to be essential for the development of natural immunity.

Evasive strategies by the organism

Although no specific evasive strategies such as antigenic variation in trypanosomes and malaria parasites are known to be deployed by *T. parva*, there are certain features of the parasite development that ensure its survival and transmission. The sporozoite stage enters very rapidly into the host cells at the tick bite site, thus evading the first line of host defense mechanisms. Following entry, sporozoites rapidly differentiate into schizonts that induce the host cells to transform, enabling the parasite to expand in numbers. Animals that ultimately recover from infection become life-long carriers, enabling successful transmission to the ticks. In some *T. parva* carrier animals, schizonts multiply in the anterior chamber of the eye, an immunologically privileged site.

Vaccines

T. annulata live vaccine

The establishment of immortalized schizont-infected cell lines in culture has been the significant breakthrough in the development of a tissue culture-based vaccine for *T. annulata*. Following several passages *in vitro* cell lines lose their virulence. Such

'attenuated' cell lines, when inoculated into cattle, establish patent infection without causing disease. They invoke protective immune responses and are now produced commercially as vaccines in Israel, India, Iran and China. The live vaccines are inoculated subcutaneously at a dose ranging between 10^6 and 10^7 infected cells per animal.

***T. parva* live vaccine**

Although *T. parva* can be attenuated *in vitro*, the tissue culture-based approach for vaccination has not been successful because schizonts of *T. parva* do not easily transfer from cell to cell and hence cattle cannot be reliably infected with attenuated cell lines. A method of immunization against *T. parva* has been developed that utilizes infection of cattle with a potentially lethal dose of sporozoites and simultaneous treatment with a long-acting oxytetracycline. This method induces a mild infection causing transient pyrexia and schizont parasitosis. Recovered animals are subsequently immune to homologous challenge. Wider adoption of this method has been slow, mainly because it has been difficult to apply in the field due to cold-chain requirement, and the immunity engendered is strain specific.

***T. parva* subunit vaccine**

A subunit vaccine based on the p67 antigen is currently under development. The recombinant form of this antigen protects approximately 70% of immunized cattle against experimental challenge. A number of studies are in progress to enhance the protective level before field testing. It is expected that a combination of antigens provoking responses directed at sporozoite and schizont stages will ultimately be used for vaccination against *T. parva*.

THY-1

Michael Schlesinger, The Hubert H Humphrey Center for Experimental Medicine and Cancer Research, The Hebrew University-Hadassah Medical School, Jerusalem, Israel

The Thy-1 antigen was discovered by Reif and Allen in 1964 as a mouse alloantigen distinguishing between the AKR/J mouse strain and many other inbred strains of mice. The antigen was initially called the Θ (theta) antigen, and its alloantigenic variants were called Θ -AKR and Θ -C3H, respectively. It was shown to be expressed preferentially in the nervous tissue of the mouse and on some

lymphocytes, with a particular high level on thymocytes. When it became apparent that the AKR/Cum inbred strain possessed the Θ -C3H rather than the Θ -AKR alloantigen, and that rats possessed the Θ -AKR determinant, the name of the Θ antigen was changed into Thy-1 and its alloantigenic variants became Thy-1.1 and Thy-1.2.

In 1969 the Thy-1 antigen was shown to be

present on a distinct subset of mouse lymphocytes that became known as T lymphocytes. Schlesinger and Yron showed that the Thy-1 antigen was characteristic for those lymphocytes that disappeared from the peripheral lymphoid system upon neonatal thymectomy or following treatment with xenogeneic antilymphocyte serum, while Raff showed that the antigen was virtually absent from the lymphoid system of nude mice.

The Thy-1 antigen was subsequently demonstrated in many other species, including humans, rats, dogs, chickens, frogs and even squids and tunicates. The tissue distribution of the Thy-1 antigen in the various species is, however, somewhat different. In almost all species studied, the Thy-1 antigen is present in the nervous tissue. In mice and rats Thy-1 was shown to be absent from glial cells but was found on neurons, with the exception of the primary olfactory neurons.

On the whole, the Thy-1 antigen has proven to be a very useful reagent for the detection and selection of the T lymphocyte subpopulation among the white blood cells of mice. Thy-1 could, however, also be detected at low concentrations on pluripotent hematopoietic stem cells in mice and in rats. The antigen was expressed on progenitor cells of the erythroid, myeloid and B lymphocyte pathway, but was absent from more mature stages of development. In humans, the Thy-1 differentiation antigen (CD90) is expressed on CD34⁺ hematopoietic progenitor cells isolated either from the bone marrow or from the peripheral blood.

Biochemical analysis of Thy-1 by Williams and colleagues indicated that it is a glycoprotein with a molecular weight of 17.5 kDa and 18.7 kDa in the brain and thymus, respectively. The Thy-1 molecule contains three N-linked oligosaccharides, which constitute about one-third of the mass of the molecule. Two of the N-linked glycans consist of complex-type oligosaccharides, while the third glycan consists of high-mannose oligosaccharides. The overall structure of the Thy-1 molecule resembles that of other members of the immunoglobulin superfamily. The Thy-1 and immunoglobulin molecules are similar in the position of the disulfide bonds, and in the high content of β sheet secondary structure with no α helices. The protein moiety of the Thy-1 molecule expressed on the surface of cells was found to consist of 111 amino acids in human and rat Thy-1 and of 112 amino acids in mouse Thy-1. In contrast, Silver demonstrated that the cDNA of Thy-1 codes for a Thy-1 molecule that should consist of 141–142 amino acids. The 31 amino acids beyond the carboxyl-cysteine at position 111 were not expressed in most Thy-1 molecules. The missing stretch of amino acids contained a 26 amino acid sequence that is extremely

hydrophobic, resembling the transmembrane segment found in many other membrane proteins. This apparent discrepancy became resolved when it was shown by Low and Kincade that most of the Thy-1 molecules do not penetrate through the cell membrane but rather are attached to a glycolipid on the cell membrane. It now seems that the entire 141–142 amino acid Thy-1 molecule is synthesized in the endoplasmic reticulum of the cell, is then cleaved off in position 111, and an amide linkage is formed between the carboxyl group on cysteine 111 and an ethanolamine amino group on a glycolipid precursor. The Thy-1 molecule, attached to glycolipid by a phosphatidylinositol (GPI) link is subsequently transported to the cell surface membrane, where it displays a distinct sensitivity to cleavage by phosphatidylinositol-specific phospholipase C. Like other GPI-linked proteins, Thy-1 is localized in distinct membrane subdomains that are glycolipid enriched and detergent resistant. Immune precipitation of Thy-1 from nonionic detergent cell lysates of T cells coprecipitates the p56^{lck} and p60^{src} src family protein kinases.

What is the function of Thy-1? Although they lack a transmembrane domain, Thy-1 molecules are involved in the mitotic triggering of T lymphocytes. A brisk mitotic response can be elicited by xenogeneic antibodies against the Thy-1 antigen and by exposure to allogeneic monoclonal Thy-1 antibodies followed by xenogeneic anti-immunoglobulin antibodies. The crucial role of the Thy-1 molecule in the mitotic triggering by Thy-1 antibodies was established by the demonstration that transfection of lymphoid cells with the Thy-1 gene conferred upon them the capacity for a mitotic response to Thy-1 antibodies. Protein kinases and possibly other accessory signaling molecules which are associated with Thy-1 molecules seem to be involved in the activation of T cells by Thy-1 antibodies.

Analysis of T cell mutants that have lost the expression of T cell receptors (TCRs) and experiments on the transfection of lymphocytes with the Thy-1 gene indicate that the TCR and particularly their ζ chain, are necessary for effective mitotic stimulation of lymphocytes by Thy-1 antibodies. Indeed, stimulation via either Thy-1 or TCR may proceed through a shared signaling pathway.

Rock and colleagues showed that T lymphocytes failed to be stimulated when they were coated with Thy-1 antibody and then exposed to anti-immunoglobulin antibodies bound to plastic. In contrast, exposure of T cells to antibodies against either TCR or the CD3 antigen, followed by exposure to immobilized anti-immunoglobulin antibodies resulted in mitotic stimulation. Thus, whereas cross-linking of

the transmembrane molecular complex of the TCR suffices for mitotic stimulation, stimulation by Thy-1 may require entry of the molecules into the cell, possibly as a mechanism for communication with other components in the interior of the T cell.

In addition to regulating the mitotic triggering of T cells, Thy-1 molecules mediate intercellular attachment. Antibodies to Thy-1 inhibit the binding of mouse thymus cells to syngeneic erythrocytes, and interfere with the attachment of activated T lymphocytes to various nucleated target cells. He *et al* established that Thy-1 mediates the adhesion of thymocytes to thymic epithelial cells through a Ca^{2+} -independent mechanism. In the nervous system, Thy-1 stabilizes neuronal connections and inhibits neurite outgrowth on astrocytes. The prevention of neurite outgrowth by Thy-1 molecules may reflect their role in mediating the adhesion between various cells within the nervous system.

THYMIC EPITHELIUM: POTENTIAL ROLE IN REGULATORY T CELL TOLERANCE

Antonio Bandeira, Unité d'Immunobiologie, Institut Pasteur, Paris, France

Two theoretical concepts on self tolerance

The most accepted view on tolerance is based on the Burnet/Lederberg theories (and developments thereof) which consider *all* autoreactivities as dangerous to the organism. *All* self reactive lymphocytes should therefore be physically eliminated (deletion) or irreversibly inactivated (anergy). Tolerance is thus established by 'default' (lack of self reactivities), that is, by 'ignorance' of what self is. For this concept, tolerance and (pathological) autoimmunity are problems which should be dealt with at the single cell or clonal level, and thus discards the notion of

interclonal regulation of lymphocyte populations and consequently the notion of system. Not surprisingly, mechanisms of tolerance based on 'suppression' or 'regulation' of self reactive cells that 'escaped' deletion have seldom been considered.

In sharp contrast, an alternative concept was developed, originally born from Jerne's network hypothesis on the *organization* of the immune system as a web of idiotypic interactions of diverse antibody populations. The key starting principle was that as a general rule of any *diverse* system of recognition, (self) recognition between components is unavoidable. In the case of the immune system of high vertebrates, the elimination of all self reactive lympho-

cytes would lead to the destruction of the system itself. Not surprisingly therefore, experimental evidence accumulated over the years indicating that functional self reactivities are rather frequent events in healthy individuals.

With these theoretical concerns in mind, a concept of T cell tolerance emerged based on observations obtained in several laboratories studying experimental systems of central (thymic) and peripheral T cell tolerance. The concept can be summarized as follows: while accepting deletional mechanisms as a way to regulate frequencies of self reactive cells, controlled autoreactivity is a natural phenomenon in physiology and, as paradoxical as it may seem, those self reactivities are fundamental for the induction and maintenance of the state of natural tolerance to organs and tissues. In other words, the immune system needs *functional* T cells, obviously committed to nondestructive activities, which should recognize at least part of the antigenic structures of the organism. The function of these cells should be the suppression or regulation of the activity of other T cells, namely those that can recognize other components of the body and capable of differentiating as aggressive effectors.

Tolerance to self is a developmental problem

In spite of the fact that many mechanisms supposed to be involved in tolerance have been identified and are currently under active investigation, the field still remains largely phenomenological. I will briefly summarize a number of observations that any theoretical concept on natural tolerance should account for, and that, in our view, the current dogma cannot bring together in a coherent scheme.

Medawar's phenomenon

In 1953, Medawar and colleagues made a fundamental demonstration in the field of transplantation tolerance: in mice, allogeneic tissue grafts (skin, heart, etc.) are accepted if an individual is exposed to donor tissues in the embryonic or perinatal life. The immune system can thus 'learn' to treat foreign tissues as 'self'. The time 'window' of tolerization for allogeneic antigens was shown to be short (less than a week) and restricted to the perinatal period of development. The immune system becomes refractory to tolerization to alloantigens after this period.

Later studies using transgenic mice for foreign antigens confirmed that tolerance operates efficiently in the embryonic/perinatal life while expression of tissue-specific antigens late in development leads to

massive tissue destruction, irrespective of the nature of antigen-presenting cells (APCs).

Hence, tolerance is a *learning* process and the immunological 'self' is composed by the set of structures that are available to immune recognition at critical developmental times.

Is antigen persistence enough to establish tolerance?

Medawar's experiments were based on the injection into newborn mice of live cells obtained from spleen and other tissues. Later in life, these animals permanently accepted skin transplants of the original donor strain.

It was subsequently shown that donor hematopoietic cells (HCs) were the cell type responsible of tolerance induction.

In contrast, adult or embryonic skin grafts failed to induce tolerance when grafted in embryos or newborn recipients. Even if grafted during embryonic life in age-matched recipients and before T cell development, the transplants which were allowed to developed normally with the host were rejected once the immune system reached full competence.

Although some cases of full tolerance or chronic/reversible rejection were described in other species (as for example extensively studied by Le Douarin and colleagues in birds), the principle that emerges from all these experiments is that allogeneic or xenogeneic tissues other than hematopoietic tissues do not tolerize to themselves.

Hence, antigen expression and persistence from early periods of development is not *per se*, in most cases, sufficient for life-long tolerance induction.

Le Douarin's phenomenon

Initially using an experimental system of chicken-quail chimeras, Le Douarin and colleagues made another fundamental demonstration in the field of tolerance: life-long tolerance is invariably obtained to a variety of embryonic tissue or organ grafts if pure thymic epithelium (TE) from the same donor is cotransplanted. In fact, the establishment of TE-induced tolerance could operate in the absence of those peripheral tissues, and TE-chimeras will accept adult tissues of TE-donor origin later in life. These observations, extensively confirmed in mice, 'broke' the dogma that in the thymus, the role of the epithelial component of the stroma was only (efficiently) ascribed to positive selection, while negative selection or tolerance was a property of the HC compartment.

Given that TE does not express the complete repertoire of antigens of the organism, an immediate

paradox of these observations is how tolerance to tissue-specific antigens is established.

Le Douarin's phenomenon can thus be phrased as follows: peripheral tissues are tolerized if TE from the same donor is functional in the recipient. Hence, tissue-specific tolerance is thymic dependent.

Developmental shift from tolerance to immunity: the time problem

Based on Medawar's window of development for tolerance induction, Burnet coherently postulated that all self reactive cells were deleted early in ontogeny, for lymphocyte production only happened during this period. This later statement was soon disproven: new lymphocytes are continuously produced throughout life. This led Lederberg to postulate that tolerance or immunity is directly related to the development of the cell: immature lymphocytes are sensitive to receptor ligation and die (tolerized by deletion or anergy), while at a later stage the cell will engage in effective immune responses upon antigen recognition. For T cells this made a great deal of sense, as they develop inside the thymus only exposed to self antigens, exogenous antigens being excluded from this organ. This new concept, however, discarded the fact that the establishment of self tolerance is restricted to the embryonic/perinatal life and, as discussed below, 'obliges' to extend even further Lederberg's 'immature window' of lymphocyte differentiation to peripheral T cells in order to cope with tissue-specific antigens.

Studies on population dynamics and repertoires of peripheral T cell pools during ontogeny revealed three additional interesting observations:

1. The peripheral T cell immune system grows exponentially by a factor of 500–1000 during the first 3–4 weeks of postnatal life; that is, the overwhelming majority of lymphocytes will be produced well after Medawar's window of tolerization is over.
2. The peripheral T cell compartment of a normal mouse is built up by accumulation of thymic emigrants, with negligible peripheral expansion and T cell lifespans of 1–2 months; that is, even if memory T cells may be capable of surviving in the organism for several months, perinatal lymphocytes will be diluted out by the exponential accumulation of new thymic emigrants.
3. Healthy adult individuals contain immunocompetent (potentially pathogenic) self reactive lymphocytes (e.g. T cells recognizing with high affinity myelin basic protein).

All these considerations led us to define one of the

central problems in the understanding of natural tolerance to tissues as the 'time' problem.

Self is only learned during development but new lymphocytes are produced throughout life and the overwhelming majority of lymphocytes are actually made after the developmental window for tolerization, that is, prone to immunity. Since lymphocyte receptor genes rearrange randomly, the adult thymus will continuously produce autoreactive T cells at a given frequency, capable of recognizing self ligands expressed only in peripheral tissues.

Since there is no way to structurally distinguish self from nonself antigens, the difference is, Medawar taught us, in the 'history' of the antigen rather than its origin (self or nonself); that is, their presence or absence in the organism during development.

Maintenance of tolerance throughout life therefore requires a state of memory of the developmental self that keeps newly-formed, immunocompetent autoreactive cells 'silent' while not interfering with the development of immune responses to foreign antigens.

What are these mechanisms, which cells are involved (and what specificities) and what dynamic properties of maintenance and renewal do they need to have?

TE-dependent selection of regulatory T cells

The thymus plays a fundamental role in the establishment of tolerance to self antigens expressed on its stroma through elimination (deletion) or inactivation (anergy) of many self reactive, differentiating T cells. The overlap between antigens expressed intrathymically and on peripheral tissues can obviously account for a major role of the thymus in tolerance induction to those antigens, without the need to invoke other mechanisms. Independent observations have shown the relative inefficiency of TE to mediate clonal deletion, and imply a differential functional capacity of TE and HCs in tolerance induction. 'Anergy' rather than deletion is the mechanism invoked in TE-induced tolerance.

In the establishment of tolerance to tissue-specific antigens, the role of the thymus is much less clear, as negative selection mechanisms of peripheral tolerance (deletion, anergy, ignorance, immunodeviation) can all dispense with thymic selection. Active suppression or 'infectious tolerance', on the other hand, can accommodate a role for the thymus in this process. Thymic-dependent specific suppression of aggressive responses to autoantigens that are not expressed intrathymically, however, is highly contro-

versal and the respective mechanisms difficult to envisage.

I shall now describe the observations obtained using a system of TE-dependent transplantation tolerance to alloantigens that led to 1) the implication of TE in the peripheral suppression of tissue-specific antigens, through the selection of a first wave of regulatory T cells; and 2) the ability of these to educate those nontolerant T cells into similar effector functions.

In mice, grafts of TE rudiments of E10 embryos, before colonization by hematopoietic cells, restore T cell development and function in allogeneic athymic mice. These TE-chimeras are specifically tolerant to grafts of peripheral tissues (e.g. skin and heart) from the TE donor strain, and tolerance in all cases is life-long. Initial analyses of the mechanisms underlying the acquired state of tolerance, based on transfer experiments, revealed that tolerant TE-chimeras harbor immunocompetent, tissue-reactive T cells that can readily reject the tolerized grafts. In support of the notion that TE-tolerance is mediated by regulatory mechanisms, CD4 T lymphocytes selected by TE were thereafter shown to specifically inhibit, in a quantitative manner, the rejection of the tolerized grafts by tissue-reactive T cells from immunocompetent donors. Because, in this experimental system, alloantigen expression is strictly limited to the TE, these results demonstrated that peripheral tolerance is centrally selected.

A number of postulates could be derived from these observations:

1. Differentiating T cells with high avidity to MHC-peptide ligands on TE are positively selected (rather than deleted), locally activated and committed to regulatory functions (rather than anergized) by the TE microenvironment.
2. Differentiating T cells positively selected on low avidity interactions with TE exit the thymus as naive, resting lymphocytes, and include the pool of tissue-specific T cells.

Recent experiments have indeed shown a dose-dependent positive selection of TCR transgenic thymocytes by 'high-avidity peptides', while deletion requires hematopoietic APCs. Furthermore, T cells selected by high avidity on TE seem refractory to proliferation upon restimulation by the selecting ligand, as in previous descriptions of 'anergy' for proliferation, that we interpret to indicate the distinct functional competence of these cells.

Figure 1 represents the theoretical selection curves describing these two postulates.

3. Most ligands recognized by TE-selected regulat-

ory T cells are ubiquitous peptides, that is, common to all tissues.

Specific activity of TE-selected regulatory T cells in the periphery requires a significant overlap between the peptide repertoires of TE and all peripheral tissues. Peripheral tissues, presenting ubiquitous peptides recognized by regulatory T cells, as well as the peptide targets for tissue-specific self-reactive T cells, would provide local conditions for the regulatory T-pathogenic T cell interactions.

Peripheral regulation of the class of T cell effector functions: the phenomenon of 'education'

T cells which were positively selected in the thymus following 'low' affinity interactions with TE cells, and passed the 'deleting HC filter', leave the thymus in a 'resting' immunocompetent state. They will constitute the vast majority of the peripheral T cell compartment, and are supposed to recirculate continuously through the body, 'chasing' possible invaders. Their lifespan in normal animals is of the order of 1–2 months and they will die after this period if they do not encounter antigen. This picture seems, however, not to be as monotonous as it looks for the notion has been that every naïve T cell reaches the periphery still in a critical state of sensitivity to TCR ligation. At this stage they are called 'recent thymic emigrants' (RTEs) as opposed to T cells that have already been in the periphery for longer. These we shall call peripheral, mature and resident (PMR) lymphocytes.

The reason to postulate this 'critical period', which could last for few hours or few days (no one knows), is directly linked to the necessity of tolerizing self reactive T cells to tissue-specific antigens not present in the thymus, and thus rescue the Lederberg concept of sensitivity to deletion/anergy of immature T cells for peripheral T cells. We know now that this is wrong: RTEs as well as mature T cells from the thymus can reject allogeneic skin transplants with the same efficiency as PMR T lymphocytes.

Interestingly, however, experimental evidence was obtained on the distinct sensitivity of RTE and PRM states to regulatory T cell-mediated suppression and 'education', thus supporting the existence of a post-thymic 'critical period' of lymphocyte functional commitment.

In TE-chimeras regulatory CD4 T cells are positively selected by the allogeneic TE, escape deletion because hematopoietic APCs express a distinct major histocompatibility complex (MHC), and can thus be produced throughout life. This contrasts with the

Figure 1 Thymic T cell selection is a function of the avidity of TCR-MHC-peptide interactions. For any given T cell the probabilities of positive selection, activation and deletion are described by logistic functions with thresholds A1, A2 and A3, respectively (dashed lines). For increasing levels of avidity, the products of these probabilities result in no selection, positive selection into resting state (naïve T cell), positive selection and activation (regulatory T cell) (shaded area in the plot), and deletion, respectively. The figure compares the selective properties of TE (A) and HC (B). It should be noted that T cells selected with a given phenotype (naïve or regulatory) on TE can be deleted by later interaction with thymic HC (as is the case for most regulatory cells in B, given the relative position of the deletion curves for the two types of stroma cells), but cannot be switched to another phenotype by a second interaction.

situation in normal mice, where the progressive colonization of the thymus by HCs is expected to restrict the putative generation of regulatory T cells to the perinatal period of thymic development. Transposing the observations on TE-chimeras to normal tissue-specific tolerance, other mechanisms have to be invoked. Thus, since the numbers of peripheral T cells increase by 1000-fold in the first 3–4 weeks of life by accumulation of RTEs, putative regulatory T cells produced around birth would be diluted out in the periphery by high numbers of tissue-specific T cells produced throughout life.

To answer these questions we have recently demonstrated that:

1. RTEs are more susceptible to suppression by TE-selected regulatory T cells than PRM T cells.
2. Both RTEs and PRM T cells display the ability to reject tissue grafts in the absence of TE-T cells.
3. The peripheral encounter of antigenic tissue *per se* does not tolerize RTEs, demonstrating both

the immunocompetence of cells at this differentiative stage, and immunogenic antigen-presentation by the grafted tissue.

4. RTEs are particularly sensitive to dominant tolerance mechanisms.
5. TE-selected, regulatory CD4 T cells are capable, together with specific antigen, of recruiting immunocompetent T lymphocytes into similar regulatory functions.
6. Only RTEs, not PRM T cells, seem susceptible to being 'educated' into regulatory functions.
7. Both CD4 and CD8 RTEs can be recruited into regulatory functions, each population mediating peripheral mechanisms of tolerance.

All these types of lymphocyte interactions are schematically represented in **Figure 2**.

T cells whose receptor happens to recognize tissue-specific antigens (not expressed in the thymus) will leave the thymus in a resting state, uncommitted to any effector function.

The functional pathway of differentiation of naïve

Figure 2 The three distinct fates of peripheral naive T cells recognizing specific antigen on an APC. Regulatory T cells recognize in peripheral tissues MHC-peptide complexes towards which they were selected and activated on TE (ubiquitous peptides). Naive T cells (RTEs or PMRs) respond to tissue peptides that are absent from the thymus (tissue specific). The specificities of the regulatory and naive T cells are thus unrelated. In (B), the variable 'ratio' applies to the numbers of regulatory versus PMR T cells interacting on the same APC.

T cells recognizing specific antigen on a peripheral APC ('professional' or otherwise) will be dictated by the local environmental conditions. As shown in Figure 2 three distinct situations can be envisaged.

1. The naive T cell is a RTE, and the APC it interacts with is concomitantly recognized by regulatory T cells. Under these circumstances the naive cell will be 'educated' such that it itself becomes a regulatory T cell. This is the situation that is expected to occur during the ontogenic development for self reactive cells.
2. The naive T cell is a PMR T cell, and the APC it interacts with is concomitantly recognized by regulatory T cells. In this case the outcome depends on the ratio of regulatory/PMR T cells at the surface of the APC. Thus, for high ratios, the PMR T cell is suppressed and remains naive. For low ratios, the regulatory T cells are too rare to control the naive PMR cells, which are therefore activated and become aggressive. The first case is the situation that again should occur for tissue-specific T cells that did not have the opportunity to encounter self antigen at the stage

of RTE. The second case would represent the local conditions to be set up for the development of an immune response against, for example, a viral antigen in the tissues.

3. The naïve T cell is either a RTE or a PMR T cell, and the APC it interacts with is not simultaneously recognized by regulatory T cells. In this case, the T cell is activated and displays an aggressive functional phenotype.

Finally, Figure 3 shows how the process of peripheral T cell education during development shifts the repertoire of regulatory T cells from TE selected to tissue specific.

From an artificial experimental system to normal immune systems

The transplantation system briefly described here has demonstrated that TE-induced tolerance to peripheral tissues operates in the presence of both non-tolerant and regulatory T cells with specificity to tissue antigens of the TE donor strain. Although direct evidence is still not available, these observations strongly suggest a role of TE in induction of regulatory T cell function. In turn, TE-selected regulatory T cells ensure peripheral tolerance of tissue-

specific antigens of the TE donor. The production of both aggressive and regulatory T cells by thymic selection in TE chimeras is explained on the basis of the established inefficiency of TE to mediate deletion of self reactive T cells. The regulatory activity generated in the thymus of allogeneic TE chimeras can be maintained in the periphery for long periods of time, even after decay of the initial pool of regulatory T cells.

These observations provided the basis for a strategy followed by the immune system to deal with potentially aggressive tissue-specific T cells produced throughout life, which is not based on their elimination or inactivation, but on their recruitment into the regulatory pool, thus progressively reinforcing peripheral tolerance. This strategy appears fully adapted to the T cell population dynamics in development.

A normal thymus is expected to delete (on hematopoietic APCs) most TE-selected regulatory T cells, such that their production and export must be predominantly restricted to the perinatal period, before full HC colonization.

A small number of TE-selected regulatory T cells produced early in ontogeny, can ensure the peripheral functional 'education' of all tissue-specific T

Figure 3 Diversification of the tissue-specific regulatory T cell pool and the corresponding 'repertoire spreading' of peptidic self markers by a chain reaction of peripheral RTE education. The chain is initiated by T cell No. 0, which is a regulatory T cell selected by TE, and, thus 1) specific for an ubiquitous peptide, and 2) the first to be produced and exported to the periphery.

cells, given that the whole T cell pool is postnatally built up by accumulation of RTEs. This process explains the establishment, maintenance and renewal of the peripheral pool of self-specific regulatory activities. Thus, it accounts for a fundamental aspect of natural self tolerance: in spite of the life-long production of newly-formed T cells in the thymus, acquisition of tolerance is restricted to the perinatal period, such that a developmental shift from tolerance to immunity occurs in normal animals.

The prediction is that the 'regulatory' T cell repertoire progressively shifts from TE-specific towards tissue-specific, through the local recruitment of tissue-specific RTEs by TE-selected T cells recognizing ubiquitous peptides, that can prevent destruction of a variety of tissues.

The finding that functional recruitment of RTEs requires antigen recognition also explains why newly formed T cells with specificities towards nonself antigens differentiate as naive resting cells to recruitment-resistant PRMs. It follows that antigens introduced in adult life will induce conventional immune responses that are no longer submitted to regulation, providing the basis for the developmental shift from tolerance to immunity.

A similar process of 'education' was previously described in mice tolerized to minor histocompatibility antigens, after *in vivo* treatment with nondepleting anti-CD4 and anti-CD8 monoclonal antibodies. This process, designated 'infectious tolerance', was shown to operate on CD4 T cells of thymectomized mice, hence on nonrecent thymic emigrants. This experimental system failed, however, to tolerize to major histocompatibility antigens.

Available observations suggest a major role of regulatory T cells in the establishment and maintenance of natural tolerance in normal animals. Neonatal thymectomy induces T cell-mediated, organ-specific autoimmune diseases that can be prevented by transfers of normal adult CD4 T cells, suggesting the operation of thymus-selected regulatory cells during normal development. Normal adult rats and mice contain subsets of T cells that can induce autoimmune disease if transferred into immunodeficient recipients, but also harbor other T cell subsets which confer protection from this autoaggressive T cell activity. The repeated findings of 'spontaneous' autoimmune disease in interleukin- or T cell-deficient mice is also most compatible with dominant tolerance mechanisms. Finally, Lafaille and colleagues

have recently shown that mice transgenic for an autoreactive tissue-specific TCR against myelin basic protein will only develop disease at high frequency if crossed into a RAG-1-deficient background; that is, in the complete absence of any other T or B cell population.

Concluding remarks

The alternative theoretical concept here described has major implications in therapeutic approaches to autoimmune diseases and organ transplantation, as well as in tumor immunology.

Nevertheless, I should again stress that regulatory T cells of the type described have so far not been isolated in any experimental system, and the corresponding molecular mechanisms are still largely unknown.

All the theoretical and experimental work here discussed is to be entirely shared with Antonio Coutinho and Yves Modigliani (Institut Pasteur) and Nicole Le Douarin and Josslyne Salaün (Institut & Embryologie Cellulaire et Moléculaire du CNRS et du Collège de France, Nogent-sur-Marne France).

THYMIC HORMONES AND PEPTIDES

Oscar J Cordero and **Montserrat Nogueira**, Department of Biochemistry and Molecular Biology, University of Santiago de Compostela Faculty of Biology, Santiago de Compostela, Spain
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Bone marrow-derived T cell precursors, termed prothymocytes, migrate to the thymus gland, undergo a stringent selection and a complex series of events leads them to the mature, major histocompatibility complex (MHC)-restricted, self tolerant T cell found in peripheral lymphoid organs. The thymus micro-environment represented by nonlymphoid cells (epithelial cells, macrophages, dendritic cells and fibroblasts) and extracellular matrix components, plays a central role.

In particular, the thymic cortical epithelial cells (TECs) control this sequential transformation, associated with the acquisition of antigenic markers and T cell function, in at least two distinct ways. First, in the early stages, by cell-cell interactions, the most important of which are mediated by the MHC products that are highly expressed on epithelial cell membranes. Second, in the final stages of maturation, by the secretion of a variety of polypeptides, such as thymic hormones, interleukin 1 (IL-1), -2, -3, -6 and granulocyte-macrophage colony-stimulating factor (GM-CSF). In addition, classical hormones and neural innervation affect lymphoid development and function.

Thymic hormones and factors

Several polypeptides have been extracted, mainly from the thymus glands of young calves, and some of them have been successfully isolated and prepared synthetically (Table 1). A variety of these compounds exhibit immunobiological activity, although the precise role of many of the factors purported to have intrathymic effects is still unknown. They include thymulin, thymopoietin, thymic humoral factor (THF) and thymosins. So far, only thymulin is recognized as a hormone in accordance with the classical endocrine and physiological criteria, i.e. it is thymus restricted and regulated in its secretion. Thymectomy does not remove the presence of the other thymic factors from serum, and their genes are expressed in other nonthymic tissues. It must be remembered, however, that these criteria are under revision and, for example, in the same way, it is now realized that the lymphocytes produce serotonin and other neural peptides that once were thought to be confined to the nervous system. Other peptides may act as components of the extracellular matrix.

Another central question remaining about these

Table 1 Thymic peptides

Name	Chemical properties
Thymosin α 1 (T α 1)	Polypeptide of 28 residues. 3.1 kDa; pI 4.2. Sequence determined
Prothymosin α (ProT α)	Polypeptide of 109–111 amino acids, exhibiting T α 1 at N-terminal position. 13 kDa; pI 3.5. Sequence determined
Thymopoietin	Polypeptide of 49 residues. 5–6 kDa; pI 5.5. Sequence determined
Thymopentin (TP5)	Pentapeptide fragment of thymopoietin residues 32–36
Thymic humoral factor (THF)	Polypeptide of 31 residues. 3.2 kDa; pI 5.7. Sequence determined
THF γ 2	Octapeptide. 918 Da. Sequence determined
Thymulin (Zn-FTS)	Nonapeptide. 857 Da; pI 7.5. Sequence determined

factors is whether they only possess intrathymic activities or whether they are secreted to act on distal sites.

Thymulin

Initially called 'facteur thymique serique', thymulin was originally purified from porcine and human serum and from calf thymus. An important characteristic of thymulin is that it is biologically active only when coupled in an equimolar ratio with zinc; patients with Crohn's disease or acute lymphoblastic leukemia are zinc deficient and have a reduction in thymulin activity. The presence of an altered zinc status is also found in the elderly.

Thymulin appears to be synthesized and released by a subpopulation of TECs. It helps regulate the differentiation of an immature thymocyte subpopulation and also the function of mature T and natural killer (NK) cells by binding to a membrane receptor with high affinity. The production of thymulin is under pleiotropic control, involving the levels of thymulin itself and of other hormones such as prolactin, growth hormone (GH) through insulin-like growth factor I (IGF-I) secretion, adrenocorticotropin (ACTH), thyroxine (T₄), the opioids β -endorphin and leu-enkephalin, and cytokines IL-1 α and β .

Behavioral results support these physiological immunoneuroendocrine connections. The serum levels of this peptide decrease with age, coincidental with thymic atrophy. However, aged thymus retains the capacity to increase thymulin secretion in response to GH and T₄.

Thymic humoral factor

Trainin and colleagues isolated a crude extract of calf thymus, THF, and, by various chromatographic systems, subsequently the octapeptide THF γ 2. Both enhance lymphocyte proliferation and IL-2 production by spleen cells from neonatally thymectomized mice or from immunocompromised patient's lymphocytes.

However, THF γ 2 was not detected in TECs grown in culture, and its serum levels are not reduced by thymic involution or thymectomy.

Thymopoietin

G Goldstein and coworkers isolated thymopoietin from calf thymus by its neuromuscular effect. Later it was found that thymopoietin binds cell membrane receptors present on prothymocytes and on mature T cells and certain T cell lines, involving, respectively, stimulation of adenylate or guanylate cyclase.

Although immunoreactive material was detected in human TEC cultures, thymopoietin mRNA is present in primary and secondary lymphatic tissues as well as other sites, such as striated muscle, heart, small intestine and cerebellum, and is particularly abundant in isolated thymocytes. Moreover, serum levels of thymopoietin are not reduced by thymic involution or thymectomy, and it is localized in the cells intracellularly and no secretagogue has been reported, thus indicating a nonendocrine role.

Three distinct human thymopoietin mRNAs have been described with distinct structural domains and functional motifs, which suggests that the proteins have unique functions and may be directed to distinct subcellular localizations. A nuclear role has been suggested.

Thymopoietin from calf thymus enhances early T cell differentiation and the expression of specific alloantigens *in vitro*, perhaps by the same mechanism as the pentapeptide composed of residues 32–36, called thymopentin (TP5), which also has distinct biological properties.

Thymosins

Thymosins are a group of low molecular weight acidic peptides isolated from the original factor thymosin fraction 5 (TF5) extracted from the bovine

thymus by AL Goldstein and colleagues. At least 30 different peptides can be identified by isoelectric focusing of TF5, including thymosin α 1 (T α 1), β 4 (T β 4) and MB35. TF5 displays potent stimulatory effects on T cell-mediated immunity, and may be involved in maintaining the size of the thymus and of thymocyte subpopulations. T α 1 induces the expression of the T cell differentiation antigens Thy-1, CD5 and CD8 and increases murine lymphocyte mitogenic responses, antibody and cytokine production. T β 4, as T α 1, increases terminal deoxynucleotidyltransferase (TdT) expression. In addition, multiple effects of these preparations on neuroendocrine function have been identified. For instance, T β 4 is able to stimulate luteinizing hormone (LH) secretion from pituitary and LH-releasing hormone from the hypothalamus, MB35 stimulates the production of prolactin and GH, and T α 1 downregulates thyroid-stimulating hormone (TSH), ACTH and prolactin secretion, at least partially, through hypothalamic pathways.

A full-length cDNA of 1200 bp for T α 1 has been cloned and studied by Eschenfeldt and colleagues. This cDNA encodes a highly acidic protein of 111 amino acids called prothymosin α (ProT α), which contains T α 1 in positions 1–28. ProT α has no N-terminal signal peptide, and its mRNA is exclusively located on free polysomes. The ProT α gene belongs to a family of six members, one of which gives rise to two mRNAs. Sequence homologies with other mammalian species are high; it is found in multiple tissues and has a nuclear targeting sequence. T α 1 has been localized intracellularly in dense vacuoles within the cytoplasm of TECs but not in the endoplasmic reticulum or Golgi apparatus. These findings suggest a nuclear function for ProT α (which is most likely the active compound) in the regulation of cell proliferation, and T α 1 is probably a decay product, because a small constitutive production has been observed, although no secretagogue has been identified.

T α 1 has sequence homologies with the vasoactive intestinal peptide (VIP) family and it is able to function as a VIP receptor antagonist with weak intrinsic activity. Recently, cell surface receptors for ProT α were found and, while not yet fully characterized, they appear to be different to those for T α 1. ProT α also has immunopotentiating activities.

T β 4 is identical to Fx, an actin-sequestering peptide which is present in many different cell types. The sequence of MB35 is identical to a portion of histone H2A, a component of nuclear protein A24.

Figure 1 Thymic epithelial cells, interleukins and proposed thymic peptide functions. Thymic peptides of epithelial or lymphoid origin may act on the enhancement of interleukin-dependent intra- or extrathymic differentiation of T lymphocytes.

Thymic peptides as immunoregulators or biological response modifiers

As mentioned above, only thymulin can today be described as a classical hormone. Nevertheless, further investigations are required regarding the physiological relevance of the numerous data showing immunological effects of thymic peptides. 1) Between 400 and 800 pg/ml T α 1 (or ProT α , this fact remains to be elucidated), 300–500 ng/ml thymopoietin and 0.5–3 pg/ml thymulin are present in human plasma. THF has also been detected. Except for thymulin, these levels are not reduced by thymic involution, but T α 1 levels are decreased or augmented in some groups of sick patients or monkeys. 2) Thymic peptides, except for THF, were secreted specifically by some epithelial cells in the thymic stroma. 3) They bind to different receptors on T cells and other cells and tissues. So while some investigators believe that thymic peptides are a result of cellular damage or death, others have postulated that certain nucleoproteins may be targeted by proteases during cellular activation to produce 'nucleokines' that in turn migrate to the cytoplasm and may be secreted.

Although the discovery and the first studies on thymic peptides (TPs) are historically linked with their role in the developmental events of T lymphocytes within the thymus, more recent investigations have

focused upon the effects of TPs on mature effector cells (Figure 1). TPs have been extensively explored as potential regulators of T cell deficits which would allow specific immunotherapeutical approaches of clinical utility. Thus, whereas the involvement of TPs in the induction of markers of T cell differentiation is of minor significance compared with the role of cytokines, TPs appear to play a potentially important role in stimulating various T cell functions in normal and in partly T cell deficient rats, mice and humans. In general, TPs tend to normalize the immune balance, either by enhancing suppressed systems or by stimulating suppressor mechanisms in hyperresponsive states. Thus, TPs may act, outside of the thymus, as fine physiological immunoregulators contributing to the maintenance of T cell subset homeostasis.

In vitro effects

Thymulin restores basal NK activity in spleen cell cultures obtained from old, but not young mice. It increases the release of interferon γ (IFN γ), IL-2 and IL-1 α by mitogen-stimulated cells of normal individuals, whereas it inhibits the release of these cytokines and also of IL-6 in systemic lupus erythematosus (SLE) patients. Inhibition of tumor necrosis factor α (TNF α) production was found in both groups. Thus, thymulin may function as an immunomodulator by exerting control over cytokine production.

Peripheral blood mononuclear cells obtained from patients with chronic hepatitis B virus infection have an increased production of IL-2 and TNF α in response to THF γ 2, suggesting an antiviral role for this peptide *in vivo*. An effect on hematopoietic progenitor cell proliferation was recently documented in which THF γ 2 increased the number of myeloid colonies of bone marrow cells from normal mice. Human erythroid and myeloid hematopoietic progenitor cells are also stimulated to growth by THF γ 2.

Thymopentin (TP5), the synthetic pentapeptide corresponding to the active structure of thymopoietin, has shown impressive immunoregulatory activity. TP5 modulates T_H1 and T_H2 cytokine response; it enhances IFN γ , TNF α and IL-2 release and reduces the levels of IL-4 in different models. In addition, bone marrow T lymphocyte precursors treated with TP5 show increased thymus colonization.

T α 1 and ProT α increase the number of high-affinity IL-2 receptors, IL-2 production and IL-2/IL-2R internalization in stimulated lymphocytes. They enhance T lymphocyte proliferative responses and improve NK- and LAK-cell activity of normal and cancer patients. Moreover, ProT α enhances MHC class II expression and mRNA accumulation in human monocytes, murine splenocytes and tumor cell lines.

In vivo effects

Thymulin and thymopentin restore antibody avidity in aged or thymectomized animals, enhance antibody production in aging mice, stimulate the male-to-female skin graft rejection, the prolongation of skin graft survival and the abrogation of delayed-type hypersensitivity. There are positive correlations between zinc levels, active thymulin and peripheral immunological parameters in young cancer patients. Additionally, thymulin reduces induced hyperalgesia in rats and mice.

TP5 reduces the susceptibility of aged mice to cutaneous leishmaniasis and modulates cytokine production by splenocytes from aged mice.

THF γ 2 injections in neonatally thymectomized mice restore myeloid colony formation. THF γ 2 reduces the metastatic load and restores immunocompetence in 3LL tumor-bearing mice receiving anticancer chemotherapy, raises the T cell activities in immunodeficient aging mice, and enhances the responsiveness of both CD4⁺ and CD8⁺ T cells to murine cytomegalovirus infection.

T α 1 and ProT α protect mice against opportunistic infection by *Candida albicans*, increase NK- and LAK-cell activity in tumor-bearing mice and stimu-

late the responsiveness to IL-2 in immunosuppressed mice. T α 1 enhances the fertilizing capacity of human sperm. It can be used in combination with an antiviral drug in controlling influenza virus. ProT α increases the production and release of migration inhibitory factor by mononuclear cells.

Clinical research

TPs have been used clinically as antiviral agents and in the immunotherapy of cancer. TP5 is a highly effective drug as an antiviral therapy in recurrent herpes simplex, herpes zoster and human papilloma virus infection, reducing the relapse rate. It has also been shown to be a safe and effective adjunct to therapy in patients with severe atopic dermatitis, in which it decreases the release of polymorphonuclear leukocyte-derived inflammatory mediators. TP5 is able to produce consistent clinical and immunological effects in melanoma patients with cutaneous metastases, and is a potentially useful agent in the treatment of a subgroup of patients with Sézary syndrome.

Combination therapies with T α 1 are used in infections and tumors, for example, AZT, T α 1 and IFN α in HIV patients. T α 1 is being used in clinical trials of head and neck cancer, advanced non-small-cell lung cancer and metastatic melanoma. T α 1 is being used in hepatitis B and C trials worldwide. Other thymic preparations such as thymostimulin (TP1) are used in combination therapies, for example in metastatic colon cancer.

THYMUS

Jonathan Sprent and Charles D Surh, Department of Immunology, The Scripps Research Institute, La Jolla, California, USA

The thymus is a bilobed structure situated above the heart in the anterior mediastinum. This organ is conspicuously large in young life and undergoes atrophy at the time of puberty. The thymus is responsible for the production and differentiation of T lymphocytes and is thus essential for cellular immunity.

History

Until 1960 the function of the thymus was obscure. In fact even in the 1950s it was not appreciated that the thymus is normally a very large organ in infancy. With the availability of chest X-rays, pediatricians were impressed with the size of the thymus and invoked the condition of ‘status thymolymphaticus’ – chronic strangulation by an enlarged thymus – to explain minor respiratory ailments. To relieve ‘pressure’ on the trachea, the thymus was exposed to irradiation! Despite such bizarre reasoning, as early as 1900 Beard, working on the stingray, had proposed that the thymus is the principal source of ‘leucocytes’. This prescient suggestion – forgotten for the next 60 years – presaged the crucial finding of Miller in 1961 that removing the thymus from neonatal mice induced a wasting syndrome associated with impaired cellular immunity. Miller’s conclusion that the thymus is the source of ‘immunologically competent cells’ and that ‘lymphocytes leaving the thymus are specially selected cells’ began the modern age of thymology.

Thymic architecture

In sections, the thymus is divided into two zones: the cortex and medulla (**Figure 1**). The cortex is the dominant zone in healthy young animals and accounts for about 80% of thymic tissue. This region is packed with small lymphocytes and has a characteristic dark appearance in sections stained with hematoxylin, a reflection of the high nuclear-to-cytoplasmic ratio of cortical lymphocytes (**Figure 1A**). The vast majority of lymphoid cells in the cortex are immature thymocytes expressing high levels of CD4 and CD8 molecules. These ‘double-positive’ (DP) cells express low levels of the $\alpha\beta$ T cell receptor (TCR). Special stains reveal that DP thymocytes reside within a rich network of epithelial cells expressing major histocompatibility complex (MHC) molecules (**Figure 1B**). As discussed later, MHC expression on cortical epithelium plays a crucial role in positive selection, the process by which a proportion of DP cells are instructed to differentiate into mature T cells.

The medullary region of the thymus contains mature T cells. These cells comprise a mixture of ‘single-positive’ (SP) CD4⁺8[−] and CD4[−]8⁺ cells expressing the $\alpha\beta$ TCR. SP cells are intermingled with antigen-presenting cells, such as dendritic cells and macrophages. Like DP cells in the cortex, SP cells are enmeshed in a dense network of epithelial cells (**Figure 1B**). The typical pale appearance of the medulla in hematoxylin-stained sections probably reflects the greater density of epithelial cells in the medulla than the cortex. In humans, medullary epi-

Figure 1 Histology of the mouse thymus. (A) Frozen thymus section stained with hematoxylin, a dye which stains the nucleus. Two zones of distinct cell density are visible: the cortex (cor) is densely packed with small lymphocytes, whereas the medulla (med) contains larger lymphocytes at a lower density. (B) A serial frozen thymus section stained with an antibody specific for epithelial cells and counterstained with hematoxylin. Note that a dense network of epithelial cells is apparent throughout the thymus: the epithelial cells in the cortex are dendritic in morphology with a thin cytoplasm, whereas the epithelial cells in the medulla show a more heterogeneous morphology.

thelial cells form cystic structures termed Hassal's corpuscles; these structures are inconspicuous in mice.

In addition to $\alpha\beta$ T cells, the thymus contains small numbers of T cells expressing $\gamma\delta$ TCRs. These cells are a minority population (<1% of total thymocytes) and are found scattered throughout the cortex and medulla.

Thymocytes, especially DP cells, are highly sensitive to the action of glucocorticoids and other steroids such as sex hormones. Because of this sensitivity to steroids, the thymus undergoes atrophy after the onset of puberty. Thymic atrophy is usually marked by mid-life, although remnants of thymic tissue are generally apparent even in old age. Thymic atrophy is also prominent in diseases associated with stress, e.g. chronic infection. With acute stress, thymic atrophy preferentially affects the cortex.

Surface markers on thymocytes

Although epithelial cells are a major component of the thymus in sections, thymic cell suspensions consist almost entirely of lymphoid cells. On the basis of CD4 and CD8 expression, thymocytes comprise four broad subsets of cells. The bulk of thymocytes (80–85%) consist of immature cortical CD4⁺8⁺ cells expressing variable levels of the $\alpha\beta$ TCR; most of these cells are small resting lymphocytes but 10–20% are blast cells. Mature SP cells account for about 15% of thymocytes and comprise a 2:1 ratio of resting CD4⁺8⁺ and CD4⁺8⁺ cells; most (though not all) of these cells display high levels of the $\alpha\beta$ TCR. The remaining cells (1–3%) are CD4⁺8⁺ and comprise a heterogeneous collection of cells, most of which act as immature precursors of CD4⁺8⁺ cells.

Effects of thymectomy

In some species, e.g. humans and sheep, the thymus develops early in ontogeny and releases substantial numbers of T cells before birth. In these species removing the thymus at birth causes only a mild decline in T cell numbers by the time of maturity. In other species, e.g. mice, the thymus develops late in ontogeny and does not produce mature T cells until just before birth. Neonatal thymectomy of mice thus precludes the formation of peripheral T cells and leads to a long-lasting state of profound T cell deficiency. Unless maintained in a pathogen-free environment, neonatally thymectomized mice fail to thrive and develop chronic infections associated with marked weight loss (runting) and death. This syndrome can be prevented by injecting the hosts with mature T cells taken from normal syngenic donors.

Ontogeny of thymic development

The epithelial components of the thymus descend into the anterior mediastinum from the third and fourth pharyngeal pouches and become colonized by stem cells derived from the yolk sac and fetal liver (depending on the species concerned). After proliferation and differentiation, these stem cells give rise to CD4⁺8⁺ cortical cells and then to CD4⁺8⁺ and CD4⁺8⁺ cells. In mice, mature SP cells are first apparent at about day 18 of gestation, i.e. at 2–3 days before birth. In humans, mature T cells begin to be produced at the end of the first trimester of pregnancy.

T cell differentiation and turnover in the mature thymus

In contrast to the peripheral lymphoid tissues, the vast majority of thymocytes turn over at a very rapid rate. Thymocyte differentiation begins with a population of stem cells which seed the thymus continuously from the bone marrow; these cells appear to be pluripotent but rapidly become committed to the T cell lineage.

The earliest stem cells in the thymus are characterized by a $CD4^{lo}8^{-} CD44^{+} CD25^{-}$ (IL-2R $^{-}$) phenotype. These cells proliferate extensively and give rise to $CD4^{-}8^{-} CD44^{+} CD25^{+}$ cells and then to $CD4^{-}8^{-} CD44^{-} CD25^{+}$ cells (Figure 2). During this transition, the cells cease to divide and then rearrange the TCR β gene and begin to upregulate both CD4 and CD8 molecules. The TCR β chain associates with a non-polymorphic α chain (gp33, pre-TCR α) and this heterodimer initiates a new wave of proliferation, perhaps by binding to a ligand on stromal cells. Proliferation is extensive at this stage and leads to the production of early $CD4^{+}8^{+}$ blast cells. Through rearrangement of polymorphic α chain genes, $CD4^{+}8^{+}$ blast cells rapidly express the typical $\alpha\beta$ TCR on the cell surface but at a low level. Proliferation ceases soon after $\alpha\beta$ TCR expression and the cells accumulate as typical small cortical $CD4^{+}8^{+} \alpha\beta TCR^{lo}$ cells; these cells are $CD44^{-} CD25^{-}$. The majority of small $CD4^{+}8^{+}$ cells survive for only a brief period (3–4 days) and die *in situ* from apoptosis. Only a small proportion of these cells undergo positive selection (see below).

The mature $\alpha\beta TCR^{hi} CD4^{+}8^{+}$ and $CD4^{-}8^{+}$ cells in the medulla are the direct descendants of $CD4^{+}8^{+}$

cells and display a relatively slow turnover. For obscure reasons, these cells remain in the medulla for up to 1–2 weeks before being released to the extrathymic environment.

Positive selection

Positive selection is a reflection of the fact that the specificity of $\alpha\beta$ T cells is not directed to native antigen but to peptides bound to MHC molecules. Since MHC molecules display extensive polymorphism, the range of peptides that associate with MHC molecules can vary considerably from one individual to another. Because of MHC polymorphism, the specificity of the T cell repertoire is unique in each individual – except in identical twins or in congenic strains of mice – and is tailored to give optimal immune responses to a broad array of foreign antigens (peptides) presented in association with 'self' MHC molecules. To prevent autoimmunity, however, mature T cells have to be rendered tolerant to peptides derived from autologous proteins. The T cell repertoire thus has to be finely tuned to be unresponsive to self (autologous antigens) but strongly reactive to slight perturbations of self (foreign antigens). This specificity is shaped in the thymus by a combination of positive and negative selection (Figure 3).

Positive selection is directed to self peptides bound to MHC class I and class II molecules expressed on cortical epithelial cells. $CD4^{+}8^{+} \alpha\beta TCR^{lo}$ cells with binding specificity for these peptide/MHC complexes receive a low-level signal which induces the cells to survive and differentiate into mature SP cells. The delivery of this survival/differentiation signal is

Figure 2 Schematic diagram of T cell developmental stages in the mouse thymus. Immature T cells undergo various maturation steps which can be followed by the expression of the cell surface markers listed in the diagram. Note the relative cell size at different stages and the transition steps which are associated with significant cell proliferation.

Figure 3 Positive and negative selection in the thymus. Immature CD4⁺8⁻ 'double-negative' (DN) cells under the capsule proliferate and differentiate into CD4⁺8⁺ 'double-positive' (DP) cells expressing a low density of the $\alpha\beta$ T cell receptor (TCR). A small fraction of DP cells express TCRs that have low but significant binding affinity for peptides bound to self MHC class I and II molecules displayed on cortical epithelial cells. These DP cells undergo positive selection. This process rescues DP cells from death and results in the cells migrating into the medulla and maturing into either CD4⁺8⁻ or CD4⁺8⁺ 'single-positive' (SP) cells. In the medulla, SP cells encounter antigen-presenting cells in the medulla, such as dendritic cells (DC) and macrophages (MΦ). These cells display MHC-bound self antigens entering from the bloodstream, and any T cells with overt reactivity for these antigens are deleted *in situ* (negative selection). As the result of positive and negative selection, only a very small proportion of total thymocytes (1–2%) are exported from the thymus; the remainder of the cells die within the thymus.

mediated by the $\alpha\beta$ TCR and is aided by CD8 or CD4 molecules. These two molecules act as coreceptors by binding to nonpolymorphic epitopes on MHC class I and class II molecules, respectively. Thus, if the T cell is recognizing a peptide bound to class I, this binding is aided by CD8 molecules. Such binding stabilizes CD8 expression but leads to down-regulation of CD4, with the result that the cell differentiates into a mature CD4⁺8⁺ cell. Conversely, positive selection to peptide/class II complexes is aided by the CD4 coreceptor and leads to differentiation into CD4⁺8⁻ cells.

The range of self peptides controlling positive selection is still unclear, but weak (antagonist) peptides seem to be particularly important. Most of these peptides are probably derived through breakdown of various intracellular proteins. Antagonist peptides may be particularly suited to provide the

weak signaling required for positive selection. This level of signaling is sufficient to induce differentiation but fails to cause cell division. As discussed later, strong TCR signaling of CD4⁺8⁺ cells is injurious and leads to rapid death (negative selection).

Positive selection involves only a very small fraction of CD4⁺8⁺ cells, i.e. 2–4%. The vast majority of DP thymocytes (>95%) have no binding specificity for the particular self MHC molecules expressed in the thymus and these cells die rapidly from 'neglect'. Death of these cells involves apoptosis, and special staining techniques reveal that apoptotic cells are rapidly cleared by adjacent macrophages. At face value the fact that the vast majority of thymocytes are doomed to die *in situ* seems wasteful and inefficient. However, this widescale destruction of immature T cells reflects the need to select only those cells that are equipped to function optimally in the

extrathymic environment, i.e. to respond to foreign peptides presented by the particular self MHC molecules of the individual. The TCR repertoire of CD4⁺8⁺ cells is presumed to be very broad and to encompass reactivity for all of the different MHC molecules expressed in the species as a whole. In any one individual, however, the range of MHC molecules is very small, with the result that specificity for these self MHC molecules is limited to a tiny fraction of DP cells. The fact that only a small number of DP cells undergo positive selection can thus be viewed as a reflection of the extent of MHC polymorphism.

Negative selection

Negative selection is designed to deplete the T cell repertoire of cells with overt reactivity for self components. Elimination of these cells is essential for self tolerance induction and the prevention of autoimmune disease. Since immature T cells cannot withstand strong TCR signaling, exposure to self antigens in the thymus deletes T cells with strong reactivity for these antigens via apoptosis. Since negative selection requires more intense TCR signaling than positive selection, negative selection is probably directed largely to agonist rather than antagonist peptides, i.e. to peptides that are immunogenic for mature T cells.

The site of negative selection in the thymus is controversial. Since most self components are conserved and expressed by all cell types, the majority of the self peptides that lead to negative selection are presumably expressed in the cortex, e.g. on epithelial cells. Indeed, negative selection in the cortex is apparent in models utilizing TCR transgenic mice. Whether negative selection occurs in the cortex under normal physiological conditions, however, is still unclear. By contrast, the medullary region of the thymus is a well-defined site for negative selection. In contrast to the cortex, the medulla is permeable to bloodborne proteins and is packed with bone marrow-derived cells with antigen-presenting function. The 'open' structure of the medulla means that any self antigens present in the bloodstream will be carried into the thymus and thus be positioned to tolerate immature T cells specific for these antigens. Conversely, self antigens that fail to enter the bloodstream, i.e. tissue-specific antigens, do not reach the thymus and thus do not induce negative selection. In this respect it is well accepted that the T cell repertoire retains reactivity for a variety of tissue-specific self antigens, e.g. myelin basic protein. When exposed to the immune system in immunogenic form, these antigens break tolerance and lead to

autoimmune disease in the tissue concerned, e.g. in the brain for myelin basic protein.

It should be emphasized that negative selection is quantitative and reflects the concentration of antigen reaching the thymus. In the case of abundant antigens such as albumin, the concentration of antigen in the thymus is high and deletes T cells with a spectrum of affinities for the antigen, including low-affinity cells. For this reason breaking self tolerance to albumin at the T cell level is difficult or impossible. Other self antigens, e.g. hormones such as insulin, reach the thymus in much lower concentrations. In this situation negative selection is incomplete: high-affinity T cells are deleted but low-affinity cells are spared. These latter cells are generally innocuous because the concentration of antigen encountered in the periphery is no higher than in the thymus. Under experimental conditions, however, self tolerance to these antigens can be broken, i.e. by injecting the antigen in very high concentrations in immunogenic form.

T cell outputs from the thymus

Because of the combined requirements for positive and negative selection, the total numbers of mature thymocytes exported to the peripheral lymphoid tissues is very limited. The vast majority of these cells are mature SP cells; DP cells are not exported. At present, quantitative information on the number of T cells released from the thymus is limited to mice. In this species, the rate of T cell export from the thymus amounts to about 1% of the total cellularity of the thymus. Thus, the large thymus of 4-week-old mice, which contains about 2×10^8 cells, releases in the order of 2×10^6 cells day⁻¹ into the periphery. With the onset of thymic atrophy, thymic outputs drop dramatically. Thus, by 6 months of age the release of T cells from the thymus is reduced to about 1×10^5 day⁻¹. Since small amounts of thymic tissue are detectable even in old age, production of new T cells from the thymus probably continues throughout life, but at a very limited rate.

Extrathymic sites of T cell production

Since the number of mature T cells in the secondary lymphoid organs remains high throughout life, it is often argued that maintenance of the T cell pool after the stage of thymic atrophy reflects *de novo* production of T cells in other organs, e.g. the gut, liver and bone marrow. Although some degree of T cell differentiation can occur in these organs, there is currently no clear evidence that such differentiation contributes to the formation of the typical $\alpha\beta$ T cells

found in the blood, spleen and lymph nodes. The most likely explanation for the maintenance of the T cell pool size into old age is that T cells are intrinsically long lived. The thymus is vital for the initial formation of the T cell pool, but once the pool reaches its maximal size in young adult life generation of new T cells by the thymus becomes relatively unimportant. By puberty the thymus is largely redundant and atrophy ensues.

THYROID AUTOIMMUNITY, ANIMAL MODELS

Noel R Rose, Department of Molecular Microbiology and Immunology, Johns Hopkins University, Baltimore, MD, USA

That autoimmunity is a major cause of thyroid disease has been evident for over 35 years, but many critical questions about the immunopathogenesis remain unanswered. This entry focuses on the prototypic autoimmune thyroid disease, chronic thyroiditis or Hashimoto disease, and aims to answer these questions by reference to experimental models. The questions pertain primarily to the molecular and genetic basis of autosensitization, to the principal thyroid antigens and the immunological characteristics of pathogenetic autoimmunity.

Two types of models are available for study in the research laboratory: spontaneous and experimentally induced thyroiditis. Injection of thyroglobulin, usually with an adjuvant, induces thyroiditis in a variety of animals including rabbits, rats, mice, guinea pigs, dogs, rhesus monkeys and chickens. This method has the advantages of dealing with a well-characterized

antigen and beginning at a defined point in time and, therefore, lends itself to precise genetic and molecular investigations. Spontaneous models of thyroiditis can be found in the OS chickens, the BUF and BB strains of rats, NOD mice and the Argonne Laboratory colony of beagle dogs. Thyroiditis and a number of other organ-specific autoimmune diseases can be produced by carefully timed neonatal thymectomy of certain strains of mice, or by adult thymectomy combined with irradiation of rats. These manipulations alter the balance of T cell subsets. These forms of the disease more closely resemble human chronic thyroiditis and are especially useful for defining the complex interactions involved in the pathogenesis of thyroiditis. For purposes of discussion, we have divided the pathogenesis of autoimmune thyroid disease into three stages: induction, progression and expression.

Induction

The induction of autoimmune thyroid disease in humans depends upon the interaction of innate and environmental factors. The balance of these two varies from situation to situation, as will be described subsequently. Family studies and twin studies show that predisposition to thyroid autoimmunity is genetically acquired. Since concordance among identical twins is less than 50%, however, clinically relevant disease is probably precipitated by environmental triggers.

The genetic traits predisposing to thyroid autoimmunity may exert their effects primarily through the immune response or through the thyroid target organ.

Genetic factors influencing immune response

The genetic factors influencing the immune response are as follows:

Immunoglobulin variable (V) gene repertoire Studies show that the full range of heavy and light chain V region gene families is involved in the induced autoimmune response to thyroglobulin in mice. Yet, there are reports of a limited number of dominant idiotypes in spontaneous thyroiditis of the BUF rat and, recently, in human thyroiditis patients, suggesting preferential use of certain V gene families in spontaneous forms of the disease.

Major histocompatibility complex (MHC) class II genes These genes act either by controlling presentation of particular antigenic determinants or by shaping the T cell repertoire during the positive selection process in the thymus. A class II gene (referred to as Ir-Tg) is the most important single determinant of the vigor of the immune response to thyroglobulin in the mouse, but its importance is somewhat overshadowed by other genes in the rat. MHC class II genes are also highly significant in spontaneous thyroiditis in the OS chicken. In human autoimmune thyroid disease the picture is mixed since there is a clear but weak association of MHC class II genes with Graves disease, but only a questionable association with Hashimoto thyroiditis on a populational basis. Within a particular family, however, siblings who share both HLA haplotypes with the patient show a great increase in thyroid autoimmunity.

T cell receptor (TCR) genes In other experimental autoimmune diseases, notably allergic encephalomyelitis, a striking restriction of TCR-V β family usage has been reported. The situation with respect to experimental thyroiditis is still under investi-

gation, but there is some evidence of restricted TCR-V β usage during the early stages of autoimmunization.

Regulation by T cells and T cell products Despite many claims in the literature, the physiological role of regulatory T cells remains unclear in human autoimmunity. However, experiments in the rat, the mouse and the chicken all point to the presence of a thymus-derived regulatory lymphocyte population. In experimental thyroiditis of the mouse, a unique antigen specific thymus-derived suppressor cell has recently been described. It is a CD3⁺, CD8⁺, I-J⁺ large lymphocyte which is MHC restricted and age related; that is, it is readily detected in young animals of most strains, but greatly reduced in older (30 months of age or more) mice.

Sex Thyroiditis is four to five times more frequent in women than in men. Using experimental thyroiditis in mice, we showed that castrated male mice given estrogen were more susceptible to disease than controls. In BUF rats, repeatedly-bred females had a higher incidence of thyroiditis than age-matched virgin females or males.

Genetic factors affecting target organ susceptibility

A number of different genetic traits pertain to target organ susceptibility.

MHC class I genes These are influential in determining the degree of thyroid damage during experimentally induced thyroiditis in the mouse.

Thyroglobulin allotypes Subtle antigenic differences among thyroglobulins have received relatively little attention in the past, but such small differences may be critical in determining the binding of thyroglobulin fragments with MHC class II products of the antigen-presenting cells.

'Disease-associated' epitopes Studies in both the mouse and human have shown that the autoantibodies associated with disease react with a restricted portion of the thyroglobulin molecule. In both species these epitopes are species specific. It is reasonable to postulate that the presence of an immune response to these epitopes is a biomarker of pathogenic autoimmunity.

Adhesion molecules LFA-1 and its ligand ICAM-1 are highly expressed in foci of lymphocyte infiltration of the thyroid gland.

Environmental factors

A number of environmental factors have been implicated in the pathogenesis of autoimmune thyroid disease. These factors may operate by increasing the immunogenicity of thyroid antigens or by heightening the immune response. 1) Diet is clearly of importance with respect to the iodine content of the thyroglobulin. It is likely that the steady increase in thyroid autoimmunity in North America and Western Europe is related to the increasing consumption of dietary iodine. There is evidence that iodine enhances the immunogenicity of the thyroglobulin molecule through its recognition by helper T cells. 2) A number of other chemicals and drugs are known to increase thyroid autoimmunity in predisposed animals. A striking example is the role of methylcholanthrene in raising the prevalence and severity of autoimmune thyroiditis in BUF rats. 3) Infection has long been postulated as one of the triggers of thyroid autoimmunity. At least two well-studied epidemics of mumps and one local paramyxovirus epidemic have been followed by clusters of thyroiditis cases. Possible molecular mimicry between thyroglobulin and *Yersinia* has been described. 4) Finally, stress is known to precipitate clinical manifestations of thyroid autoimmunity, probably by affecting steroid or peptide hormones.

These examples of genetic and environmental factors that influence the induction of thyroid autoimmunity are cited not as an exhaustive list, but as illustrative of the fact that the induction of thyroid autoimmunity is both multifactorial and polygenic. None of the genes described above is 'abnormal'; rather they encode traits distributed widely in the general population. The conjunction of a number of normal genes together with appropriate environmental triggers is responsible for the initiation of autoimmune thyroid disease. The particular mix of genes varies from animal to animal. Thus, MHC class II genes are prominent risk factors in some species but not in others. Similarly, environmental factors may be more or less important depending on the circumstances. A powerful stimulus, like Freund's complete adjuvant, plus homologous thyroglobulin will induce thyroiditis in virtually every immunized rabbit regardless of its genetic constitution.

Progression

It has long been known that B cells binding autologous thyroglobulin are present in normal mice. These B cells are probably responsible for the low level of 'natural' autoantibodies found in normal sera. When they are immortalized by hybridization they produce low-affinity IgM antibody directed to the conserved

portions of the thyroglobulin molecule. These naturally occurring autoantibodies may well serve a physiological function in facilitating the removal of intact thyroglobulin that escapes the thyroid follicles and enters the bloodstream.

The critical requirement for the progression of an autoimmune response to autoimmune disease is the stimulation of self-reactive T cells. There is indirect but firm evidence that T cells reactive with autologous thyroglobulin are not entirely deleted in normal mice. One premise is that these thyroglobulin-reactive T cells are not fully eliminated in the thymus because they are of relatively low affinity. Since they are not easily triggered, an adjuvant, such as Freund's complete, lipopolysaccharide, or poly A:U, is mandatory to initiate their proliferation.

If self-reactive T cells are stimulated, there is a stronger possibility that an autoimmune response will progress to pathological autoimmunity. The expression of autoimmune disease depends upon the elaboration of cytokines emanating from the stimulated T cells. Very little information is available, as yet as to what determines the mix of cytokines produced by stimulated T cells.

Additional important factors influence pathological progression of autoimmunity to autoimmune disease, such as immunological escalation. Cytokines such as interleukin 1 (IL-1) lower the threshold of activation of self-reactive T cells and promote the expression of activation markers, such as IL-2 receptor, Ia and LFA-1. Under these conditions even the lower affinity T cells can be triggered.

Therefore, once autoimmune inflammation has begun, other organ-specific antigens of the thyroid add to the overall autoimmune response. Experiments have shown that primates immunized with purified thyroglobulin eventually develop autoantibodies to thyroid peroxidase (thyroid microsomal antigen). The initial thyroid inflammation serves as the equivalent of an adjuvant, permitting additional organ-specific antigens of the tissue to express themselves. It is significant that in all of the organ-specific autoimmunities studied to date more than one organ-specific reaction is demonstrable.

Expression

The expression of autoimmunity after stimulation of self-reactive T helper cells depends upon the mixture of lymphokines liberated. For example, IL-4 and IL-6 effect isotype switch of B cells and help to determine the affinity and biological properties of antibodies produced, whereas IL-2 and interferon γ (IFN γ) favor cell-mediated immunity.

In the case of autoimmune thyroid disease, at least

three antibody-mediated functions have been described. They include 1) complement-mediated lysis, 2) antibody-dependent cellular cytotoxicity (ADCC), and 3) immune complex deposition. Complement-mediated lysis entails action upon a thyroid cell membrane antigen. The antigen is lost rapidly during *in vitro* cultivation of the thyroid epithelium and, therefore, has not yet been characterized. ADCC has been demonstrated using thyroglobulin-coated erythrocytes or mastocytoma cells. The identity of the killer cell involved in these reactions is uncertain, but it appears to be a large granular lymphocyte, morphologically resembling the natural killer (NK) cell. Immune complex deposition of thyroglobulin antithyroglobulin has been found in the kidneys of rabbits with experimental thyroiditis (as well as patients with Hashimoto's thyroiditis). In addition, immune complexes have been found within the thyroid gland itself in OS chickens and contribute to the final pathological picture. It is important to recall that local production of antibody is a major feature of spontaneous autoimmune thyroid disease in the chicken and the rat, as evidenced by the presence of plasma cells and of germinal centers.

The production of cytotoxic T cells may depend primarily upon the elaboration of such lymphokines as IL-2 and IFN γ by the helper T cells. In the mouse, cytotoxic T cells are both H-2 restricted and thyroglobulin specific, showing that at least some antigenic determinants of thyroglobulin are expressed on the surface of the thyroid epithelial cell in culture.

Tumor necrosis factor (TNF) is another lymphokine produced by stimulated helper T cells and, experimentally, TNF α has been shown to injure rat thyroid tumor cells. The role of TNF α and TNF β in experimental or spontaneous thyroiditis, however, has not yet been established.

Finally, activated macrophages are prominent in experimental thyroiditis in the mouse, rat and rabbit, and spontaneous thyroiditis in the chicken and rat. Since they are an important source of cytokines, hydrolytic enzymes, nitric oxide, oxygen free radicals and prostaglandins, they may contribute significantly to the final pathologic picture.

Summary

Both genetic and environmental factors contribute to

the induction of autoimmune thyroid disease. A number of genes, acting by diverse mechanisms, converge to provide the genetic susceptibility to thyroid autoimmunity. MHC class II genes are the major genetic determinants of susceptibility in most species. The response to the principal thyroid antigen, thyroglobulin, is not clonally restricted on the B cell level, but clonal restriction of T cells is still a possibility. Autoimmunity begins as a response to a restricted region of the thyroglobulin molecule, but a number of different epitopes is represented in that region. The pathogenetic expression of autoimmunity differs from species to species. In the mouse, for example, experimental thyroiditis is produced mainly by cytotoxic T cells whereas antibody plays a significant pathogenetic role in spontaneous thyroiditis of the OS chicken.

In areas of the world where dietary iodine intake is adequate, autoimmune mechanisms are the commonest cause of thyroid disease. In this situation autoimmune thyroid disease (AITD) occurs in up to 4% of the population and manifests itself clinically, predominantly as either thyroid overactivity (hyperthyroidism) with or without characteristic changes in the eyes (ophthalmopathy) or thyroid underactivity/failure (hypothyroidism). In both situations the thyroid may be enlarged (goitre). Clinical descriptions of the disease states long predate our understanding of their cause. Depending on where one's national loyalties lie and one's reading of the historical descriptions, hyperthyroidism with diffuse enlargement of the thyroid and ophthalmopathy is variously referred to as Graves' disease, von Basedow's or Parry's disease. In contrast, thyroid failure attributable to AITD is best referred to collectively as chronic autoimmune thyroiditis, in which lymphocytic infiltration is characteristic and can be subdivided, depending on the clinical presentation, into goitrous (Hashimoto's) thyroiditis and atrophic thyroiditis (primary myxedema) in which the thyroid is not palpable.

The turning point in our understanding of these disease states came in 1956. The establishment of an animal model of AITD by Rose and Witebsky and the demonstration by Roitt, Doniach and their colleagues of autoantibodies to thyroglobulin in the sera of patients with Hashimoto's thyroiditis opened an era of intense research activity. An equally momentous observation, also in 1956, was that by Adams and Purves, who demonstrated in the sera of patients with hyperthyroid Graves' disease an activity distinct from thyroid-stimulating hormone/thyrotropin (TSH), which stimulated the uptake of radioiodine into the guinea pig thyroid with a delayed time course of action as compared with TSH; thus was both the concept of the long-acting thyroid stimulator (LATS) which was shown by Kriss and colleagues in 1964 to be an immunoglobulin.

Etiology

Graves' disease and chronic autoimmune thyroiditis belong to the group of organ-specific autoimmune diseases, which includes insulin-dependent diabetes mellitus (IDDM), myasthenia gravis, pernicious anemia, Addison's disease, primary ovarian failure and

viteligo. These diseases, besides occurring together in the same individual more frequently than one would expect by chance, are also found commonly in the families of affected individuals though no clear pattern of inheritance is recognizable. Additionally, well-recognized HLA associations are known to occur with these diseases and they are commonly associated with chromosomal anomalies such as trisomy 21 and Turner's syndrome and in familial Alzheimer's disease. Concordance rates in Graves' disease in monozygotic (30–60%) and dizygotic (3–9%) twins further emphasize the importance of genetic factors. Historically, most effort has been directed at the contribution which genes in the HLA region on chromosome 6 make towards genetic susceptibility in patients and families with AITD. In Caucasians with Graves' disease a weak but consistent association with HLA-DR3 is well established. A stronger association with HLA-DQA1*0501 (which is in linkage disequilibrium with DR3) has been reported which is still present when DR3-positive individuals are excluded. The examination of associations of polymorphisms in other relevant, non-HLA genes with Graves' disease, including genes for immunoglobulins, cytokines, the T cell receptor and the TSH receptor, have not been rewarding.

Family studies to date have not contributed significantly towards characterizing the major genetic determinants contributing towards the development of AITD, primarily because of the small number of families studied and the small number of genetic markers used. The examination of a large number of multiplex families using automated technology and a large number of microsatellite markers spanning most of the human genome (as pioneered in studies of IDDM) offers exciting prospects for understanding the genetic contribution to the development of AITDs. The AITDs occur more commonly in females and are characterized by circulating autoantibodies and activated T cells and in addition lymphocytic infiltration of the target organ (thyroid). If we feel more confident now (as discussed below) in our understanding of the pathogenic mechanisms leading to AITDs the same cannot be said of their etiology. The consensus view would have to be that the organ-specific AITDs are multifactorial diseases which arise in genetically predisposed individuals in whom the onset of disease is triggered by an insult which may be constitutional or environmental.

In the context of AITDs a number of constitutional factors have been implicated which include the age, sex and race of the individual and their hormonal status; these diseases remit during pregnancy but commonly present at times of major hormonal alteration such as at puberty, in the postpartum period and at the menopause. Although less than 25% of patients presenting with Graves' disease are male, men who get the disease have much more severe disease with higher levels of antibody at presentation and higher relapse rates following antithyroid drug treatment, compared with women with the disease. Stressful stimuli can influence both thyroid function and the immune system. In seeking to define potential mechanisms considerable interest and activity has focused on examining the implications of the resulting induction of heat shock proteins by stressful stimuli on the subsequent development of AITDs. In supporting the potential role of stress in inducing AITDs a number of studies highlight the increased frequency of negative life events in the 12 months preceding the development of hyperthyroid Graves' disease in patients as compared with matched healthy controls. Such retrospective, subjective observations need to be extended by more robust data but the association observed does seem likely.

The establishment normally of a state of self-tolerance, particularly during development in the thymus when as part of T cell maturation, T cells with a high affinity for self antigens are deleted, protects against the induction of AITDs. These diseases follow the breakdown of self-tolerance. Breakdown is likely to occur in genetically susceptible individuals when target organ damage by an environmental insult (perhaps an infectious agent) damages a target organ, thus exposing previously sequestered self antigens to the immune system. The resulting autoimmune response is determined by factors such as the antigen dose, type of antigen presenting cell, major histocompatibility complex (MHC) class II haplotype and cytokines involved which direct the differentiation of previously naive CD4⁺ T cells into either T_H1 or T_H2 subsets. This latter process determines whether a humoral (antibody-mediated) or cell-mediated immune response is then generated. Cytokines themselves may be directly cytotoxic. Definition of the epitopes within target autoantigens against which the humoral and cell-mediated immune response are directed is a major focus of the research effort into AITDs.

Environmental factors have been extensively studied, particularly in the context of Graves' disease. The seasonal and geographic influences which are well recognized almost certainly reflect differences in dietary intake of iodine. Across Europe the frequency

with which Graves' disease is the commonest presenting cause of hyperthyroidism ranges from 45% of patients in Goettingen, Germany (an area of iodine deficiency) to 87% of patients in Athens, Greece (an area of higher than normal iodine intake). In the UK the seasonal variation in Graves' disease may well have a similar explanation. The major source of iodine in the UK is milk and its content of iodine almost doubles during the winter months when cattle are brought indoors and are fed on food supplements rich in iodine, particularly iodized salt licks. The pattern of Graves' disease seems to follow this pattern with the disease presenting most commonly immediately after winter and being most uncommon immediately before winter. Recurrence of Graves' disease, following thyroid surgery to cure it, is most likely in areas of iodine excess (Reykjavik, Iceland) compared with areas of lower iodine intake (Aberdeen, Scotland).

The other major potential environmental inducers of AITDs which have attracted attention are infectious agents. In this area results to date have been disappointing, though modern recombinant DNA technologies in conjunction with characterization of the target autoantigens will undoubtedly lead to previous seemingly inaccessible agents such as viruses being open to examination. Elegant work on *Yersinia enterocolitica* and common strains of gut commensals such as *Escherichia coli* have shown clear evidence of cell surface constituents which bind TSH with similar characteristics to that of the TSH receptor on thyroid cells. The concept that is beginning to emerge is that through molecular mimicry an immune response directed against these organisms could include the generation of immune mechanisms which, in a genetically susceptible individual, not only control the microorganisms' proliferation but also, because of the homology between their 'TSH receptor-like constituents' and the thyroid TSH receptor, allow the development of Graves' disease.

A further important environmental insult increasingly implicated in the development of AITDs is cigarette smoking. This is particularly relevant to the development and worsening of Graves' ophthalmopathy. The mechanism remains uncertain.

Whilst enormous advances have been made in the past 40 years the most exciting developments have come in the last few with the cloning of the thyroid enzyme, thyroid peroxidase (TPO) and the TSH receptor and the demonstration that these are the key target autoantigens in AITDs, against which the aberrant autoimmune response is directed.

Graves' disease

The diffusely enlarged thyroid gland detected clinically or by radioisotope scan in conjunction with the presence of ophthalmopathy, and less commonly changes in the skin on the front of the legs (pretibial myxedema) and in the nails (thyroid acropachy), allows the diagnosis of Graves' disease to be made confidently in a patient presenting with hyperthyroidism. It is the commonest cause of hyperthyroidism in the UK accounting for 75% of the cases seen.

The disease is due to autoantibodies to the TSH receptor. Historically these antibodies have proved a source of great confusion since a wide variety of assay systems for their detection have been developed and have resulted in a wide variety of terms being used to describe the activity detected. The antibodies are unique in that not only do they bind to the TSH receptor but they are also able to stimulate thyroid function and thus themselves induce hyperthyroidism, acting through the adenylate cyclase second messenger system. Assays to detect these activities are therefore able to detect binding of these autoantibodies to the TSH receptor (radioreceptor assay) or measure the ability of the antibodies to stimulate thyroid cell function (bioassay). In the radioreceptor assay measurement is made of the ability of antibodies to inhibit the binding of radio-labeled TSH to a thyroid membrane preparation. Bioassays, using predominantly human thyroid cells in primary culture or the rat FRTL5 thyroid cell line, measure end-points of cell activation which are mediated via the TSH receptor. With the increased sensitivity of the assay systems TSH receptor antibody activity is detectable in the vast majority of patients with Graves' disease when they first present with hyperthyroidism. In responses to treatment the antibody activity falls and failure of the antibody to disappear in response to treatment makes disease recurrence almost certain. The antibody does therefore seem to correlate fairly closely with disease activity.

The best evidence, however, that the antibody is indeed pathogenetic comes from studies in the offspring of mothers with Graves' disease. TSH receptor antibodies are of the immunoglobulin G1 (IgG1) class and therefore cross the placenta. When the level of antibody is high enough in the mother it will, by crossing the placenta, induce hyperthyroidism in the fetus and newborn which lasts as long as the antibody is present at sufficient concentration in the neonate (6–8 weeks).

In addition to autoantibodies which stimulate thyroid cell function, it is now also clear that autoanti-

bodies exist which, by binding to the TSH receptor, inhibit thyroid cell function. These TSH receptor blocking antibodies (TSHRBAb) can also be detected by the radioreceptor assay, but this assay does not itself distinguish between stimulating and blocking TSH receptor antibodies. However, a modification of the bioassay can be used to examine the ability of these antibodies to inhibit TSH-induced cyclic AMP production by thyroid cells.

Yet another group of antibodies have been described which rather than acting to stimulate or block thyroid function, are involved in inducing or inhibiting thyroid growth. Considerable controversy surrounds these antibody activities: Are the assay systems measuring parameters of growth reliable? Are the effects mediated via the TSH receptor? Is there any difference between TSH receptor-stimulating antibodies and thyroid growth stimulating antibodies? The answers are not yet available.

What is not in doubt is the fact that the spectrum of clinical presentations of AITDs with changes in both thyroid gland function and size occurring not only in different individuals but also in the same individual points to the presence of a spectrum of autoantibodies acting as agonists and antagonists and able to influence both thyroid cell function and growth. With the cloning of the TSH receptor clear characterization of the antibodies binding to it and the different epitopes of the receptor recognized by these antibodies will very soon confirm or refute the presence of antibodies which stimulate and block both thyroid function and growth.

The cloning in 1989 of the TSH receptor by the groups of Vassart and Rapoport has provided a major impetus to the work on Graves' disease. The receptor consists of a single polypeptide of 764 residues which, in keeping with other G protein-coupled receptors traverses the cell surface membrane seven times. The extracellular part of the receptor comprises 395 residues and that this is the region involved in the interaction with the glycoprotein hormone TSH and with TSH receptor antibodies has been confirmed with expression of the recombinant protein in eukaryotic cells. The field is moving rapidly; B cell epitopes are being defined and T cell epitopes will follow. Elucidation of the interaction of the spectrum of autoantibodies to the TSH receptor with the receptor is at hand.

Graves' ophthalmopathy

Clinically, the changes occurring in the eyes of patients with Graves' ophthalmopathy (GO) are, when overt, easily recognized and well described. In a significant number of patients the changes are more

subtle, not detectable clinically or only demonstrable with highly specialized investigations such as computerized tomography of the orbits. As a result the true frequency of GO and the frequency of its association with AITD remains controversial. Is it a distinct organ-specific autoimmune disease or is it an associated feature of the AITD? We do not yet know. It certainly occurs most frequently in patients with Graves' disease. Clinically, its importance lies in helping to define the cause of hyperthyroidism in a patient presenting with the disease but it is also important to recognize, since in a small group of patients with GO (perhaps no more than 5%) it can progress to threaten vision. Why this progression occurs and what causes it we do not know.

Examination of the orbits of patients with GO at postmortem reveals marked extraocular muscle hypertrophy with an increase in surrounding fat and connective tissue. Histology of these tissues reveals inflammatory and immune cell infiltrates. The pathogenesis remains as uncertain as the natural history. Are there autoantigens on orbital tissues which share epitopes with autoantigens in the thyroid? Data have accumulated to suggest that both antibodies and T lymphocytes may recognize determinants on extraocular muscles or orbital fibroblasts and lead to antibody-dependent or antibody-independent cell-mediated cytotoxicity. The area remains confused and controversial. In all of endocrinology GO remains one of the great enigmas and one of the least well understood and most poorly managed clinical problems. Until we can characterize confidently the autoantigen targets and obtain them in sufficient quantities naturally or through cDNA expression systems, prospects for understanding the disease are poor.

Thyroiditis

Patients with chronic autoimmune thyroiditis most commonly present with clinical and/or biochemical evidence of thyroid failure with or without goitre. Clinically they can be divided into those with goitrous (Hashimoto's) thyroiditis and those with atrophic thyroiditis (primary myxedema). Historically, establishment of their autoimmune basis has relied on the presence of autoantibodies to thyroglobulin (in the minority) and to the thyroid microsome (in the majority), detected by immunofluorescence or hemagglutination assays. More sensitive assays, particularly using ELISA techniques, have allowed accurate quantitation of the autoantibody activity and the production of monoclonal antibodies to the thyroid microsome (TMA).

Understanding of the pathogenesis of these dis-

eases, and particularly the significance of autoantibodies to the TMA, was limited by the recognition that the TMA was an intracellular constituent of the thyroid cell exocytotic vesicle carrying thyroglobulin (TG) to the apical cell surface of the cell for its processing and maturation to thyroid hormones. The demonstration, with highly purified polyclonal and monoclonal antibodies, that the TMA was in fact expressed on the cell surface (at the time that the exocytotic vesicle released TG) and was therefore accessible to the immune system, awakened interest in the TMA as a potential target autoantigen. With these autoantibodies it was rapidly shown to be a 105 kDa molecular weight protein and screening of thyroid cDNA λ gt11 libraries allowed detection of a protein of 933 amino acids which turned out to be thyroid peroxidase (TPO), the key thyroid enzyme involved in the generation of thyroid hormones from TG.

Considerable evidence has accumulated to demonstrate that TPO is the major autoantigenic determinant of TMA. DNA expression systems making use of the polymerase chain reaction have provided TPO recombinant proteins and allowed the rapid mapping of B cell epitopes. Whilst a spectrum of autoantibodies are now recognizable as being directed against the TPO molecule, their significance remains uncertain. Unlike the situation in Graves' disease, the passage of TPO antibodies across the placenta is not associated with any alteration in thyroid function in the offspring. Investigations as to the role of antibody-dependent or independent cell-mediated cytotoxic mechanisms directed against TPO in the induction of thyroid failure are now ongoing. T cell clones established from the thyroid lymphocytic infiltrates and recombinant TPO and peptides spanning the molecule will allow characterization of the T cell epitopes and evaluation of the significance of T cells in the pathogenesis of the thyroid cell destruction leading to hypothyroidism.

Whilst antibodies to TPO are detectable as frequently in patients with atrophic thyroiditis as in those with goitrous thyroiditis, an interesting additional or alternative explanation for the pathogenesis of atrophic thyroiditis has emerged with the demonstration in perhaps as many as half the patients of TSHRBAb. These antibodies, on crossing the placenta, cause transient neonatal hypothyroidism and therefore almost certainly represent a pathogenetic mechanism which would explain, by the blockage of access of TSH to its receptor, both the atrophy of the thyroid as well as its failure to synthesize thyroid hormones.

Postpartum thyroid dysfunction

An interesting variant of the group of AITDs are the syndromes of transient postpartum thyroid dysfunction (PPTD). Described initially in Japan by Amino and his colleagues, these syndromes occur in at least 5% of women postpartum. Women who are shown to have autoantibodies to TPO when they present to prenatal clinics and who are (if Caucasian) HLA-A1, -B8, -DR3 positive, are at particular risk of developing PPTD, irrespective of their past medical history. The syndromes are usually subclinical but biochemical monitoring of the postpartum period reveals changes in thyroid function which include hyperthyroidism, hypothyroidism or hyperthyroidism followed by hypothyroidism. The syndromes are important to recognize since they may well contribute to the etiology of the well-documented changes in mood and behavior that occur in the postpartum period and, more importantly, although initially transient they may be the first signals of subsequent permanent thyroid failure.

The pathogenesis of these syndromes remains to be fully elucidated. The hyperthyroid phase contrasts with Graves' disease in that the thyroidal radioisotope uptake is low or undetectable and antibodies to the TSH receptor are not detectable. The evidence to date suggests that the hyperthyroid phase results from immune-mediated thyroid cell destruction and therefore thyroid hormone release. If this process is severe enough it is followed by hypothyroidism, the duration of which is determined by the extent of destruction and the time it takes for thyroid tissue recovery.

Conclusions

The clinical syndromes of AITD are well established. The pathogenetic mechanisms are now also increasingly well understood. Recombinant DNA technology has provided the necessary tool for the elucidation and characterization of the target autoantigens. Establishment of B cell epitopes and, through cloning of target tissue T cells, the definition of T cell epitopes, will almost certainly tie up the pathogenesis story. Two issues remain: what is the etiology and in this context what does the environment contribute, and can we modulate or prevent AITD?

Cloning of the autoantigens will allow an answer to the first question through approaches such as examination of homologies between these autoantigens and infectious agents. The second question is more difficult. With the understanding we now have and the strategies available there seems little reason, once the relevant autoantigenic epitopes are established, why prospects for autoimmune disease should be any different from those of infectious diseases and why immunization against AITD should not become a reality. Studies in animal models of AITD using oral tolerance as a therapeutic option also offer an exciting alternative strategy.

What is tissue typing?

Most commonly, tissue typing refers to the testing of lymphocytes for their human leukocyte antigens (HLA). Although other cells or 'tissues' could be used, in actual practice lymphocytes are almost exclusively used as the targets. 'Types' can also mean many other polymorphisms, but again, commonly it is the HLA antigens which constitute the tissue type. Red blood cell types may also be on certain tissues, but historically, since they were first found on red cells, types such as type A, B and O are said to be red cell types.

Although red cell types were first discovered about 90 years ago, it has only been about 30 years since the tissue types came to be generally recognized. In this relatively recent past, very great strides have been made in defining over 300 'types'. Much of the development has been fueled by the parallel advances in the field of clinical transplantation, for the main clinical utility of tissue typing is transplantation. Today, tissue typing is performed on over 20 000 kidney transplants annually and about 10 000 other types of transplants, such as heart, liver, pancreas and bone marrow.

How is tissue typing done?

Similar to determining red cell types, it was recognized early that the best approach would be to find antibodies directed against cells other than red cells, namely white cells. The earliest attempts, therefore, used a similar agglutination reaction against white cells to that used for red cells. The first antibody to a type or specificity was found by Dausset in 1958 in sera from patients immunized by transfusions, using the leukoagglutination reaction. Patients immunized by pregnancies were also shown, by Payne, to have agglutinating antibodies to leukocytes. Because the reactions produced were so complex, van Rood introduced the use of computers to identify sera which were similar to each other. In this way, he first defined an allelic group of sera, 4a and 4b.

It was at this point in 1964 that the micro lymphocyte cytotoxicity method of Terasaki and McClelland was introduced. This method, together with some modifications, has been adopted and used universally for the past 30 years. The basic feature of

requiring an extremely small volume of antisera (0.001 ml per test) and a small number of lymphocytes was critical to its widespread adoption.

In 1969, a group of investigators met at the National Institutes of Health (NIH) and agreed to use identical incubation times (30 minutes with anti-serum and 60 minutes with complement) to standardize the test (often, since, called 'the NIH test').

Starting with the discovery of the molecular structure by Bjorkman in 1987, and through the subsequent establishment of the amino acid sequence of each of the HLA specificities and the development of the polymerase chain reaction (PCR) in recent years, it has become possible to determine HLA type by DNA-based methods. These methods have the advantage of not being dependent on rare, specific antisera, but rather on probes and primers which can be readily synthesized. In addition, they do not rely on living lymphocytes, as DNA can be isolated from any nonviable nucleated cell. The end-point of the tests is also not influenced by the viability of cells or the activity of complement. Perhaps most importantly, DNA typing can identify 'splits' or variants in the specificities which are impossible to detect serologically.

Currently, one drawback to the DNA tests is that they take a longer time to perform (3–6 hours). This time is further extended when all the specificities are typed. The expense is considerably higher, particularly for class I. Many of the amino acid substitutions detected by DNA typing may not be relevant for transplantation as they do not all form immunogenic epitopes against which the body reacts. When antibodies are formed against an epitope, it is clear that the target epitope is one to which the host responds immunologically. The relevance of each variant remains to be established, particularly for solid organ transplantation. For bone marrow transplants, the 'minor' mismatches appear to have some effect on the success of the transplant.

Methods

Serology

Lymphocytes are isolated from blood by immunomagnetic beads coated by monoclonal antibodies against T cells or B cells. Once the cells adhere to the beads, the beads are pulled to one surface of the

test tube with a strong magnet. After washing, the beads and the attached cells are reacted in the tissue typing tray. Alternatively, lymphocytes are isolated with a monoclonal antibody cocktail which contains antibodies to all unwanted cells, such as red cells, platelets, granulocytes and B lymphocytes, in order to obtain T lymphocytes for typing. The cells are then stained with carboxyfluorescein in the fluorescence test.

Next, lymphocytes are added to the predotted tissue typing tray. These trays contain highly selected antisera either from pregnant women or from monoclonal antibodies produced in mice. Each antibody reacts to an epitope which is unique to a certain HLA specificity. Typically, the tray will have 72 or 96 different antisera. Each of the valuable antisera are pre-dispensed on the tray in 0.001 ml volumes, and stored frozen until needed.

After incubation of lymphocytes with antibody for 30 minutes, rabbit complement is added (0.005 ml) and incubated for an additional hour. With monoclonal antibodies, rabbit complement can be incorporated into the first step, thus reducing the total incubation time to 1 hour or less.

After the addition of ethidium bromide or propidium iodide, the reactions are read by the fluorescence test. Living cells are stained green with carboxyfluorescein while dead cells are stained red with ethidium bromide or propidium iodide. In the eosin dye test, dead cells are stained red with eosin and living cells appear bright white under phase-contrast microscopy. In both tests, dead cells denote a positive reaction in which antibody and complement reacted. For example, if cells from a given individual are killed by antibodies against HLA-A2, the person is said to have A2.

An essential element in the micro cytotoxicity test is a drop of mineral oil which is placed in each well. This prevents the evaporation of the small quantities of reagents used. In addition, it allows for the repeated addition of reagents simply by 'injecting' them into the wells. These reagents automatically sink to the bottom and are resealed by the oil. In this way, it is not necessary to cap and uncapped the reaction 'vessel' for each new reagent.

DNA methods

DNA is extracted from nucleated cells, usually white blood cells, by phenolchloroform extraction or guanidine proteinase K precipitation followed by ethanol precipitation of DNA. One of the most common methods of identifying the HLA alleles is the sequence-specific oligonucleotide probe (SSOP) method. This consists of first amplifying all DNA common to a given HLA region, such as DR, by the

PCR reaction. Then, the reaction with various oligonucleotide probes is detected. Another common method is sequence specific primer (SSP), which consists of directly amplifying the specific HLA alleles and detecting them by gel electrophoresis or by a fluorescent dye.

The most accurate way of determining the alleles is by sequencing the nucleotides. Because of the expense, this method is usually only performed to type cells with questionable reactions and for standard reference typings.

The HLA antigens

The HLA antigens were established as a result of an unprecedented large-scale international effort over the past 25 years. Through 11 international Histocompatibility Workshops, hundreds of laboratories worldwide collaborated on defining the HLA antigens present in the human race. In the early stages, antisera discovered were shared among the laboratories to compare the reactions they produced in different populations. As the specificities became clearer, a World Health Organization nomenclature committee met after each workshop to assign internationally agreed names to each specificity. Over 300 laboratories have also collaborated in a monthly exercise of typing cells from unknown individuals for the purpose of assuring international standardization of test results.

The HLA specificities and alleles are listed in Table 1. Numbers given in parenthesis are the 'broad' specificities which include the narrower 'splits'. For example, A9 was the broad specificity first discovered. Two 'splits', A23 and A24, were later identified and included in A9. A23 and A24 are denoted as cross-reactive specificities of A9. This phenomenon, which was also discovered for many other specificities, is attributed to A23 and A24 molecules having a unique common site, A9.

Transplantation

Bone marrow transplants

HLA typing is essential to bone marrow transplantation. Most of the transplants performed are between HLA-identical siblings, which provides the highest rate of success. One-quarter of the siblings are HLA identical. Transplants are not all successful, in that graft-versus-host reactions often occur even with HLA-identical sibling donor grafts due to incompatibility for minor histocompatibility antigens. Recurrence of leukemia is also often a problem.

In recent years, volunteer bone marrow donor

banks have been established throughout the world. The National Donor Program (NMDP) in the USA has two million donors registered and pretyped for HLA class I types. Similar but smaller registries have been formed, including those in England, Europe, Australia, Taiwan and Japan. Because of the high polymorphism of the HLA system, these large registries are necessary to enable most patients requiring a bone marrow transplant to find a compatible donor. To date, over 4000 bone marrow transplants have been performed from unrelated donors using the NMDP.

Although serologic typing is usually sufficient for identifying an HLA identical sibling within a family, DNA typing is an important means of assuring the most accurate typing and matching for unrelated donors.

Kidney and other solid organ transplants

Over 3000 kidneys have been shipped among transplant centers throughout the USA in order to provide transplants with zero HLA-A, -B and -DR specificity mismatch. Such matched grafts were shown to have an 88% 1-year graft survival and a 15-year half-life. In comparison, mismatched transplants had an 80% graft survival with 8-year half-life. Thus, due to this nationwide sharing of kidneys, a group of patients with outstanding graft survival now exist. Again because of the high polymorphism of HLA, only about 10% of the 30 000 patients waiting on dialysis in the USA were able to obtain such well-matched grafts. The matching was performed by serological methods. If matching were done for all the known specificities by DNA typing, the number of zero A, B, DR mismatched transplants would probably be less than 1%. Thus, not all the known specificities can be utilized on a practical level for selecting cadaver donors for kidney transplants.

A similar effect is expected for heart, liver and pancreas transplants once it is possible to share these organs on a large scale. Currently, heart and liver patients cannot be maintained for long periods of time on artificial support, although there have been considerable advances in cardiac assist devices. Also, the maximum cold ischemia times for these organs are shorter than for kidneys, thus making them more difficult to ship.

Disease association

It has been shown that the HLA is associated with susceptibility to disease. The most useful marker has proved to be the association of HLA-B27 with ankylosing spondylitis. Other disease associations are important for basic studies of the disease but, in

practice, none has sufficiently high relative risk to provide clinical utility. Certainly, HLA has been useful for genetic counseling in diseases such as juvenile diabetes, idiopathic hemochromatosis and 21-hydroxylase deficiency.

Studies on the immune response

It is generally assumed that the extremely diverse HLA system evolved in response to the increasing variety of microorganisms against which an immune response is required. Extensive studies are underway to define the peptides which 'fit' into the groove of the HLA molecule. Certain peptides are shown to fit into the groove of certain HLA alleles but not others. This contact is thought to be a critical step in the immune response, accounting for the fact that some individuals in one species are resistant to a microbe while others are not. Even the response to cancer antigens is thought to be controlled by the HLA specificity present in the patient.

Anthropological studies

Because of the extensive polymorphism of HLA, the system is a powerful tool for anthropological studies. A major survey of world distribution was made in 1972 at the Fifth International Histocompatibility Workshop. A similar survey with many more populations and with about four times the number of markers was completed in 1991 as part of the Eleventh International Histocompatibility Workshop. In the Twelfth Workshop of 1996, DNA-based alleles were first used in anthropological studies.

New DNA typing methods have increased the power of HLA in anthropological studies. The samples can be stored and studied more carefully by DNA typing because viable cells are not necessary. HLA-A2, for example, which is the most 'successful' HLA allele, in that it is most prevalent in the world, exists in 17 variants which Parham has shown to have a characteristic distribution. Eventually the frequencies of all HLA alleles throughout the world will be established. The occurrence of point mutations and the spread of gene conversions through migration for each HLA allele can be followed.

T LYMPHOCYTE ACTIVATION

Stephen G Ward, Department of Pharmacology, School of Pharmacy and Pharmacology, University of Bath, Bath, UK

Carl H June, Immune Cell Biology Program, Naval Medical Research Institute, Bethesda, Maryland, USA

T cells, unlike B cells, do not recognize antigens by themselves and instead require an antigen-presenting cell for T cell activation. Thus, the T cell has developed a more complex receptor for antigen recognition and activation. Significant progress continues to be made in understanding the cascades of biochemical events that occur during the first few seconds, minutes and hours of T cell activation. These biochemical signals culminate about 24 h later in the initiation of DNA synthesis and, soon thereafter, in cell division. The events of this period can be divided, conceptually, into three temporal phases: activation, proliferation and differentiation. The activation phase begins with the stimulation of the T cell receptor by cognate antigen and ends with the secretion of interleukin 2 (IL-2), an autocrine growth factor for T cells. The second, or proliferative phase, encompasses the replication of the cellular DNA, and the creation of a pair of daughter cells. The third, or differentiation phase, may require several rounds of proliferation before it is complete. The initial biochemical events involved in T cell activation are the focus of this entry.

The activation phase, during which T cells change

from quiescent (G_0) cells to blast transformed (G_1) cells, is a complex cell process. More than 70 genes are newly expressed during the first 4 h of T cell activation. To put the cascade of events leading to the secretion IL-2 into perspective, the activation period encompasses the initiation of several parallel, temporally staggered programs, each of which is an important part of the preparation for cell division. These programs include turning-on of the secretory, translational and transcriptional machinery or acceleration of their rate of product generation.

Binding of the T cell receptor by antigen/MHC is necessary but insufficient for optimal activation

T cell activation requires interactions between multiple T cell surface structures and their respective ligands on antigen-presenting cells. Among these surface structures are the specifically rearranged heterodimeric T cell receptor, T_i , and its associated invariant complex, CD3. Discovered in 1983, this complex is referred to as the T cell antigen receptor (TCR) and is comprised of eight protein chains. Under physiologic conditions the binding of antigen/MHC (major histocompatibility complex) to the TCR is necessary, but this interaction is insufficient to result in T cell proliferation. Instead, the induced coassociation of a number of accessory receptors, among them CD4 or CD8, and CD45 is required for immediate signaling events. Yet another set of sur-

face structures appears to enhance T cell adhesion to the antigen-presenting cell, to amplify TCR-stimulated signal transduction, and may ensure the ability of the T cell to respond flexibly to antigen presented by different types of antigen-presenting cells.

The transduced signal

Protein tyrosine kinases and phosphatases

The principal structural unit that regulates coupling of the TCR to downstream signal transduction is termed the immunoreceptor tyrosine-based activation motif (ITAM) or alternatively, antigen recognition activation motif (ARAM) (Figure 1). Each ITAM consists of two YXXL/I repeats separated by 6–8 residues. There are one each in the cytoplasmic domains of CD3 γ , δ , ϵ and three in the TCR ζ chain (ζ 1, ζ 2 and ζ 3). Since each TCR can contain a TCR ζ dimer and two CD3 dimers ($\epsilon\delta$ and $\epsilon\gamma$), each TCR can contain a total of 10 ITAMS. This is many more than are present in other lymphocytes such as B cells, natural killer (NK) cells and mast cells. The first biochemical event that has been measured following the triggering of the human T cell receptor is the activation of protein tyrosine kinases (PTKs), enzymes that phosphorylate tyrosine residues in proteins. This is observed as an increase in the phosphate content of several tyrosine-containing proteins and occurs within 5 s of stimulation of the TCR. At least three families of PTKs are associated with the TCR. Two

of these kinases, p59^{fyn}, and p56^{lck}, are members of the Src family of nonreceptor protein tyrosine kinases. p59^{fyn} is associated with the TCR while p56^{lck} is also associated with CD4 and CD8, CD28 and the IL-2 receptor. A third kinase, ZAP-70 is a member of a distinct kinase family that also includes the Syk kinase expressed primarily in B cells. ITK, a member of still another family of PTKs is also associated with the TCR via poorly defined mechanisms. The fact that the proteins ZAP-70, Lck, Fyn and ITK exist as T cell-specific kinases underscores their central importance in T cell activation. A primary function of the Src family kinases is to phosphorylate key tyrosine residues within ITAMs. Recent work has suggested that at least two such tyrosine phosphorylated proteins may be the proto-oncogene Vav and the newly cloned SLP-76 which are expressed exclusively in hematopoietic cells and are both readily tyrosine phosphorylated in response to TCR ligation. Deletion of Vav leads to defective antigen receptor-mediated proliferation of mouse B and T cells. Other nonreceptor substrates of these PTKs are still being elucidated, and several are indicated in Figure 2.

In other systems, such as the metabolic cascade that results in the synthesis of glycogen and the concomitant inhibition of glycogenolysis, the action of kinases is opposed by specific phosphatases. In T lymphocytes, the tyrosine phosphatase CD45 and the serine/threonine phosphatase calcineurin have been identified as having important roles in TCR signal transduction. CD45 is an integral membrane protein tyrosine phosphatase that plays a critical, although apparently nonessential role in T cell activation, since T cells from mice with a genetically engineered absence of CD45 can still be activated. There is evidence to suggest that the phosphatase activity of CD45 is involved in the activation of the TCR-associated PTKs. It is thus possible that the CD45 tyrosine phosphatase is required to maintain activation of both the TCR and/or CD4-associated kinases. It is now recognized that downstream of the T cell receptor and the initial activation of PTKs are at least three essential biochemical pathways that convey activation signals: 1) calcium pathways; 2) protein kinase C pathways; and 3) Ras pathways (Figure 2).

Figure 1 Immunoreceptor tyrosine-based activation motifs (ITAMs) are expressed in T and B cell antigen receptors, the mast cell receptor for IgE, and in the viral glycoproteins of bovine leukemia virus (BLV) and Epstein-Barr virus (EBV) latent membrane protein 2A.

The calcium pathway

The activation of the TCR-associated tyrosine kinases is followed within 15 s by the activation of another enzyme, phospholipase C (PLC), which may be activated by phosphorylation on tyrosine residues. Activation of PLC is accompanied by binding of a 36 kDa protein which may have a role as an adapter protein in localizing PLC to the cell membrane. PLC

Figure 2 Signaling complexes and pathways associated with the T cell antigen receptor (TCR). The eight chain TCR and the CD4 and CD45 coreceptors are shown with associated kinases Ick, fyn and ZAP-70. There are 10 ITAM motifs encoded in the TCR subunits. Tyrosine kinase activation results in the phosphorylation of a number of substrates, including phospholipase C (PLC). Activation of PLC results in increased calcium concentration and protein kinase C (PKC) activity. Tyrosine kinase activation also leads to activation of Ras via several mechanisms. mSOS, mammalian Son of Sevenless; GRB-2, growth factor receptor-bound protein 2; IP3R, inositol triphosphate receptor; SHP-1, SH2-containing tyrosine phosphatase 1; pyK2, proline-rich tyrosine kinase 2.

cleaves a membrane phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP_2) into a cyclitol polyphosphate, inositol, 1,4,5-triphosphate (IP_3) and a diacylglycerol, (DAG). Both of these enzymatic products function in the subsequent steps of the signal transduction cascade. IP_3 is the ligand which operates a receptor, located in the endoplasmic reticulum and plasma membrane, to release a nonmitochondrial, ATP-dependent store of ionized calcium. In some T cells, the IP_3 receptor is a substrate of the TCR-associated p59^{fyn} tyrosine kinase. As a result of the actions of IP_3 the concentration of intracellular calcium ion rises briefly from resting levels of $0.1 \mu\text{M}$ to $0.5 \mu\text{M}$ or higher. Calcium activates the serine/threonine phosphatase calcineurin. One target of calcineurin is NFATp, a transcription factor that has a role in IL-2 gene expression. Calcium has many roles in cellular homeostasis and cell activation, and it is clear that calcium-mediated signaling pathways that are both calcineurin dependent and independent, exist in T cells. Several reports have indicated that isolated cytosolic free calcium elevations in T cells tend to provoke apoptosis or anergy. This can occur by apparently independent mechanisms involving alterations of TCR signaling, by the

absence of costimulatory signaling or by treatment of cells with calcium ionophore.

The PKC pathway

DAG, the other product of PLC activation, along with cofactors such as Ca^{2+} and phospholipids, activates protein kinase C (PKC), a family of serine/threonine kinases that phosphorylate a number of substrates, initiating the PKC pathway. PKC has been implicated in the control of many signaling pathways, including p21^{ras} and the MAP kinases such as ERK, and c-JUN N-terminal kinases (JNK-1/2). The role of specific PKC isozymes is poorly understood, although $\text{PKC}\epsilon$ and $\text{PKC}\theta$ can regulate the transcription factors AP-1 and NFAT in leukemic T cells, and a recent study indicates that $\text{PKC}\theta$ may have a special role during antigen activation of T cells. Phorbol esters activate many forms of PKC, however it is now clear that many effects of phorbol esters on T cells that were previously attributed to PKC are in fact Ras mediated. *In vitro* studies have shown that the PKC isozymes δ , ϵ , η , λ and ζ are activated by D-3 phosphoinositide lipids. $\text{PKC}\zeta$ has also been suggested as a direct target for ceramide

and thus may play a critical role in sphingomyelinase signaling.

Ras pathways

The 21 kDa guanine nucleotide-binding Ras protein (p21^{ras}) family has been implicated in TCR signaling. Triggering of the TCR perturbs the guanine nucleotide-binding cycle of p21^{ras} and results in the rapid and prolonged accumulation of active p21^{ras}-GTP complexes. The coupling of the TCR to p21^{ras} activation occurs via a PTK-dependent mechanism. The level of active p21^{ras}-GTP complexes is determined by a balance of the rate of hydrolysis of bound GTP and the rate of exchange of bound GDP for cytosolic GTP. The importance of Ras activation in T cell signal transduction has been demonstrated most clearly in studies using mutant forms of the Ras protein that are either dominantly negative or constitutively active. Transfection of a dominant negative Ras inhibited the induction of transcriptional events including the induction of the IL-2 gene and induction of the nuclear factor NFAT. In contrast, transfection of the constitutively active Ras could, in conjunction with a calcium signal, induce NFAT and IL-2 gene transcription. There are both positive and negative regulators of p21^{ras} activity: the GTPase-activating proteins (GAPs) such as p120-GAP can increase the intrinsic GTPase activity of p21^{ras} leading to inactivation, whereas the Cdc25-like homologs help in the dissociation of GDP leading to p21^{ras} activation. The inhibition of Ras-GAP proteins is almost certainly one mechanism used by the TCR to regulate the Ras guanine nucleotide-binding cycle.

Role of adapter molecules in TCR coupling to p21^{ras}

In a variety of cell types many receptors regulate p21^{ras} by stimulating the guanine nucleotide exchange protein SOS, which is associated with the adapter protein GRB-2 (Figure 2). GRB-2 is composed of two SH3 domains that bind to a guanine nucleotide exchange protein that activates p21^{ras}, and an SH2 domain that interacts with tyrosine phosphoproteins that regulate cell localization/function of this p21^{ras}-exchange protein. In T cells, at least two tyrosine phosphoproteins can potentially interact with GRB-2 SH2 domains, namely SHC and the membrane-located tyrosine phosphoprotein p36, which may be related to the Lnk protein recently cloned from rat lymph node. Indeed, the major tyrosine phosphoprotein to associate with GRB-2 SH2 domains in TCR-activated cells is a 36 kDa molecule (p36). In TCR-activated T cells, both SHC and p36

are tyrosine phosphorylated and *in vitro* can be shown to bind GRB-2 SH2 domains. SHC has an SH2 domain that can bind to the tyrosine phosphorylated TCR ζ chain, hence tyrosine phosphorylated SHC could potentially recruit GRB-2 and SOS to the TCR complex in activated cells. However, reports disagree about the formation of SHC-GRB-2-SOS complexes after TCR ligation, having only been demonstrated in murine T cell hybridomas but not TCR-activated peripheral blood derived T cells. This illustrates that there may be considerable heterogeneity of TCR responses in different cell types. In addition, it appears that the SHC interaction with TCR ζ chains is of relatively low affinity as compared with the binding of tyrosine kinases such as ZAP-70 or p59^{lyn}. This may ensure that SHC interaction with ζ is transient and only sufficient to bring SHC to the TCR complex where it can be tyrosine phosphorylated, but is insufficient for the formation of stable TCR-SHC complexes. The formation of p36-GRB-2-SOS complexes is a rapid response to TCR ligation that correlates well with p21^{ras} regulation. The failure to find tyrosine-phosphorylated SHC binding to GRB-2 and SOS in TCR-activated cells may be due to competition between p36 and SHC for the SH2 domain of GRB-2.

In addition to GRB-2, it is clear that there are several other adapter molecules that may be involved in coupling the TCR to the p21^{ras} pathway. For instance, T cells express another protein termed C3G which can catalyze guanine nucleotide exchange on p21^{ras} and which binds to the SH3 domains of the adapter molecule CRK. Three forms of CRK are found in T cells and CRK has a single SH2 domain and one or two SH3 domains. TCR triggering results in tyrosine phosphorylation of CRK-binding proteins such as a Cbl, analogous to the TCR regulation of GRB-2 binding complexes. A constitutively active Cbl mutant has been demonstrated to stimulate Ras-dependent and calcium-stimulated activation of NFAT. In fact, there is evidence that GRB-2 is constitutively associated with Cbl regardless of the activation of Jurkat cells. Another report has demonstrated that TCR ligation stimulates tyrosine phosphorylation of Cbl which correlates with the dissociation of the GRB-2-Cbl complex and the formation of CRK-Cbl complexes via the CRK SH2 domain. The reasons for the redundancy in the coupling of the TCR to p21^{ras} remain unclear. One possibility is that these multiple mechanisms provide several contingency routes in the event of malfunction of one or more of these mechanisms. A leading alternative hypothesis is that subtle differences exist in the pathways downstream of Ras.

Role of PKC in p21^{ras} activation

There is an alternative p21^{ras} pathway activation mediated by PKC which, unlike Ras expression, is not ubiquitous but is restricted to T lymphocytes. Hence, phorbol esters inhibit GAP activity in T lymphocytes allowing GTP to remain bound to p21^{ras}, biasing the GTP/GDP balance on p21^{ras} toward GTP. This suggested role for PKC in the activation of p21^{ras} is not involved in mediating TCR-driven p21^{ras} activation which is entirely PTK dependent. It is possible that there is a PKC-sensitive, T lymphocyte-specific Ras exchange protein and one candidate molecule is the proto-oncogene Vav which is expressed only in hematopoietic cells. This protein possesses a region homologous to guanine nucleotide-releasing factors such as yeast Cdc24 or rodent Cdc25Mn. Vav is rapidly tyrosine phosphorylated upon CD3 ligation, but Vav cannot explain the apparent lymphoid specificity of the PKC–p21^{ras} link because Vav is expressed in all hematopoietic cells and mast cells or myeloid cells that do express Vav do not express a PKC-mediated route for p21^{ras} regulation. Moreover, the role of Vav as a Ras guanine nucleotide exchange protein is controversial and structurally Vav is a more likely candidate for an exchange protein for the Ras-related Rho/Rac proteins.

The MAP/ERK pathways

The best-defined signaling cascade initiated by Ras in T cells is the activation of the extracellular signal-regulated kinases (ERKs) which are members of a family of mitogen-activated kinases (MAPKs) (Figure 3). MAPKs are a group of protein serine/threonine kinases that have been termed 'dual specificity kinases' because they are activated by phosphorylation on conserved threonine and tyrosine residues. T cells express ERK-1 and ERK-2, both of which are activated in response to TCR ligation. Two intracellular pathways for ERK-2 regulation coexist in T cells: one mediated by Ras and the other by PKC. The TCR activates both p21^{ras} and PKC but p21^{ras} and not PKC couples the TCR to the regulation of MAP kinases. Activation of ERKs is achieved by a kinase cascade which is regulated by a balance of specific kinase and phosphatase activity (Figure 3). An MAP kinase kinase (MEK or MKK-1) phosphorylates on both tyrosine and threonine residues and stimulates the ERK-1 and -2 kinases directly. MEK activity is itself controlled by phosphorylation and hence an MAP kinase kinase (MEKK) plays a crucial role in the regulation of ERK-1 and -2. The serine/threonine kinase Raf-1 has been identified as an MEKK and the

Figure 3 Mitogen-activated protein kinase (MAPK) pathways serve as a major cascade to connect cell surface receptors to specific transcription factors. Signals from the TCR are sufficient to activate the Ras pathway, leading to ERK activation. In contrast, costimulatory signals are required for activation of JNK, and perhaps the p38 kinase. ERK, extracellular signal-regulated kinase; HPK1, hematopoietic progenitor kinase 1; PAK, p21-activated kinase; JNK, c-JUN N-terminal kinase; SAPK, stress-activated protein kinase; ATF2, activated transcription factor 2; MEF2C, myocyte enhancer factor 2C.

N-terminal regulatory domain of Raf-1 can interact directly with activated GTP-bound p21^{ras}. The role of Ras may be to recruit Raf-1 to the membrane where it is activated. In T cells, several observations collectively indicate that Raf-1 is one effector molecule for p21^{ras}: 1) constitutively active Raf-1 can mimic the effect of activated Ras and synergize with calcium signals to induce the IL-2 gene; 2) activated Raf-1 can also mimic the TCR and stimulate ERK-2; 3) a dominant negative Raf-1 prevents TCR stimulation of ERK-2.

ERK-2 is reported to regulate the Elk1 transcription factor and AP-1 activity. Phosphorylation of Elk1 by ERK appears necessary for the induction of the *c-fos* gene. Accordingly, the role of Ras in coupling the TCR to ERK-2 and the ability of ERK-2 to translocate to the nucleus where it can directly modulate transcriptional factors could explain the role of p21^{ras} in TCR signal transduction. Fos proteins are components of the AP-1 complex that is clearly important for NFAT activity and cytokine gene induction. However, not all RAS functions are mediated by the MAP kinase ERK-1/2 cascade. For example, in transgenic mice experiments, a dominant negative MKK can mimic inhibitory p21^{ras} mutants and suppress positive selection of thymocytes. However, inhibitory Ras mutants prevent TCR-induced proliferation of thymocytes, whereas an inhibitory MKK mutant does not. Also, in transfected T cell lines, expression of a dominant negative MKK can abrogate NFAT induction analogous to the effects of dominant negative Ras, but expression of a constitutively active MKK cannot substitute for constitutively

acute Ras and induce AP-1 or synergize with calcium dependent signals to induce NFAT.

Two additional MAP kinase signaling pathways have been characterized which allow parallel regulation of the kinases JNK-1/2 and p38 MAPK. These pathways appear to mediate cell survival or death in response to some forms of receptor activation. The role of the p38 MAPK in T cell activation remains unclear, although regulation of the JUN kinases 1 and 2 has been reported to be a point of convergence for the TCR and costimulatory CD28 signaling pathways. JNK-1/2 are activated by dual phosphorylation on threonine and tyrosine by SEK, a kinase homologous to MEK in the MAPK pathway. SEK is itself regulated by a serine/threonine kinase termed MEKK forming a cascade analogous to, but distinct from, that which links Raf-1 and MAPK. SEK conveys survival signals as studies with cells with genetically deleted SEK indicate that it protects thymocytes and T cells from TCR- and Fas-induced apoptosis. The activation of JNK-1 in T cells seems to require calcium/calcineurin signals, CD28 signals and other TCR-derived signals.

Costimulatory signals

Induction of cell cycle progression requires the sustained activation of PTKs, PLC and the Ras pathway. The affinity of peptide/MHC ligand to TCR, and especially the off rate, has important consequences for the nature and duration of the transduced signal, as does the receipt of one or more costimulatory signals delivered by the interaction between accessory receptors on the T cell and the antigen-presenting cell. Among the most well-studied of these accessory receptors are CD2, CD4/8, CD28 and CD152 (CTLA4).

CD2 is a single-chain glycoprotein of 47–55 kDa that is expressed on thymocytes, all T cells and on large granular lymphocytes. It plays roles in T lymphocyte adhesion and in signal transduction. A physiologic ligand for the CD2 receptor is CD58 (LFA-3), a glycoprotein found on the surface of many hematopoietic and nonhematopoietic cells. Select pairs of monoclonal antibodies to CD2 have been shown to be capable of activating PTKs and PLC, and of inducing a proliferative response, suggesting either that CD2 might be an antigen-independent signal transduction molecule, or that CD2 amplifies the TCR-mediated signal. In mice, injections of CD2 antibody induce a state of antigen unresponsiveness.

CD4 and CD8 function in MHC-restricted antigen presentation by binding to invariant regions of the MHC molecules. CD4 and CD8 transmit signals important for T cell activation and growth via the

associated protein tyrosine kinase, p56^{lck}. These coreceptor molecules provide an essential contribution for the TCR supramolecular complex (Figure 2). Recent studies suggest that the efficiency of CD4 recruitment to the TCR is a key factor in determining whether peptide–MHC complexes will display agonistic or antagonistic functions for CD4 cells.

The CD28 receptor family is the best understood of the costimulatory T cell receptors. CD28 is a 44 kDa homodimer and a member of the immunoglobulin gene family. It is an example of a heterophilic cell adhesion complex, in which its cognate receptors are the ligands CD80 (B7-1) and CD86 (B7-2). CD28 appears to regulate a signal transduction pathway that is distinct from the TCR in some aspects and has a major role in the induction of cytokine secretion and the expression of the cell survival gene Bcl-x_L. The CD28 cytoplasmic tail has no obvious enzymatic activity and unlike the TCR, it does not encode for ITAM motifs. The intracellular domain of CD28 does encode a (p)YXXM binding motif that can bind to the p85 regulatory subunit of phosphatidylinositol 3-kinase. It may be of clinical importance that CD28 signal transduction is resistant to a number of immunosuppressive agents. CD152 (CTLA4) is related to CD28 and shares the same ligands, CD80 and CD86. However, the signal transduction pathways used by CTLA4 appear to be distinct from CD28 and to primarily induce downregulation of T cell activation. *In vivo*, it is likely that CTLA4 has a major role in maintaining tolerance to self antigens.

CD154 (CD40L) is a type II membrane protein that is expressed on T cells. CD40L is not constitutively expressed on T cells and expression is induced by TCR signals, and in some cases, by costimulatory signals. It appears that CD40L has a role as a master regulator of the immune system for both humoral and cellular immunity. The role of CD40L is to signal antigen-presenting cells. This occurs by ligation of CD40 on antigen-presenting cells and precedes upregulation of the CD28 ligands CD80/CD86 on the antigen-presenting cell.

Anergic, agonistic and antagonistic signal transduction

T cells activated by the TCR in the absence of costimulation signals lose the capacity to secrete interleukin 2, a state called clonal anergy. Anergy induction appears to involve the calcium/calcineurin pathway as it is blocked by cyclosporine and can be partially mimicked by the calcium ionophore ionomycin. Analysis of CD3- and CD28-induced signal transduction has revealed that p21^{ras} remained unac-

tivated and found reduced ERK and JNK enzyme activities in murine anergic T cells. Thus a block in Ras activation may lead to defective transactivation of AP-1 sites in anergic cells and may enable T cells to shut down IL-2 production selectively during anergy.

Initial predictions were that the TCR would function as a simple 'on-off' switch for the T cell. Recent studies have indicated that T cell activation is not an all-or-none event, but rather involves a spectrum of biochemical events depending on the precise structure of the peptide-MHC ligand. Altered peptide ligands are analogs of immunogenic peptides in which the TCR contact sites have been substituted. These analogs may have agonistic, partial agonistic or antagonistic effects on T cells. Altered patterns of tyrosine substrate phosphorylation and selective activation of the calcium-signaling pathway are induced by altered peptide ligands. The mechanistic basis for altered ligand signaling remains unknown. The simplest notion to resolve the marked differences in cellular outcome between antigen ligands of differing affinity is to propose a time lag for the full assembly of the TCR signaling complex. Thus, the dissociation rate of the ligand from the TCR most likely determines whether antigen recognition will result in partial or full cellular activation. McKeithan has proposed a kinetic model of TCR signaling in which the complexity inherent in the TCR pathways serves to permit TCRs to finely discriminate between ligands. Some partial peptide agonists induce a state of T cell anergy while others induce altered patterns of cytokine secretion and fail to induce T cell proliferation. It is likely that signal transduction induced by altered peptide ligands has substantial physiologic importance as the pool of altered ligands *in vivo* is likely very large compared with the number of specific ligands that have selected the T cell repertoire.

T LYMPHOCYTE CLONAL EXPANSION

The most remarkable feature of the immune system is its ability to respond specifically to a potentially vast number of foreign pathogens. How can such a diverse repertoire of potential responses be generated and maintained in an organism? In 1957, Burnet and his colleagues proposed the clonal selection hypothesis, suggesting that individuals generate a multitude of lymphocytes that each can recognize and respond to a distinct antigenic determinant. If an antigen derived from a pathogen activates one of these pre-existing clones, only then does that cell proliferate to a high frequency (a clonal expansion). Then this expanded clone can efficiently eliminate the pathogen.

This theory has largely been proven for T lymphocytes and accepted as a cornerstone of immunology. When antigen is presented to a unique naive T lymphocyte with appropriate costimulatory signals, the T cell will rapidly proliferate and differentiate into an effector cell population. In addition, it is now known that the immune system tightly regulates both the extent of clonal expansion, as well as the functional activity of the differentiated T cell population.

Naive T cell expansion

T cells first mature in the thymus, and then emerge as CD4⁺ or CD8⁺ naive lymphocytes. The ability of these mature T lymphocytes to respond to a pathogen is dependent on the expression of a heterodimeric T cell antigen receptor (TCR). During their development in the thymus, TCR α and β genes each undergo an ordered and specific DNA recombination event that results in the generation of a unique TCR on each T cell. This enables each T cell to recognize only a specific antigenic peptide bound in the groove of a major histocompatibility complex (MHC) molecule which is expressed on the surface of an antigen-presenting cell (APC).

An immune response is initiated when a naive T cell recognizes and responds to a peptide bound to the MHC molecules of an APC within lymphoid tissue. Naive T cells express the homing receptor L-selectin enabling them to circulate between the blood, spleen and peripheral lymph nodes. Antigenic peptide derived from a pathogen enters the lymphoid tissue either through afferent lymph or via APC migration. Within the periarteriolar lymphoid sheaths of the spleen or paracortex of the lymph

node, naive T cells interacting with antigen and APC are induced to secrete the autocrine growth factor interleukin 2 (IL-2), resulting in a rapid expansion. The extent and duration of this expansion depends on both antigen dose, and on the affinity of the TCR for the peptide/MHC complex. The frequency of a naive clone of any given specificity is approximately 1 in 10⁶–10⁸, and expansions of 1200-fold over 6 days have been observed in the primary response *in vivo* (Figure 1).

To be fully activated, naive lymphocytes must receive costimulatory signals from the APC in addition to TCR ligation. These costimulatory signals result largely from the interaction of the CD28 molecule on the T cell and a B7 counter-receptor (B7-1 or B7-2) on the APC. The insult of infection induces APCs to express high levels of B7, and B7-derived costimulatory signals allow the presented peptides to be immunogenic. CD28 signaling in naive T cells promotes IL-2 production by enhancing both the activity of transcription factors (e.g. AP-1, NF κ B) at the IL-2 promoter and by increasing the stability of the IL-2 mRNA. This CD28 signal transduction remains poorly understood; however, it appears to be biochemically distinct from TCR signaling and may involve phosphatidylinositol 3-kinase, as well as the Jun N-terminal kinase (JNK).

Effector cell generation

During the course of a primary immune response, most antigen-stimulated T cells differentiate into an effector cell phenotype. Unlike naive cells that only produce IL-2, differentiated T cells develop the capacity to produce effector cytokines such as IL-4, IL-5 and/or interferon γ (IFN γ). The type of APC, the amount of antigen available, the affinity of the TCR for the antigen, and the lymphokine milieu all influence the T cell's subsequent cytokine production profile. Two principal effector phenotypes have been observed in both human and murine CD4⁺ cells (T_H1 or T_H2). T_H1 cells produce mostly IL-2 and IFN γ and are important in cell-mediated immunity by helping, for example, in both the differentiation and expansion of cytolytic precursors (CD8⁺) and in the generation of delayed-type hypersensitivity responses. In the presence of IFN γ and IL-12 (but in the absence of IL-4) differentiating lymphocytes tend to become T_H1 cells. On the other hand, T_H2 cell

Figure 1 CD4⁺ T cell activation, expansion and differentiation that occurs during primary and secondary immune responses. The graph indicates the relative numbers of T cells that occur at each of the stages represented in the cartoon above. After exposure to the antigen and costimulatory signals, the cells first undergo differentiation to the TH1 or TH2 phenotype influenced by the cytokines IL-4, IFN γ , or IL-12. The cells continue to rapidly expand during the first generation of effector cells. Most of the effector cells then undergo an activation-induced cell death that appears to be mediated by the Fas and FasL molecules. A few T cells survive and are considered the memory cells and thought to be long-lived. The secondary response demonstrates many of the same properties of the primary response except that the T cells expand more quickly after exposure to antigen and costimulation and the peak expansion occurs more quickly as well.

development is enhanced by IL-4, and these cells produce IL-4 and IL-5 and are potent helpers for antibody production. CD8⁺ helper cells have also been found to fall into the same pattern of cytokine production after differentiation (TC1 or TC2 cells).

These differentiated T cells continue to expand when exposed to antigen, and this effector population then carries out its function to eliminate the antigen/pathogen. At the end of the primary T cell immune response there is tremendous cell death. Many studies *in vivo* indicate that the majority of

these effector cells exist for as few as 5 days. Nevertheless, it is clear that there remains a significant population of long-lived 'memory' cells following the response. These cells lack L-selectin and spend little time in the lymphoid structures. As a result of upregulation of integrin adhesion molecules (e.g. LFA-1, VLA-4) on their surface, they quickly leave the circulation and percolate through the parenchymal tissues to provide surveillance against infection.

Compared to the primary response, memory cells expand more rapidly upon activation and also reach

their peak expansion much more quickly. This allows for a more robust immune response following a second exposure to antigen. This gain of function is for two reasons: 1) the antigen-specific memory clone has an increased frequency within the lymphocyte repertoire (up to 30–40-fold) even after the contraction of the effector population; 2) these cells have enhanced responsiveness to APC due to increased expression of adhesion molecules and growth factor receptors.

Like naive cells, T_H1 - and T_H2 -type memory cells require costimulation for proliferation and may depend on it for continued survival. CD28 costimulation upregulates the expression of the death repressor Bcl- x_L , a molecule that enhances the cell's resistance to apoptosis. T_H1 cells also require CD28 signaling for maximum IL-2 production, whereas costimulation allows T_H2 cells to respond and proliferate better to their autocrine growth factor, IL-4. In contrast, costimulation does not appear as important for the effector functions of these highly differentiated cells, such as cytotoxicity, or IFN γ secretion. This may be important to allow them to target pathogen-infected cells that do not express any costimulatory ligands.

Negative regulation of expansion

Effector cells exist at high frequency only transiently during an immune response. Once the antigen/pathogen has been cleared (or in the event that it cannot be cleared), effector cells eventually stop proliferating and die. This negative regulation may prevent exceedingly strong and persistent immune responses that could be damaging to the host. In addition, the apoptosis of no-longer-needed effector cells may prevent the buildup of T cells that could dilute out naive responders and take up valuable space in the immune system.

The CTLA4 molecule appears to play a critical role in this negative regulation of clonal expansion. Unlike CD28, this receptor for B7 has been found to exert a negative effect on lymphocyte proliferation. CTLA4 expression is delayed following activation, corresponding to the time when the immune system begins to limit further lymphocyte expansion. Remarkably, CTLA4 homozygous-mutant mice (that do not express this molecule on their T cells) are found to have both an expansion of T lymphocytes and lymphoproliferative disease. Thus, ligation of CTLA4 by B7 may serve as an important control mechanism in limiting immune responses.

The principal mechanism for the eventual clearance of effector cells appears to be an activation-induced cell death (AICD). Persistent TCR signaling

causes effector T cells to slowly upregulate the death receptor Fas and its counter-receptor Fas-ligand (FasL). This expression results in death of the T cell and other Fas⁺ cells, as Fas signaling triggers apoptosis. Interestingly, the mutant mouse strains *lpr/lpr* and *gld/gld* have defective Fas and FasL, respectively, and their effector lymphocytes are resistant to AICD. This results in the accumulation of lymphocytes in these strains, which in turn appears to cause autoimmune disease. Thus, AICD may be essential to control the expansion of potentially deleterious effector cells.

Prevention of expansion

Although negative selection of T cell precursors in the thymus is effective in eliminating cells with strong reactivity to self antigens expressed in the thymus, not all self antigens are expressed there, and some are expressed only at later times in an individual's life (e.g. the human chorionic gonadotropin protein in pregnancy). Therefore, the immune system needs mechanisms to prevent expansion of potentially deleterious T cells that are responsive to these self antigens.

Like naive cells, memory cells that receive only the TCR signal without costimulation (CD28) fail to proliferate. More importantly, these cells can be induced into a functionally unresponsive state called clonal anergy, as a result of the stimulation. Anergic T cells are incapable of proliferating in response to antigen unless they are also exposed to an exogenous growth factor (IL-2). Proliferative anergy in T_H1 -like cells is caused by a defect in the production of IL-2. In mouse helper T cells, this appears to be related to poor activation of the AP-1 enhancer sequences within the IL-2 promoter. Recent studies further suggest that clonal anergy blocks Ras-dependent signaling through the extracellular signal-regulated kinase (ERK) and JNK protein kinases, preventing the induction of an AP-1 response. Anergic T_H2 cells, on the other hand, still produce their autocrine growth factor IL-4; however they are unable to grow in response to it. Finally, the failure to produce growth factors or respond to them probably reduces the capacity of anergic T cells to resist apoptosis, leading in some cases to the physical elimination of deleterious clones (Figure 2).

Clonal anergy may occur *in vivo* when a clone specific for a pathogen is also cross-reactive with a self antigen, so that after the pathogen is cleared, the immune system turns off the clone (anergy) perhaps until it may be needed again. Most nonhematopoietic tissues do not express costimulatory molecules even though they may be induced to express MHC mol-

Figure 2 This model illustrates intracellular signaling pathways during T cell activation. T cell receptor (TCR) interacts with peptide on the MHC molecule of the antigen presenting cell (APC) to initiate signaling. Costimulator signals arise from CD28 on the T cell interacting with its counter-receptor B7 on the APC. These signals in the naive T cell result in production of the growth factor interleukin 2 (IL-2). Arrows indicate direction of activation signals, and gray-shaded areas are molecules that have been reported to be defective in anergic T_H1 T cells. TCR signaling involves the following molecules: ζ chain of CD3, phosphatidylinositol biphosphate (PIP_2), diacylglycerol (DAG), $p21^{ras}$, ZAP70, protein kinase C (PKC), Grb-2/son of sevenless (Sos), calcium ions, calcineurin, nuclear factor of activated T cells (NFATp), extracellular signal-regulated kinase (ERK), Jun-N-terminal kinase (JNK), Fos, Jun, AP-1 (heterodimer of Fos and Jun), nuclear factor- κ B (NF κ B). IL-2 upstream transcription sites include: NF-AT, OCT, κ B, CD28RE, AP-1, and OAP-OCT

ecules during an inflammatory response. Therefore, self antigens expressed on these tissues will tend to induce the anergic state.

Conclusion

The effector arm of the immune system is very dependent on the clonal expansion of T lymphocytes after their first interaction with antigen. It is through this clonal selection mechanism that the immune system is poised to respond to such a wide variety of foreign pathogens. Recent studies also demonstrate that the immune system tightly regulates the expansion of these clonal populations to prevent inappropriate responses. A better understanding of these regulatory mechanisms in the future should allow the immune response in human disease states to be modulated 1) to increase the kinetics or magnitude of the clonal expansion early during the course of infection, or 2) to blunt the growth and/or survival of harmful T cells responding against self peptides in the setting of autoimmune disease.

T LYMPHOCYTE DIFFERENTIATION

Ada M Kruisbeek, Division of Immunology, The Netherlands Cancer Institute, Amsterdam, The Netherlands

Two characteristic conditions distinguish the development of B lymphocytes from that of T lymphocytes. First, although both T and B cells develop from hematopoietic stem cells, B cells are generated in the bone marrow, while T cell differentiation occurs, at least early in ontogeny, most efficiently in the thymus. Although other prominent sites of T cell development have been described (most notably, the gut-associated epithelial tissues), intrathymic development is the focus of this review because much of our detailed knowledge of the many different stages T cells pass through before becoming an end-stage mature T cell has been acquired by studying that organ. The second feature that distinguishes T cells from B cells is determined by the distinct way in which T cells recognize antigens: B cells can recognize antigens in solution, while T cells can recognize foreign antigens only when they are presented, in the form of short peptides, by the body's own major histocompatibility complex (MHC) molecules. The thymus in fact has a dual role in establishing the particular features that distinguish T cells from B cells: it functions not only as a microenvironment supporting early T cell commitment steps, but also as a sieve which selects, out of the broad repertoire of randomly generated antigen receptors that developing T cells express, the ones with the appropriate MHC restriction specificity.

Many membrane proteins on T lymphocytes are involved in ultimately generating an immune response against the foreign antigenic peptides that are presented by the MHC molecules on the surface of antigen-presenting cells (APCs). These include many cell adhesion molecules and so-called costimulatory receptors, the coreceptors CD4 or CD8, and receptors for cytokines. It is, however, the clonally distributed T cell antigen receptor (TCR) which actually recognizes the antigenic peptides presented by a

given set of MHC molecules, and which therefore dictates the specificity of the response. This TCR forms a complex with nonpolymorphic membrane proteins (collectively referred to as CD3) which are noncovalently associated with the TCR and provide the TCR with signaling capacity. On most T cells, the TCR consists of two disulfide-linked chains (Figure 1) termed α and β , and cloning of the α and β genes revealed that generation of diversity among these chains is accomplished through a process of rearrangements of multiple variable (V) gene regions to diversity (D) and joining (J) segments associated with either one of two constant (C) region genes, in a process similar to that used during immunoglobulin gene rearrangements in developing B cells. A comparable type of TCR has been identified on small subsets of T cells: the chains composing this TCR are termed γ and δ , are also disulfide linked, generate diversity through rearrangements, are associated with the same set of nonpolymorphic CD3 proteins as the $\alpha\beta$ TCR, and can display similar effector functions upon TCR-mediated signaling as $\alpha\beta$ TCR-expressing T cells.

During the past 10 years, our understanding of the molecular mechanisms of T cell development has been dramatically increased through many key advances:

1. After the TCR α , β , γ and δ genes had been cloned, the order of appearance of TCR-gene rearrangements and transcription during thymic development could be determined, and from that information, studies on the regulation of these T cell lineage-determining events have been initiated.
2. Monoclonal antibodies (mAbs) against numerous T cell surface proteins represent another set of tools that proved invaluable: these allowed a detailed analysis of the order of appearance of

Figure 1 Models of the TCR (left) and pre-TCR (right).

surface structures critically involved in antigen recognition, cell adhesion and growth during development; this has resulted in the definition of an increasing number of intermediate differentiative stages amongst developing T cells (Table 1), with better prospects for gaining insights into the regulatory mechanisms a clear result.

- Once transgenic mice in which all T cells express the same TCR became available, direct visualization (by a combination of functional analysis and flow cytometry) of both the positive and the

negative selection process was achieved; also, transgenic introduction of model self antigens to specific sites, through the use of suitable regulatory elements, has allowed a better definition of the many different ways in which self tolerance can be acquired in the immune system.

- Perhaps the greatest contribution to our understanding of T cell development has been made by the application of gene-targeting experiments; molecules critically involved in defined T cell differentiative stages have been identified by

Table 1 Stages of intrathymic mouse and human T cell development

documenting at which stage T cell development was arrested in mice lacking such molecules (see **Figure 2**), and these studies have marked the 'checkpoints' that developing T cells go through to ensure that useless T cells do not complete differentiation.

Definition of developmental stages

In the mouse, the embryonic thymus is seeded by stem cells from the fetal liver around days 11–12 of gestation, while the adult thymus is repopulated by stem cells from the bone marrow. The human thymus is repopulated by stem cells from fetal liver around 8 weeks of gestation, while the bone marrow cells can function as a source of stem cells from 16 weeks of gestation onwards. Mature functional T cells can be identified in the developing mouse thymus around the day of birth (days 19–20 of gestation), and in the human thymus around 20 weeks of gestation. Although it is clear that the developmental pathways of fetal and adult lymphopoiesis are not identical, they follow by and large similar successive steps. The cell surface markers currently available allow, together with a few other essential features (**Table 1**), an overall distinction into two stages during embryonic thymocyte development: 1) an early pro- and pre-T cells stage during which commitment to T cell development is imposed, and 2) a later phase during which committed precursors further expand and differentiate.

Early phase

This major expansion phase, during which all thymocytes express a CD3⁺CD4⁺CD8⁺ (triple positive, TP) phenotype, marks the time that progenitors gradually lose their multipotent developmental potential, and become irreversibly committed to T cell development. The TP thymocyte subset is not homogeneous, as further subdivisions can be made on the

basis of size and expression of the CD44 glycoprotein, and the receptors for stem cell factor (CD117) and interleukin 2 (IL-2, CD25 (in the mouse)). Such cytokine receptors represent a crucial role for these types of growth factors in early lymphoid development.

In the human thymus, the markers CD34, CD38 and CD1 mark distinct progenitor populations within the TN compartment. Importantly, the earliest progenitors in the TN population are not yet exclusively committed to the T cell lineage, and progenitors that do not express CD25 (for the mouse) or CD1 (for the human) can still develop into a special subset of dendritic cells, and into natural killer (NK) and B cells. At the same time, these progenitors appear to have lost the ability to develop into the myeloid or erythroid lineages. For the mouse, irreversible commitment to T cell lineage development occurs sometime during the CD25⁺ stage and coincides with initiation of TCR β chain gene rearrangements: CD25⁺ cells that express CD44 still have the TCR β chain genes in germline configuration and can still become dendritic cells, while loss of CD44 coincides with appearance of extensive rearrangements. In the human, it appears to be the CD34⁺CD1⁺ stage that marks the committed T cell precursors, while a stage corresponding to the uncommitted CD25⁺ lymphoid progenitors in the mouse, with potential for development into dendritic cells, B cells and NK cells, is represented by the CD34⁺CD1⁺ population. What is important to realize in the type of precursor-progeny studies that have led to these nominations of developmental stages (**Table 1**), is that they have yet to be performed at the clonal level or with clonal markers. It is still possible that the studies that have led to the concept of a multipotential lymphoid progenitor for B, NK, T and dendritic cells, are in reality due to the circumstance that the cell populations used contain a mixture of committed precursors for dendritic, B, NK and T cells. Introduction of suitable marker genes in early progenitors should help resolve this issue in future studies.

The most pertinent feature of the early TN period of thymocyte development is, from the point of T cell commitment, the beginning of rearrangements and transcription of TCR gene loci. It is not clear, however, whether these rearrangements themselves determine T cell commitment, or whether they are linked to some yet to be defined control mechanism. When rearrangements are prevented, such as in mice lacking the recombinase-activating genes (RAG), T cell development is arrested at the early pre-T cell stage (**Table 1**). TCR gene loci are in germline configuration among the earliest progenitors, while the

Figure 2 Scheme of T cell differentiation, summarizing the phases discussed in this article, and indicating the block in development observed in mice carrying the indicated mutations.

proportion of cells undergoing γ , δ and β chain rearrangements can be seen to progressively increase following RAG gene expression. Thymocytes with rearrangements in one TCR locus tend to have rearrangements in the other loci, such that a given cell apparently undergoes synchronous rearrangements of all TCRT loci. Yet, rearrangements do not occur simultaneously for all TCR loci: completion of certain defined V-D-J and V-J rearrangements in the δ and γ loci, respectively, is achieved earlier than that in the TCR β loci, while the β chain rearrangements occur later, and V-J α chain rearrangements are not even initiated until TCR β chain rearrangements have been completed. This ordered appearance of rearrangements is also reflected at the level of transcription: full-length γ and δ gene mRNA can be detected first, followed by β gene transcripts, and α chain mRNA coming last. Interestingly, preferential usage of particular V_γ and V_δ segments has been observed during early and late days of fetal ontogeny, fuelling suggestions that specific $\gamma\delta$ cells exhibit defined functions in early T cell differentiation.

The complete TCR β chain forms a heterodimeric pre-TCR complex with a nonpolymorphic glycoprotein termed 'pre-T α ' (see Figure 1), which becomes expressed at the cell surface and employs the CD3 chains for signal transduction. While the precise order of appearance of the different components of the CD3 complex (consisting of ϵ , δ , and γ chains, and $\zeta\zeta$ dimers; see Figure 1) is not known, it is clear that they are available for formation of the pre-TCR complex as soon as the TCR β chain and the pre-T α chain are expressed. There is some debate as to which CD3 components are expressed in the pre-TCR as compared to the mature TCR (Figure 1), but CD3 ζ , CD3 γ and CD3 ϵ have been positively identified in the pre-TCR. It remains to be established whether the different CD3 chains have unique or overlapping functions in T cell development, and other nonpolymorphic proteins associated with the pre-TCR are being identified.

In the adult thymus, a TN subset can also be found; it constitutes a minor (<5%) portion of all thymocyte subsets, and precursors of all T lineage cells (both CD4⁺CD8⁺, double positive (DP), and CD4⁺CD8⁻ or CD4⁻CD8⁺, single positive (SP) cells) can be found among the TN cells of both fetal and adult origin. Such TN cells have, upon i.v. transfer into irradiated recipients, the capacity to home back to the thymus where they differentiate in a single wave, indicating their limited self-renewal capacity. Both homing and precursor activity are contained within a subset of adult TN cells with a CD44⁺CD25⁻ phenotype, and these adult TN cells,

like their fetal counterparts, pass through a CD25⁺ stage before they lose CD25 and CD44 and give rise to DP cells. Again, this stage marks the loss of ability to generate NK and dendritic cells, and true commitment to T cell development.

Later phase

Completion of TCR α gene rearrangements, appearance of mature T cell surface proteins such as CD4 and CD8 at the cell surface, and upregulation of the TCR-CD3 complex at the cell surface mark the subsequent phase of thymocyte development. $\alpha\beta$ T cell precursors in fact do not enter this stage if they have not completed their TCR β gene rearrangements. Small numbers of thymocytes begin to express CD8 first (the so-called 'immature single positive stage', ISP in Table 1), and this is followed by appearance of CD4 expression, such that after both relative and absolute increases, the majority of thymocytes exhibit the double positive or DP (CD4⁺CD8⁺) phenotype. Early DP thymocytes express only low levels of the TCR-CD3 complex, but this gradually increases. The proportion of DP T cells expressing low levels of the $\alpha\beta$ TCR-CD3 complex progressively increases, and single positive (SP) CD4 or CD8 cells with notably higher levels of the $\alpha\beta$ TCR-CD3 complex finally appear. The precise function of DP cells was for many years unclear, but it has been conclusively demonstrated that these DP cells contain precursors for the SP thymocytes. T Cell functions such as cytotoxicity and cytokine production can be induced through receptor-mediated activation in a subpopulation of SP cells, so these cells have apparently differentiated to a mature stage.

During the final stage of T cell development, selection of the T cell repertoire has to occur (see also below). Potentially harmful cells, such as autoreactive cells, must be eliminated or inactivated (a process termed 'negative selection'), and events favoring preferential differentiation of T cells capable of recognizing foreign antigens in association with self MHC products (a process termed 'positive selection') must allow for the generation of useful T cells. It has been recognized for many years that final T cell selection for export is a consequence of interactions between surface proteins on immature thymocytes and the nonlymphoid elements in the thymus. Thymic selection must logically involve the MHC gene products (class I and class II), the $\alpha\beta$ TCR, and the CD4 and CD8 molecules, as antigen recognition by the $\alpha\beta$ TCR is facilitated by the CD4 and CD8 coreceptors. These coreceptors not only increase the affinity of interactions between T cells and MHC (CD4 molecules can bind to MHC class II, and CD8 molecules can bind to MHC class I), but also func-

tion as signaling molecules in mature T cells and immature thymocytes. Thymic selection can only begin after expression of the CD4, CD8 and $\alpha\beta$ TCR-CD3 complex has occurred, and consequences of its effects are therefore first observed in these late stages of thymic development. The contribution of adhesion and costimulatory receptors is only beginning to be addressed, as is the identification of the signaling pathways involved. Features yet to be accounted for include the fact that the T cell repertoire is nonrandomly expressed in the two main subsets of T cells, i.e. most MHC class II-restricted T cells are CD4⁺CD8⁻, and most MHC class I-restricted T cells are CD4⁻CD8⁺.

The nonlymphoid (stromal) cells that present the MHC-peptide complexes to developing T cells can be divided into two main cell populations: bone marrow-derived cells, such as dendritic cells, and non-bone marrow-derived cells, such as epithelial cells. Many experimental models have attempted to define whether positive and negative selection can be compartmentalized, i.e. whether specialized stromal cells can determine the fate of TCR-expressing thymocytes interacting with the MHC antigens expressed on the surface of stromal cells. Both types of stromal cells can express class II and class I MHC antigens, and earlier studies established some basic rules about the role of epithelial and hematopoietic cells in T cell selection.

Hematopoietic cells are responsible for the induction of clonal deletion in potentially self-reactive DP thymocytes, as a result of presumably high-affinity interactions between such DP cells and self MHC-peptide complexes. Since hematopoietic cells can also effectively function as APCs for activation of mature T cells, induction of clonal deletion is clearly not a consequence of intrinsic properties of such APCs. Rather, signals delivered by hematopoietic cells must be perceived differently by TCR-expressing DP thymocytes than by SP mature T cells, and it is clear that the genetic make-up of DP cells poises them for death. It has long been known that DP thymocytes do not display the same set of functions as mature T cells do upon TCR-mediated signaling, and death may be as pertinent a function for immature T cells as 'conventional' hallmarks of activation, such as cytokine production and cytolysis, for mature T cells. Nevertheless, signals delivered to DP cells by epithelial cells result in a different outcome: preferential differentiation (positive selection), if their TCR fits the MHC-peptide complexes presented with a presumably lower level of affinity. It is not clear which factors determine the difference between positive and negative selection, nor have any differences between signals delivered by epithelial cells and dendritic cells

been identified. Among the more likely possibilities currently studied is differential participation of costimulatory signals, and it will be a true revelation in immunobiology indeed when this fascinating puzzle is solved.

Crucial selection events in T cell development are determined by actions of the pre-TCR and TCR

Out of the diverse repertoire of TCR specificities generated through rearrangement events in the thymus, each individual selects those that are useful, i.e. able to recognize foreign peptides when presented by his or her own MHC, and not harmful, i.e. unable to see self peptides. T cells with an $\alpha\beta$ TCR learn, somewhere during their developmental pathway, how to recognize MHC molecules as presenters of foreign peptides, to be able to adequately fight off infections once the T cells have migrated out of the thymus. At the same time, T cells have to be able to 'see' the difference between MHC molecules presenting foreign peptides and those presenting self peptides: if they did not, harmful autoreactivity would be the result. The Nobel Prize for Physiology and Medicine 1996 went to Rolf Zinkernagel and Peter Doherty who, together with others, contributed much to our understanding of this learning process.

The ability to 'learn' the difference between self and nonself MHC is acquired in the thymus, and we call this screening process 'positive selection': it is thought that differentiating thymocytes are tested for their MHC restriction specificity by interactions between their TCRs with MHC molecules expressed on the thymic epithelium, and only T cells with a TCR that recognizes the MHC molecules expressed in the thymus (and thus elsewhere in the body) are allowed to mature further and migrate to the peripheral lymphoid organs. Insights into how the thymus allows for selective differentiation of self MHC-restricted cells were particularly well-visualized in studies with TCR-transgenic mice. In mice with either class I- or class II-restricted receptors, mature thymocytes develop only when the thymus expresses the MHC product for which the transgenic receptor has restriction specificity. The concept that interactions between TCR and MHC are crucial for positive selection to occur has been further extended with the finding that the appropriate MHC has to be expressed on thymic epithelial cells rather than hematopoietic cells (see above). Generation of DP thymocytes is not affected by the MHC, indicating that positive selection occurs late in the DP stage. The MHC restriction specificity of a given transgenic TCR determines the phenotype of mature T cells gen-

erated also in other ways: T cells with a transgenic class I-restricted TCR express mostly the CD8 phenotype, while CD4 T cells preferentially develop in transgenic mice with a class II-restricted TCR. Whether the TCR determines expression of CD4 or CD8 by instruction or selection is not clear. The requirements for TCR-MHC interactions in positive selection have meanwhile also been observed in normal mice, while antibody-blocking studies and gene targeting experiments designated the CD4 and CD8 coreceptors as additional participants in the interactions leading to positive selection. Much current research focuses on the identification of the signaling pathways that may be involved, and components of the MAP kinase pathway have already been identified as important mediators.

Before migrating to the periphery, developing thymocytes have to be screened for a second feature: they must not recognize thymic MHC molecules too eagerly, because then they would, if allowed to mature and migrate out of the thymus, cause harmful autoimmunity. Self MHC plus self peptide-reactive T cells are therefore eliminated in the thymus by clonal deletion, and this 'negative selection' process plays a major role in the acquisition of self tolerance, at least for those antigens that are expressed in the thymus, or for circulating native self proteins that have access to the thymus. The first major breakthrough in the understanding of acquisition of tolerance was made in 1987 by Kappler, Roehm and Marrack, when it became clear that T cells expressing an $\alpha\beta$ TCR with $V_{\beta}17a$ (identified with a specific mAb) exhibit preferential reactivity for a given class II MHC-peptide combination, regardless of the α TCR chain or J, N and D region sequences in their TCR. T Cells with such a $V_{\beta}17a$ TCR were found to be eliminated in mouse strains that possess a functional $V_{\beta}17a$ in their germline but express the particular MHC-peptide complex recognized by $V_{\beta}17a$. The elimination was evident among peripheral T cells, as well as among the $\alpha\beta$ TCR-expressing single positive thymocytes, but not much among the DP thymocytes, implying that deletion occurred at or after the DP stage of T cell development in the thymus. Subsequent studies generated additional correlations between expression of particular class II MHC-peptide combinations and deletions of T cells (both thymocytes and peripheral T cells) with defined V_{β} chains. Eventually, formal evidence for clonal deletion of developing thymocytes and T cells came from studies in TCR-transgenic mice expressing the appropriate antigens intrathymically. Clonal deletion originating in the thymus has thus been documented as a major mechanism for acquisition of self tolerance, although it clearly is not the only mechanism.

During the past few years, it has become clear that T cells are not only subject to selection processes late in their development, based on the specificity of their TCR, but also early on, at the time they have not even begun rearrangements in the TCR α locus. TCR β gene rearrangements are necessary for further maturation of $\alpha\beta$ T cells, which stops at the early pre-T cell stage (Figure 2) in mice that have been unable to produce a TCR β chain protein. How the TCR β chain may direct further expansion and differentiation has been suggested by recent data: at the surface of early pre-T cells, TCR β is disulfide linked to a nonpolymorphic protein termed 'pre-T α ' (pT α). This chain has potential signaling motifs, which, together with the signaling motifs of the CD3 proteins also associated with the TCR β /pT α dimer, endows this 'pre-TCR' with signaling capacity. Which types of ligand, if any, needs to be recognized by the pre-TCR has not been elucidated, but it does use the p56^{lck} tyrosine kinase to act as the mediator of what we could call the checkpoint of 'β-selection': no further proliferation and differentiation occurs when this pre-TCR cannot be formed or signal because crucial components are missing. A human counterpart of this checkpoint presumably exists, since human pT α has been cloned and its expression pattern corresponds to that in the mouse.

Summarizing, we now know that T cells with an $\alpha\beta$ TCR are subject to three selection steps during their maturation: β -selection (which checks whether further differentiation is useful; there is no point in initiating TCR α chain rearrangements and subsequent differentiation events if there is no TCR β chain), positive selection (which checks for ability to see thymic MHC once the mature $\alpha\beta$ TCR has been formed), and negative selection (removing potentially harmful T cells with an autoreactive $\alpha\beta$ TCR). Perhaps additional checkpoints will be defined in the future, and one putative checkpoint that is the subject of much research (and summarized below) is the point where the $\alpha\beta$ and $\gamma\delta$ lineages diverge.

Lineage commitments

A small percentage of fetal thymocytes (<5%) express a TCR-CD3 complex at an early stage of development when thymocytes still express a TN phenotype, but the TCR portions of these receptors are entirely composed of γ and δ chains (not to be confused with the invariant γ and δ chains of the CD3 portion of the TCR-CD3 complex). This is not surprising, since the TCR γ and δ loci are the only TCR gene loci having completed rearrangements by this time. This $\gamma\delta$ TCR-expressing subset remains a minor population of thymocytes throughout fetal

development and in adult life. Yet, it is not a homogeneous subset: it undergoes changes with respect to the V_δ and V_γ chains used, as a consequence of a developmentally regulated order of rearrangements in the γ and δ genes, and subsets of defined V_γ and V_δ -expressing cells home to certain tissues, such as skin, spleen, lung, intestinal epithelium and reproductive organs. It should be noted that such fetal $\gamma\delta$ TCR-CD3-expressing cells are already functional: both cytokine production and cytotoxicity can be induced through CD3-mediated signaling, and by these criteria, $\gamma\delta$ T cells represent the earliest mature T cells in the thymus, appearing several days before T cell function can be detected among the $\alpha\beta$ TCR-CD3-expressing SP cells.

Since $\gamma\delta$ T cells are expressed before $\alpha\beta$ T cells during fetal thymic ontogeny, the question arises whether $\gamma\delta$ cells might include precursors for $\alpha\beta$ cells. Could individual cells sequentially rearrange their γ and δ loci first and their α and β loci later? Or are $\alpha\beta$ lineage commitments largely independent of the status of prior γ and δ gene rearrangements? TCR γ , α and β genes are all unlinked, but the δ gene is located between the V_α and J_α sequences of the α locus. How commitment to either $\gamma\delta$ or $\alpha\beta$ development is regulated is a matter of much debate. Expression of a TCR β chain is an absolute determinant of T cell commitment, but not of $\alpha\beta$ versus $\gamma\delta$ diversification: V-DJ β rearrangements are frequently in-frame in $\gamma\delta$ cells. Compatible with a successive rearrangement model, V-JC γ rearrangements are often nonproductive in $\alpha\beta$ cells, suggesting that commitment is related to whichever rearrangement has been completed first. On the other hand, the frequency of productive V-DJ δ rearrangements in $\alpha\beta$ T cells has been found to be either random or nonrandom, making it difficult to decide whether the nature of the initial successful rearrangement dictates lineage commitment. It therefore remains to be determined at what point the $\alpha\beta$ and $\gamma\delta$ lineages diverge, and how the nature of the initial rearrangements is regulated.

Conclusions

The consequences of the positive and negative selection process have finally been clearly defined, most notably using TCR-transgenic mice and monoclonal antibodies that identify distinct TCR. Also, consensus has been reached with respect to the order of events during initiation of TCR gene transcription and rearrangements and appearance of the most critical T cell surface proteins during fetal thymocyte development. Yet, many questions remain to be answered, and those that are the subject of the most

active areas of research include those regarding selection and commitment:

1. What is the molecular nature of the signals leading to clonal deletion of immature thymocytes, and how are these different from signals leading to activation of mature T cells?
2. What is the nature of the signals involved in selection of the T cell repertoire that dictate the difference between positive and negative selection?
3. What is the nature of the signals leading to initiation and termination of TCR gene rearrangements?

Clearly, future research will be focused on identification of components of signaling pathways and regulatory molecules, and identification of lineage determining genes. These studies will no doubt reveal connections to developmental biology in other systems, a prediction illustrated nicely by the 'winged helix' class of gene regulators, which determine cell fate in *Drosophila*, while regulating development of the thymic stroma in mice.

T LYMPHOCYTES

William R Heath, The Walter and Eliza Hall Institute of Medical Research,
Post Office Royal Melbourne Hospital, Melbourne, Victoria, Australia

To define the term 'T lymphocyte' it is first necessary to provide a definition for the word 'lymphocyte'. These cells were originally defined by morphological criteria to have a large nucleus to cytoplasm ratio, with cytoplasm rich in free ribosomes, containing a number of mitochondria, a small Golgi area and few lysosomes. Lymphocytes are found in high proportions in the bloodstream, lymphoid organs and the lymphatics. They have been divided into small, medium and large, although their size distribution is continuous rather than trimodal.

The term T lymphocytes (or T cells) was originally given to 'thymus-derived lymphocytes' by Roitt and colleagues (1969) several years after the discovery by Miller (1961) of a population of circulating lymphocytes that was produced in this organ. This definition was used to refer to those lymphocytes that matured in, and were exported from, the thymus rather than cells that simply occupied this organ. Host cells found in the thymus are referred to as 'thymocytes'. These consist of T lymphocyte progenitors at various stages of differentiation.

Phenotype of the T lymphocyte

Defining the T lymphocyte as a 'thymus-derived lymphocyte' would be satisfactory if we were only interested in providing a semantic definition. But this does nothing for our ability to identify such cells once they leave the thymus. Since the discovery of a thymus-derived population of lymphocytes, there has been an explosion of immunohistologic reagents available for the characterization of different blood cell types.

This has allowed immunologists to phenotype various lymphocyte subsets. In this process, several cell surface markers have been found to be relatively specifically expressed on T lymphocytes. The primary marker of a T lymphocyte is its receptor for antigen; this is referred to as the T cell receptor (TCR). Most T lymphocytes express T cell receptors of the $\alpha\beta$ type, which function by recognizing antigen in the context of major histocompatibility complex (MHC) class I and class II molecules. A smaller subset of T lymphocytes express $\gamma\delta$ T cell receptors, the specificity of which is unclear. When we describe the T lymphocyte as a lymphocyte with a receptor for antigen, it is important to distinguish these cells from B lymphocytes, which also express receptors for antigen. There are, however, major functional differences between these populations of lymphocytes: B lymphocyte antigen receptors recognize antigen in its native state, and when these lymphocytes are activated they secrete their receptors as soluble molecules known as 'antibodies' or 'immunoglobulin'. In contrast, the receptors on T lymphocytes generally recognize processed peptide antigens bound to molecules encoded by the MHC. This is known as MHC restriction. Furthermore, activated T lymphocytes do not secrete their receptors but rather use them to recognize cell-associated antigens. At a phenotypic level, all T lymphocytes express the CD3 complex, which is associated with the T cell receptor and is required for signaling during antigen recognition. The CD3 complex is not expressed by B lymphocytes.

Most T lymphocytes in the mouse express Thy-1

(CD90) on their surface, which distinguishes them from B lymphocytes and is often used as a general marker for these cells. Thy-1 can be expressed by other cell types, however, and is not expressed by a minority of T lymphocytes. The other classical molecules expressed by T lymphocytes are the coreceptor molecules CD4 and CD8. These molecules are involved in recognition of relatively nonpolymorphic regions of MHC-encoded molecules and are expressed on mutually exclusive T lymphocyte subsets. CD4 is usually expressed by cells bearing MHC class II-restricted T cell receptors, whereas CD8 is expressed on MHC class I-restricted T lymphocytes. Once again, however, these markers can be expressed by a minority of other cell types and are not found on all T lymphocytes.

T lymphocyte development

T lymphocytes develop from bone marrow-derived cells that migrate to the thymus. The earliest thymic progenitor is the CD4^{lo}CD8⁻CD3⁻ thymocyte. This progenitor passes through many stages of maturation, including a CD3⁻CD4⁻CD8⁻ stage and then a CD3^{lo}CD4⁻CD8⁺ stage, before becoming a fully mature CD3^{hi}CD4⁺CD8⁻ or CD3^{hi}CD4⁻CD8⁺ T lymphocyte. Early in this process, before the CD3^{lo}CD4⁺CD8⁺ stage, there is a branch in this pathway towards development of a subset of $\gamma\delta$ T lymphocytes. Other subsets of $\gamma\delta$ T lymphocytes develop in the thymus during fetal but not later life.

T lymphocyte function

Functionally, T and B lymphocytes perform the role of cells that, upon specific encounter with antigen, are activated to provide immunological functions usually associated with fighting infections. These cells are also responsible for the specific memory aspect to immune responses, such that secondary encounter with the same antigen results in a more rapid and aggressive immune response. While B lymphocytes are responsible for the secretion of antibody molecules, T lymphocytes are the central players in cell-mediated immune responses. CD4⁺ $\alpha\beta$ ⁺ T lymphocytes are the major subset of T lymphocytes and are classically referred to as helper T cells because they provide 'help' to B cells for the production of T-dependent antibodies. This subset of T lymphocytes recognizes class II-restricted antigens and plays a pivotal role in most types of immunity – especially in inflammatory cell-mediated responses. They are responsible for production of many different cytokines and, when stimulated by antigen, develop into activated cells that can be loosely divided into two

broad subsets, T_H1 and T_H2, based on the types of cytokines they secrete. T_H1 cells produce interferon γ (IFN γ), interleukin 2 (IL-2) and lymphotoxin (tumor necrosis factor β , TNF β), whereas T_H2 cells produce IL-4, IL-5, IL-6, IL-9 and IL-10. CD4⁻ T lymphocytes can also be cytotoxic, but this function is primarily the responsibility of the other major subset of T lymphocytes, the CD8⁺ $\alpha\beta$ ⁺ T lymphocytes. These class I-restricted cells are generally referred to as cytotoxic T lymphocytes or killer T cells and are primarily responsible for the killing of viral-infected or tumor cells. CD8⁺ T lymphocytes also secrete various cytokines and have been loosely divided into T_C1 and T_C2 cells on the same basis as described for T_H1 and T_H2 cells. Induction of effective cytotoxic T lymphocyte responses may require 'help' from CD4⁻ T lymphocytes.

There are also a number of $\gamma\delta$ T lymphocyte subsets, but the function of these cells is less well defined and beyond the scope of this description.

Some problems with this definition

As with all definitions, it can be somewhat problematic when taken too literally. Lymphocytes can be broadly divided into three groups: the B lymphocytes, the T lymphocytes and natural killer (NK) cells. NK cells also have receptors for antigens, but the antigens these receptors recognize appear to be the MHC molecules themselves. In contrast to T lymphocytes, these cells are activated when their receptors fail to encounter such molecules on target cells. Thus, NK cells kill cells that do not express MHC molecules. NK cells are not classically encompassed by the definition of the T lymphocyte, but they can be generated in the thymus, thus fulfilling the definition of a thymus-derived lymphocyte. However, they do not express the CD3 complex, which is expressed by $\gamma\delta$ and $\alpha\beta$ T lymphocytes. This criterion becomes more relevant when we consider that small numbers of lymphocytes with indistinguishable properties to those of T lymphocytes can be generated extrathymically. For example, in nude mice, which do not possess a thymus, there are some T lymphocytes present in the circulation.

Thus, while the classical definition of the T lymphocyte is a 'lymphocyte that is derived from the thymus', such cells may be more accurately described as 'lymphocytes that express the T cell receptor and CD3 complex and are generally derived from the thymus'.

T LYMPHOCYTES, AUTOREACTIVE

Maurice Zauderer, Immunology Division, University of Rochester Medical Center, Cancer Center, New York, USA.

Diverse mechanisms contribute to immune tolerance of self antigens. Because of the importance of this immune function the appearance of autoreactive T cells in various diseases is regarded as a failure of normal regulation. While this is certainly true in the case of pathological manifestations, there is substantial evidence that autoreactive T cells are a normal and even necessary part of the immune system. An important distinction to make here is between the 'inappropriate' activation of resting T cells by self and the continued stimulation and expansion of T cells that have previously and appropriately been activated by foreign antigen. Cells of the former type, specific for well-defined tissue antigens, have been described in certain disease models. This entry focuses on the latter population, normal T cells specific for foreign antigens that can also give rise to autoreactive progeny.

Origin

The origin and persistence of autoreactive T cells is most readily understood from a consideration of the requirements for T cell maturation. The mature peripheral T cell population is restricted to recognize foreign antigens in association with only those major histocompatibility complex (MHC)-encoded molecules expressed in the thymic differentiation environment. Since foreign antigens are not, in general, present in that environment, this clearly means that at an early stage of differentiation T cell precursors are self reactive. It is presumed that some process of negative selection prevents seeding any very high

affinity self reactive clones in the mature population. Nevertheless, antigen-specific, MHC-restricted peripheral T cells must derive from thymic precursors that express a functional affinity for self MHC, possibly in association with other self molecules. The basis for this transition from an autoreactive thymic precursor to an antigen-dependent, MHC-restricted peripheral T cell is not understood. Present evidence suggests that this transition cannot be explained by somatic mutation of rearranged T cell receptor genes. It appears, therefore, that T cell maturation must be accompanied by physiological changes that modulate T cell activation signals or activation thresholds such that self MHC recognition does not, in general, suffice to induce clonal expansion of resting peripheral T cells. Such changes could reflect properties of mature T cells relative to thymic precursors as well as properties of the stimulatory environment in secondary lymphoid tissues relative to the thymus. The nature of these physiological changes is not known and their stability cannot be predicted. A considerable body of evidence suggests, however, that some mature T cells either have retained or reacquired the ability to be stimulated by self MHC in the absence of foreign antigens.

Autoreactive T cells and T cell lines derived from normal individuals have been independently described in many laboratories. Such T cells are activated in the absence of any identifiable foreign antigen by class II MHC syngeneic but not MHC allogeneic stimulators. In particular, autoreactive responses have been demonstrated in the absence of

xenogeneic serum components. It has been suggested that such T cells manifest the autoreactive specificity that was the basis for positive selection in the thymus. This is supported by evidence that autoreactive T cells can derive from antigen-specific precursors. It has been shown that, under well-defined conditions, the specificity of autoreactive T cell clones selected from antigen-primed populations reflects the predominant MHC restriction specificity of T cells specific for the immunogen. Thus, I-E subregion specific autoreactive T cells are detected at a much higher frequency in populations primed with a foreign antigen whose presentation is I-E-restricted than in populations primed with antigen whose presentation is predominantly I-A-restricted. A striking confirmation and extension of these observations has been noted in the analysis of T cell receptor gene expression in autoreactive T cell clones selected from pigeon cytochrome *c*-stimulated populations. The diversity of germ-line T cell receptor variable region genes expressed in the pigeon cytochrome *c*-specific T cell repertoire is relatively limited. It has been observed that autoreactive T cells also arise in pigeon cytochrome *c*-stimulated T cell lines and that the same T cell receptor genes predominate in these autoreactive T cells as in the antigen-specific T cells. These results strongly support the conclusion that autoreactive T cells can derive from antigen-stimulated precursors.

Such 'normal' autoreactivity may represent a particular physiological state that recapitulates the conditions of thymic selection and is induced in many antigen-specific, MHC-restricted peripheral T cells as a result of normal antigen-dependent activation. In keeping with the suggested physiological difference, there is evidence that autoreactive T cells have unique activation requirements distinct from the activation requirements of antigen-specific, MHC-restricted T cells. In particular, it has been shown that autoreactive T cells are more dependent on interleukin 1 (IL-1) and on signals transduced through recognition of MHC class II on the stimulator cell than are antigen-specific T cells.

Significance

Even if autoreactivity is a transient physiological state in activated normal peripheral T cells, it could make a substantial contribution to clonal expansion and amplification of immune functions. The functional capabilities of autoreactive T cells have been investigated in a number of laboratories. In general, they have been found to provide the same physiologi-

cal signals as other CD4⁺ T cells. Both lymphotoxin and interferon γ (IFN γ) producing autoreactive T_{H1} and IL-4 secreting autoreactive T_{H2} have been isolated. Examination of the helper functions of both murine and human autoreactive T cell clones has clearly demonstrated that these T cells can provide helper signals that serve to enhance B cell proliferation and maturation of immunoglobulin secretion. Autoreactive T cells that secrete other lymphokines, including lymphotoxin and IFN γ , may play an important role in inflammatory responses. *In vivo* injection of autoreactive T cell clones in footpads of syngeneic mice induced delayed-type hypersensitivity reactions in the dermis. In addition, autoreactive T cell clones with cytotoxic activity (lymphotoxin secretion) induced skin lesions with infiltration of lymphocytes in the epidermis and epidermal cell damage.

As suggested by these observations, autoreactive T cells could play a role in both normal and pathological immune responses. Their contributions *in vivo* cannot be fully evaluated until the mechanisms that must limit their expansion have been identified. The available evidence suggests that autoreactive T cells derive from mature antigen-dependent precursors which have undergone a physiological transition that restores their thymic selected ability to respond to self. This could be a normal reversible transition which frequently accompanies specific T cell activation. In this case any mechanism that returns T cells to a resting state would eliminate autoreactive expansion until another cycle of stimulation is induced by a specific foreign antigen. Under conditions of chronic stimulation, when high levels of MHC class II are continuously expressed and/or immune regulation is abnormal, autoreactive T cells could give rise to severe and persistent inflammation.

TNF RECEPTORS

David Wallach, Department of Membrane Research and Biophysics,

In multicellular organisms immune defense mechanisms are coordinated, as, in fact, are all other cellular functions, by receptors – proteins that are capable of binding specific extracellular ligands. This regulation occurs by activation of signaling cascades, a series of allosteric modulations initiated by the binding of the ligand to its receptors and terminating in activation of intracellular enzymes that affect specific mechanisms of defense.

The activities regulated by the tumor necrosis factors (TNFs) and their receptors are multitudinous. Some of the signaling pathways involved in their function already existed very early in evolution (e.g. the stress-activated protein kinase 2 (p38/RK kinase) cascade and its yeast analog, the Hog kinase pathway). The TNFs themselves and their receptors have so far been fully characterized only in mam-

mals. However, there is some evidence that they occur in various other organisms as well, and also appeared rather early in evolution. Understanding of the role of the TNFs in immune defense is still limited. Nevertheless, our knowledge of the mechanisms by which they act has been greatly advanced through studies of the TNF receptors and their mode of signaling.

The TNFs are produced mainly by cells of the immune system. Their receptors, however, are of wide occurrence. Although they are expressed by various professional immune cells and regulate their functions, they are much better known for their action in cells that are not considered as part of the immune system, such as endothelial cells and fibroblasts. They are best known for their ability to induce activities of cells that participate in inflam-

Figure 1 Interactions of the known cell bound and soluble TNF receptors and ligands. DD, death domain.

matory processes, as well as for the various destructive effects, particularly the cytotoxic effects, that they can trigger.

The receptors and their binding properties

The terms TNF and TNF receptors relate respectively to a number of ligands and receptor molecules that can interact in different ways (see Figure 1). Three structurally related ligands, TNF α , lymphotoxin α (LT α) (or TNF β) and LT β , and three receptors with structurally related extracellular domains are currently known to operate in this response system. Two of the receptors have received CD designations, though other names are also still in use. One of these receptors is designated CD120a (or the type I, the p55 or the p60 receptor) and the other CD120b (or the type II, the p75 or the p80 receptor). The third is termed the LT β receptor (LT β -R), the type III TNF receptor or TNFR-RP. Both the ligands and the receptors belong to growing families of structurally related molecules, known as the TNF-ligand and the TNF/NGF receptor families.

TNF α and LT α have been shown to act as homotrimers, and this is apparently true for all other members of the TNF-ligand family. Another common feature of most of these ligands, including TNF α and LT β , is that they are functionally active not only as soluble molecules (like most of the known cytokines) but also as cell surface, type II transmembrane proteins, from which the soluble forms are derived proteolytically. LT α is the only known ligand of the TNF family which is released by cells as a secreted protein. It has the ability to bind to LT β molecules and thus, even though formed as a soluble molecule, it also occurs in a cell-bound form, comprised of heterotrimers of LT α and LT β (see Figure 1). As discussed below, both the ligands and the TNF receptors occur in cell-bound as well as in soluble forms, the latter being derived from the cell surface forms following cleavage by cell bound metalloprotease(s).

The known interactions between the three ligands and the three receptors are illustrated in Figure 1. Both CD120a and CD120b can bind to the cell-bound as well as to the soluble forms of homotrimers of TNF α and LT α . CD120b, however, binds more effectively to the cell-bound form of TNF α and is preferentially activated by it. The LT β -R binds only to heterotrimers of LT α and LT β .

Location

Most of our knowledge of the cellular expression of the TNF receptors is based on their occurrence in

cultured cells; little has been done so far to assess their expression *in vivo*. From the cell culture studies it appears that almost all cells express TNF receptors, though the proportion of the different receptors on the cells varies. CD120a is constitutively expressed in almost all cells; indeed, its promoter displays house-keeping features. In contrast, the expression of CD120b is quite restricted. It is constitutively expressed in certain hematopoietic cells, such as lymphocytes and mononuclear phagocytes, where its amounts may greatly exceed the amounts of CD120a. Many other cells express little of this receptor, but can be induced to express it by certain stimuli (e.g. TNF itself and interleukin 1). Almost nothing is known about the cellular pattern of expression of the LT β -R.

Structure

CD120a, CD120b and the LT β -R are single transmembrane type I proteins. The three receptors bind to their ligands via a shared extracellular repetitive cysteine-rich motif that characteristically occurs also in the other members of the TNF/NGF receptor family. Their intracellular domains are structurally unrelated. Several functionally distinct regions have been defined in these domains. Of these, the only one found so far to show sequence homology with regions in other proteins is the 'death domain' (DD), a protein-binding motif of about 80 amino acids, found in CD120a. This region is involved in self-association of CD120a as well as in its association with other proteins, including some that also contain DDs and bind through their DDs to the DD in CD120a (see below).

Function

CD120a

Selective triggering of CD120a in cultured cells by antibodies to the receptor results in the induction of a wide range of TNF effects, including cytotoxic, growth stimulatory, antiviral, antichlamydial, prostaglandin-inducing actions and others. In fact it appears from these experiments that most of the known effects of TNF are triggered by this receptor. Accordingly, knockout mice for CD120a are deficient in several of the most pronounced *in vivo* activities of TNF. For example, these mice are resistant to the lethal effect of bacterial lipopolysaccharide (measured under conditions of sensitization to this effect, i.e. when hepatic RNA synthesis is blocked). They also display a highly increased vulnerability to certain intracellular pathogens, such as *Listeria*.

CD120b

As the prevalent TNF receptor in professional immune cells such as lymphocytes and monocytes, and apparently the only receptor expressed by them in certain differentiation states, CD120b is likely to play an important role in the immunoregulatory activities of the TNFs. However, present knowledge of its function lags significantly behind knowledge of the function of CD120a. Studies of CD120b function in cultured cells indicate that this receptor 1) assists the binding of TNF to CD120a; 2) signals, in certain cells, for effects identical to those triggered by CD120a, e.g. cytotoxicity, activation of the transcriptional factor NF κ B, and growth enhancement. As mentioned above, CD120b was recently shown to be preferentially triggered by the cell-bound form of TNF, suggesting that it acts primarily as a mediator of paracrine TNF effects (effects induced in the close vicinity of the TNF-producing cell).

LT β receptor

Because this receptor has been known only for a relatively short time, knowledge of its function is still very limited. Only two *in vitro* effects of its triggering have been observed so far: activation of NF κ B and, in some cells, induction of a cytotoxic effect. Although at the time of writing LT β -R^{-/-} mice had not yet been produced, indirect information on the *in vivo* function of the receptor could be gained by comparing the phenotype of LT α ^{-/-} mice to those of CD120a^{-/-} and CD120b^{-/-} mice. The data point to a unique role of LT β -R *in vivo*, which is distinct from those of the two other TNF receptors, namely, signaling for effects which are needed for the embryonic development of peripheral lymph nodes.

Signaling mechanisms

The TNF receptors signal for both gene activation-dependent and -independent effects. Knowledge of the signaling mechanisms for both kinds of effects, though still fragmentary at present, is increasing rapidly. Several transcription factors involved in the gene activation-dependent effects of the receptors have been identified. The most extensively studied is NF κ B, a transcription factor (or rather a family of related factors) which participates in the transcriptional regulation of many genes related to defense. Studies of the cytotoxic effect, the best characterized of gene activation-independent TNF effects, revealed a critical role of several ICE/CED3 proteases in this death induction, resembling in that sense other programmed cell death processes. Several protein kinases whose activities change rapidly after receptor

triggering have been identified, including those comprising the three currently known main mitogen-activated protein (MAP) kinase cascades (the stress-activated protein kinase 1 (JUN N-terminal kinase, JNK), stress-activated protein kinase 2 (p38 kinase), and the extracellular signal-regulated kinase (ERK) cascades). In addition, several lipases, including a phosphatidylcholine specific phospholipase C and the cellular phospholipase A₂, are activated by the receptors. Signaling by the TNF receptors is initiated as a consequence of interaction of two or three receptor molecules, caused by their binding to the trimeric ligand molecules (or by cross-linking with TNF receptor-specific antibodies). Triggering results in recruitment of several adapter and signaling molecules.

The known receptor-associated adapter proteins and some of the signaling molecules that they activate are illustrated in Figure 2. They include a group of structurally related adapter proteins called the TRAFs (TRAF1, 2, 3 and 5), which bind through a shared C-terminal sequence motif (termed the TRAF domain) to distinct regions in CD120b and LT β -R (though not to CD120a). They also include three adapter proteins, TRADD, MORT1/FADD and RIP, which contain DDs and bind through them to the DDs in CD120a and in the structurally and functionally related receptor CD95 (Fas/Apo1). These three proteins do not bind to CD120b or to the LT β -R. Both TRAF2 (which binds to CD120a and to the LT β -R, as well as to some other members of the TNF/NGF family, such as CD40) and TRAF5 (which binds to the LT β -R) are involved in the activation of NF κ B by these receptors. TRADD, a DD-containing adapter protein that binds to CD120a, is involved in cell death induction, which most probably occurs through the binding of its DD to that of MORT1/FADD, a DD-containing adapter protein that binds directly to Fas/Apo1. TRADD is also involved in the activation of NF κ B by CD120a, most likely through interaction of the region upstream of its DD with TRAF2.

Events further downstream in the death-inducing cascade include recruitment of a CED3/ICE protease called MACH (or FLICE or Mch5 or caspase-8) to MORT1/FADD, and its consequent activation. They also include activation of several other ICE/CED3 proteases, including CPP32/Apopain/Yama (caspase-3) and Mch3/ICE-LAP3 (caspase-7), which is most probably a consequence of activation of MACH/FLICE. Activation of the acid sphingomyelinase, phospholipase A₂ and JUN kinase by the TNF receptors may also participate in the death-induction process. The most crucial events further downstream in activation of NF κ B by the receptors

Figure 2 Signaling molecules that bind to the intracellular domains of the TNF receptors and some of their functions.

are the induced phosphorylation and consequently the proteolytic degradation of I κ B. The exact sequence of molecular events leading to this phosphorylation is not yet known, except that it appears to involve the participation of TRAF2 and a protein called TANK or I-TRAF, which binds to TRAF2. A MAP kinase kinase kinase called NIK, which binds to TRAF2 and apparently participates in NF κ B activation, was recently identified.

A few TNF receptor-associated adapter proteins that signal for other TNF effects have also been identified. One of these is FAN, an adapter protein that is apparently involved in the TNF-induced activation of the neutral sphingomyelinase. FAN binds to a distinct region in the CD120a intracellular domain upstream of the DD.

Taken together, the emerging molecular picture reveals a rather wide diversity of receptor-activated signaling cascades, consistent with the wide range of activities that these receptors are able to trigger. Another interesting feature is an extensive interac-

tion among the molecules that participate in the signaling activities of the three TNF receptors, as well as between these molecules and those that participate in the signaling for effects of other receptors of the TNF/NGF family. Such interactions apparently account for the ability of these different receptors to induce many common effects.

Soluble TNF receptors and their therapeutic uses

There is a growing list of pathological situations in which much harm is caused by the effects of TNF, and where blocking of TNF function can be therefore beneficial. One of the current approaches in the attempt to inhibit TNF functioning in disease involves injection of soluble TNF receptors. This approach reproduces a naturally occurring control mechanism. In various inflammatory processes, serum concentrations of the soluble TNF receptors are greatly increased as a result of their proteolytic

cleavage triggered by various stimuli associated with inflammatory processes, such as TNF itself. The soluble TNF receptors bind to TNF. They are capable both of competing with the cell surface TNF receptors for TNF and of stabilizing TNF by preventing its spontaneous dissociation into inactive monomers, and thus may affect TNF function in a complex manner. When present in sufficiently high concentrations, however, they act purely as TNF inhibitors.

Ongoing clinical trials with recombinant preparations of soluble receptors, as well as with high molecular weight derivatives of these molecules with lower rates of clearance from the blood circulation (such as soluble receptors fused to the Fab portion of immunoglobulin G (IgG) or linked to polyethyleneglycol), demonstrate their significant therapeutic effects in diseases that involve deleterious action of TNF, including rheumatoid arthritis, the inflammatory bowel diseases, and septic shock.

TNF viroceptors

An impressive example of the functional significance of the soluble TNF receptors is provided by the action of their virus-produced analogs. Several viruses, all of the poxvirus family, have been found to encode such 'TNF viroceptors'. These molecules are comprised of the same cysteine-rich repeated motifs that occur in the extracellular domains of the cellular TNF receptors. They also contain a unique C-terminal region, which in some of these receptors imposes formation of receptor dimers. Some of those viroceptors bind TNF α only, whereas others bind both TNF α and TNF β . Deletion of the DNA regions encoding these viroceptors from the genome of the viruses does not affect their replication in cultured cells. However, it significantly compromises their pathogenicity in infected animals, indicating that the viroceptors counteract a rather effective antiviral function of TNF.

TOGAVIRUS, INFECTION AND IMMUNITY

Ian McConnell, Department of Clinical and Veterinary Medicine, University of Cambridge, Cambridge, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The Togaviridae family of small positive-strand RNA viruses are responsible for a large number of diseases of domestic animals and humans. Illness varies from mild inapparent infection to acute fevers and in many cases severe fulminating diseases with high morbidity and mortality. Many of the infections reach epidemic proportions, are arthropod borne (usually mosquitoes) and, for some of the viruses, reservoirs of infection exist within wild vertebrates such as birds, rodents and primates, where infection is inconsequential. In other cases the major source of infection is human. The viruses cause their characteristic diseases on transmission to humans and domestic animals which can be tangential to the wildlife cycle. Togaviruses are important zoonoses with humans becoming infected as a consequence of vector transmission from domestic livestock (e.g. pigs, horses). Studies on infection and immunity with these viruses have revealed particular facets of immune responses to viruses in terms of mechanisms of immunity, immunopathology and immunological tolerance.

Togaviridae are small (60–65 nm diameter) positive-stranded RNA viruses with a characteristic icosahedral capsid and 'close fitting' envelope (hence the original description as TOGA-viridae). Many of the viruses of the various genera have now been cloned and sequenced (Table 1). Prior to molecular data the flaviviruses were regarded as a genus within the

Togaviridae, but they are now considered a separate family.

The Togaviridae are amongst the most simple enveloped viruses and comprise three genera and two members: alphaviruses (e.g. Sindbis virus, Semliki Forest virus, eastern equine encephalitis); rubivirus (e.g. rubella); pestiviruses (e.g. hog cholera or swine fever virus, bovine viral diarrhoea virus – BVDV – and border disease virus of sheep – BD). Also included in the Togaviridae are equine arteritis virus (arterivirus) and lactate dehydrogenase (LDH) virus of mice. The latter is nonpathogenic but represents a good model for studying factors involved in control of viremia *in vivo* as it grows to extremely high titers in infected mice (10^9 infectious particles ml^{-1} of serum) which can persist for the lifetime of the animal without causing significant disease. Not all viral infections with these viruses are transmitted by vectors. Rubella and pestiviruses are directly transmitted between individuals by droplet infection and transplacental transmission.

The small nonsegmented RNA genome (10–11 kb 4×10^6 mol.wt) functions as mRNA and encodes three to four nonstructural (NS) proteins, a core protein closely associated with the nucleocapsid and one or two envelope proteins designated E1 and E2. The Togaviridae 49S RNA genome has a 7-methylguanosine cap and is polyadenylated at the 3' end with the order of the genes being nonstructural at the 5' end

Table 1 Some properties of Togaviridae

Genus (no. of spp.)	Disease	Main host(s)	Vector	Virus
Togaviridae				
Alphavirus (26)	Fever, encephalitis	Horse/human	Mosquito	Eastern equine encephalitis Western equine encephalitis Venezuelan equine encephalitis
	Myositis, encephalitis	Mouse/human	—	Sindbis ^a Semliki Forest
	Fever, arthritis, rash	Human	Mosquito	O'Nyong-nyong Chikungunya
Rubivirus (1)	Epidemic polyarthritis	Human	Mosquito	Ross River
	Fever, rash, arthritis, congenital infection	Human	None	Rubella
Pestivirus (3)	Viral diarrhoea mucosal disease	Cattle	None	Bovine viral diarrhoea
	Swine fever	Pigs	None	Hog cholera
	Congenital disease of skin and nervous system	Sheep	None	Border disease
Arterivirus (1)	Arteritis, abortion	Horse	Not known	Equine arteritis

^aSpecies type.

(four genes) and structural at the 3' end (four genes). The nonstructural proteins are translated directly from the full length RNA but the structural proteins are derived from a subgenomic 26S mRNA which is identical in sequence to one-third of genomic RNA at the 3' end. The Flaviviridae genome comprises a single uninterrupted reading frame which is not polyadenylated at the 3' end. Molecular cloning of one of the pestiviruses (BVDV) has revealed that the bovine pestivirus is closer to the Flaviviridae family than the Togaviridae. A strong case has been made for the reclassification of pestiviruses as members of the Flaviviridae family.

Rubella in humans, and BVDV and BD in ruminants can be inapparent infections in young individuals but severe problems arise if infections occur during pregnancy. Infection of the fetus results either in abortion or congenital malformations, or birth of animals which are immunologically tolerant to the infecting virus. Rubella in adults can induce an acute arthritis and skin lesions, and in 0.06% of cases a viral-induced encephalopathy can be a serious complication.

Immunity

Infections with many of the viruses can result in life-long immunity. In rubella the success of vaccination programmes in nonpregnant women has resulted in a significant drop in the number of rubella-induced congenital diseases. Epizootics of Venezuelan equine encephalitis virus in horses have been successfully controlled by attenuated vaccines. Establishment of vaccinal immunity in domesticated livestock can break the cycle of transmission from wild reservoir → domestic animal → human and thereby indirectly protect humans by vaccination of the intermediate host.

There is clear evidence that antibodies to the E1 protein (usually the hemagglutinin) as well as the E2 protein can both neutralize and passively protect in mouse and monkey models of alphavirus infection. Antibodies to the nonstructural proteins (e.g. NS-1) are also recognized on the surface of infected cells. By comparison with anti-E1 antibodies, anti-NS-1 antibodies are extremely efficient at triggering complement activation on cell surfaces and causing lysis of infected cells. Since these viruses mature from infected cells by budding through cytoplasmic membranes it is also extremely likely that T cell recognition of nonstructural proteins on the surface of infected cells represents an important mechanism of immunity in these infections. In view of the importance of nonstructural antigens and the need for vaccination with live virus rather than recombinant

proteins, vaccinia virus constructs expressing non-structural proteins have been constructed and used as vaccines experimentally. The recent evidence that epitopes on the nonstructural proteins may be more highly conserved between virus strains indicates that these immunogens could be extremely useful in stimulating broadly cross-reactive immunity.

In the alphaviruses the E1 proteins are involved in cell surface adsorption and fusion. The E2 proteins contain important virulence determinants and changes in either can affect host range and virulence. A single amino acid substitution in the E2 of Sindbis virus of an arginine for a serine at position 114 results in a strain with reduced neurovirulence for young mice. Studies with recombinant proteins reveal that in general virulence determinants map to the N-terminal half of the E2 glycoprotein. The E1 gene is more conserved than the E2 in the alphaviruses. Now that infectious clones of many of the viruses have been constructed it will be possible through site-directed mutagenesis to pinpoint virulence determinants and to use this information in the generation of attenuated clones for vaccination purposes.

Enhancement

Antibody-mediated enhancement of viral replication is thought to be mediated by Fc receptor (FcR) uptake of virus as immune complexes by FcR⁺ cells of the macrophage-monocyte series. Enhancement is mediated in a dose-dependent manner by subneutralizing concentrations of antibodies that bind to the E proteins of the virus. It is not observed with antibodies to the nonstructural proteins as these are not exposed to the virus surface. Viral immune complexes may exacerbate the disease in rubella where congenital infection gives rise to viremic children.

Tolerance

In the pestivirus group, transplacental infections of the fetus can cause congenital disease and induction of immunological unresponsiveness to the virus in the fetus. In the ruminant pestiviruses (BVDV, BD), there are two virus biotypes – cytopathic and noncytopathic. This difference correlates with distinct differences in viral polypeptides between the two biotypes. In the first 3 months of pregnancy BVDV infection of pregnant cattle with the noncytopathic BVDV virus may result either in fetal death or, as is more common, the birth of apparently normal animals which are virus positive but antibody negative. The same applies to BD infection of sheep. If infection occurs early in pregnancy during the develop-

ment of the immune repertoire, virus antigen is seen as self and animals become immunologically tolerant to the virus following *in utero* infection. These virus-positive, antibody-negative animals represent an important reservoir of infectious virus. On infection of these tolerant animals with the more virulent cytopathic virus, a fulminating infection results and animals die from a mucosal disease syndrome associated with destruction of the gut epithelium, inflammatory lesions of the alimentary tract and depletion of lymphoid tissue in the Peyer's patches.

Pestivirus infection in ruminants has analogies with rubella in humans. Congenital infection of the fetus with rubella is a chronic nonlytic infection associated with little inflammation but severe multi-system congenital abnormalities; 80% of congenitally infected children shed the virus and can secrete virus for up to 20 months after birth. The mechanism of rubella teratogenesis is unknown; nor has it been established how rubella escapes immune elimination in these children. It is possible that this could arise either because of some impairment in the capacity to make high titer antirubella immunoglobulin G (IgG) perhaps through T cell tolerance. The presence of antibodies (either host or maternal) may also exacerbate the disease and cause immune-mediated damage. The latter is not seen in the congenital pestivirus infections in ruminants as there is no transplacental passage of antibody during fetal life. The ruminant pestiviruses provide a valuable animal model for congenital rubella as well as being challenging diseases of veterinary importance.

TOLERANCE, CENTRAL

Pawel Kisielow, Basel Institute for Immunology, Basel, Switzerland

Self-tolerance, a natural state of an organism characterized by the inability to mount an immune attack against the body's own tissue components, is achieved by many different 'central' and 'peripheral' mechanisms which supplement and complement each other. In this way imperfections of one mechanism may be corrected by another. Traditionally, the term 'central tolerance', as opposed to 'peripheral tolerance', has been used to describe a state which is established by mechanisms that operate during development of lymphocytes in primary lymphoid organs

(i.e. thymus and bone marrow) and prevent immature cells expressing self antigen-specific receptors from becoming functionally mature autoreactive T and B lymphocytes. However, recent results suggest that the mechanisms thought to operate only during selection of the primary repertoire of antigen receptor specificities are also active in germinal centers during selection of the secondary repertoire of antigen specific receptors. What do we know about these mechanisms?

Almost 40 years ago Joshua Lederberg suggested

that 'The suppression of maturation [of self antigen specific lymphocytes] is a sufficient attribute to account for tolerance and this need not involve so drastic an event as the destruction of the cell. However, the destruction by premature reaction can safely be invoked as the means of the suppression.' Experiments performed during the last 10 years, which used antigen receptor-specific monoclonal antibodies and T cell receptor (TCR) and B cell receptor (BCR) transgenic mice to trace the development of lymphocytes with defined specificity for self antigens, fully substantiated this prediction. Direct evidence was obtained that self antigen-induced death of immature T and B lymphocytes represents the main mechanism purging the immune system of autoreactivity but that other, more gentle ways of establishing central tolerance, for example anergy and 'receptor editing', are also involved (Figure 1). Studies of lymphocyte development in transgenic and gene-deficient 'knockout' mice carrying targeted mutations in genes of choice continue to have a great impact on our present understanding of the mechanisms responsible for the establishment of central tolerance. This understanding is however far from being complete and despite impressive progress in identifying cells, proteins and genes involved in preventing the maturation of self antigen-specific lymphocytes, the ability to induce central tolerance to

transplanted tissue or to self antigens causing auto-immunity, remains a desired but as yet unattainable goal.

The two key issues in studies concerned with the mechanisms of induction of central tolerance are: 1) the role of antigen-specific receptors (and other cell surface molecules involved in intercellular communication) in triggering the biochemical reactions, which prevent the development of immature self antigen-specific lymphocytes into functionally mature cells and 2) the identification and characterization of the molecular pathways triggered by antigen receptors at different stages of lymphocyte development, which underlie deletional and nondeletional mechanisms responsible for central tolerance (Figure 2).

Numerous investigations have shown that the outcome of TCR or BCR engagement on developing lymphocytes, i.e. death, anergy, developmental arrest, survival or induction of differentiation, depends on a multiplicity of factors which include: 1) the developmental stage at which the lymphocyte encounters self antigen, 2) the nature of the antigen-presenting cell, 3) the concentration and mode of presentation of self antigen, 4) the affinity and avidity of antigen-specific receptors and 5) involvement of coreceptors and other auxiliary molecules influencing the function of TCR and/or BCR.

Figure 1 Mechanisms of central tolerance. Central tolerance is established by negative selection which prevents immature self antigen-reactive lymphocytes from developing into mature autoreactive T and B cells. The main mechanism of negative selection is apoptosis but developmental arrest, receptor editing and anergy also play a role.

Figure 2 How immature lymphocytes expressing self antigen-specific TCRs or BCRs are prevented from maturation into functionally competent autoreactive T or B cells. This schematic, which purposely ignores the actual data, is intended to illustrate the complexity of intercellular and intermolecular interactions which are involved in deciding about the fate of immature autoreactive lymphocytes. Better understanding of the molecular mechanisms of central tolerance requires elucidation of the role of the everincreasing number of individual components of inter- and intracellular communication systems.

Central T cell tolerance

The bulk of the information on central tolerance comes from studies of intrathymic development of CD4⁺8⁺ and CD4⁺8⁻ T cells expressing $\alpha\beta$ TCR. By comparison, very little is known about tolerance induction during development of $\gamma\delta$ and CD4⁺8⁻ $\alpha\beta$ T cells.

Role of developmental stage

The $\alpha\beta$ TCR is first expressed at low levels on the surface of CD4⁺8⁺ (double positive, DP) thymocytes. DP thymocytes either die by apoptosis within 3 days from neglect (i.e. from the lack of TCR engagement) or are actively selected (either positively or negatively) by TCR ligands which consist of class I or class II major histocompatibility complex (MHC) molecules binding peptides derived from intracellular thymic proteins or from bloodborne antigens. Positive selection of DP thymocytes, a multistage process which involves rescue from programmed cell death

and induction of differentiation into single positive (SP) CD4⁺8⁻ and CD4⁺8⁺ cells, is accompanied by upregulation of TCR expression and by other phenotypic and functional changes. Several *in vitro* and *in vivo* experiments with TCR transgenic mice have shown that the same antigen which activates mature (HSA^{lo}, TCR^{hi}) SP thymocytes or T cells to perform their function, induces rapid apoptotic death of DP thymocytes expressing the same TCR. These results demonstrated that, as postulated by Lederberg, the developmental stage at which antigen is encountered is an important determinant of the lymphocyte fate.

Several approaches were used to identify more precisely the stage at which the developing cells become refractory to antigen-induced deletion. The important question was whether signals for positive selection induce resistance of DP thymocytes to antigen-mediated deletion. The results led to the conclusion that thymocytes undergoing positive selection remain susceptible to the rapid antigen-induced deletion until the 'semi-mature' SP (i.e. HSA^{hi},

TCR^{hi}) stage. However, the conditions and mechanisms responsible for deletion of DP and SP thymocytes seem to differ with regard to the dependency on Fas/FasL interaction and CD28-mediated costimulation. Since DP thymocytes reside in the cortex while SP thymocytes are found in the medulla, it is clear that negative selection can occur in both areas of the thymic architecture.

Recent studies by Kelsoe and colleagues suggest that in contrast to the majority of peripheral T cells, germinal center CD4⁺ T cells may undergo negative selection by mechanisms which usually affect immature thymocytes; i.e. they are very sensitive to the anti-TCR antibody-induced apoptosis and express the Nur77 transcription factor.

Role of antigen-presenting cells

The *in vitro* and *in vivo* studies demonstrated that not only bone marrow-derived cells, including thymocytes themselves, but also thymic epithelial cells, both cortical and medullary, have the capacity to induce negative selection of immature self antigen-reactive thymocytes. Thus, it seems that the ability to prevent maturation of self antigen-specific thymocytes is not restricted to the 'professional' bone marrow-derived antigen-presenting cells. However, the physiological relevance of the findings indicating the role of other cell types is not always clear.

Most evidence indicates that recognition of self antigen on different cells (dendritic cells, B cells, epithelial cells, thymocytes and fibroblasts) induces apoptosis and results in clonal deletion of thymocytes. However, induction of anergy in developing T cells, recognizing self antigens on thymic epithelial cells, was also reported. Despite intensive experimentation it remains unclear which factors determine whether deletion or anergy will be the outcome of antigen recognition by developing thymocytes.

Role of antigen concentration and mode of presentation

The concentration of antigen reaching the thymus is an important parameter. It was shown in several systems using different antigens (e.g. liver F protein, hen egg lysozyme, alloantigens or viral antigens) that suboptimal concentrations fail to induce full tolerance in the thymus and may be responsible for some forms of 'split tolerance'.

The role of the mode of antigen presentation in the process of negative selection is well exemplified by the results of two recent studies. One, analyzing T cell tolerance to C5, a complement component, demonstrated that exposure to circulating C5 completely deleted CD4⁺ SP thymocytes but caused only weak deletion of DP thymocytes. In contrast,

exposure to C5 in peptide form resulted in rapid elimination of DP cells. In another study it was shown that nuclear protein (β -gal) was able to induce tolerance in CD4⁺ T cells when expressed in medullary thymic epithelium which can use an MHC class II endogenous presentation pathway but not when expressed in bone marrow-derived cells which are unable to use this pathway. Tolerance in CD8⁺ T cells could be induced by both types of antigen-presenting cells.

Role of TCR affinity and avidity

According to the presently prevailing view, the most important factors determining the outcome of an interaction between immature thymocyte and stromal cells in the thymus are the affinity of the TCR for MHC-peptide complex and the number of TCRs engaged, both of which determine the 'strength' and kinetics of the interaction. In view of this so-called 'affinity/avidity model' of intrathymic T cell maturation, the complete lack of interaction or interactions below a certain threshold results in apoptosis from neglect; low-affinity/avidity interactions generate survival signals and result in positive selection, while high-affinity/avidity interactions generate death signals responsible for negative selection (Figure 3). Strong support for this model comes from investigations of the effects of altered peptide ligands (APLs) which indicate that TCR can interpret subtle structural changes in its ligand and selectively engage some parts, but not others, of its signaling machinery. Recent studies have assessed the role of different amounts of antagonist or agonist peptides in positive and negative selection of thymocytes and in mature T cell activation. The general conclusion from these studies seems to be that raising the concentration of peptides on MHC molecules above a certain threshold leads to negative rather than positive selection of thymocytes and that negative selection can be induced by T cell receptor interactions of a lower affinity than those required for full T cell activation. In agreement with the notion that the 'strength' of the TCR-ligand interaction plays the important role in determining the fate of developing thymocytes it was recently demonstrated that reduced expression levels of the male (H-Y) antigen-specific TCR in TCR transgenic CD3 ζ -deficient mice resulted in a shift from negative to positive selection of autoreactive T cells.

Role of other cell-interaction molecules

In addition to the TCR/MHC-peptide complex, several other pairs of molecules e.g. CD4/MHC-II, CD8/MHC-I, CD28/B7-2, CTLA-4/B7-1, LFA-1/CD54, CD2/CD58, Fas/FasL, gp39/CD40 and

Figure 3 Affinity/avidity model of negative and positive selection of immature thymocytes.

others, may be involved in interaction of thymocytes with antigen-presenting cells and may influence the outcome of antigen recognition. Thus far, the analysis of the role of cell-interaction molecules in negative selection of thymocytes has generated inconclusive and sometimes conflicting results. Studies in CD2, CD4, CD8, CD28, Fas, FasL, or gp39-deficient mice indicated that although some inhibition of antigen- or superantigen-mediated negative selection was observed in several cases (e.g. in CD4^{-/-}, CD8^{-/-} or gp39^{-/-} mice), none of these molecules appears to be absolutely required for the induction of central T cell tolerance. On the other hand, the requirement for a costimulatory signal from antigen-presenting cells was clearly demonstrated in *in vitro* studies, in which ligation of TCR alone was insufficient to induce apoptosis of DP thymocytes. Inconsistent results were obtained with regard to the role of CD28 molecules and the search for the molecules generating the secondary signal(s) required for negative selection of immature thymocytes continues.

Signals for negative selection of thymocytes

The biochemical reactions triggered by the engagement of TCR at different stages of thymocyte development hold the clue to understanding the nature of signals that prevent self antigen-reactive immature thymocytes from becoming functionally competent self-destructive T cells. The important questions are: 1) Are reactions triggered by ligands inducing different responses of developing thymocytes qualitatively or quantitatively different? 2) What is the role of the

individual components of the TCR/CD3 complex in sensing the difference between various negatively selecting and positively selecting ligands and in translating those differences into biochemical signals that activate appropriate cellular responses? 3) What is the role of signals mediated by other cell-interaction molecules or by glucocorticoid and cytokine receptors in modifying the TCR-mediated signals? 4) What genes mediate apoptosis and nondeletional forms of negative selection of thymocytes? Although the complete answers to these questions are lacking, the progress in providing partial answers is breathtaking and can be summarized here only briefly.

Three types of approach have been used to investigate the role of various intracellular proteins in transducing signals for negative selection: pharmacological inhibition, targeted inactivation of genes and transgenic expression of mutated, dominant negative proteins. As a result, the evidence is accumulating that negatively selecting ligands may induce qualitatively different biochemical reactions from those induced by positively selecting ligands. It was shown for example, that a transgene encoding a dominant-negative p21^{ras} protein substantially blocked TCR-mediated positive selection without compromising the negative selection of thymocytes. Moreover, the results of another study suggest that the JAK3 Janus kinase plays a crucial role in negative but not in positive selection of thymocytes. Recent experiments suggest also that cyclosporine-sensitive signaling pathways mediated by calcineurin are important for positive but not negative selection.

It is now clear that the TCR/CD3 complex consists of more than one signal transducing 'modules' but it is unclear whether there are any functional differences between signals mediated by distinct CD3 components. The notion that selective engagement of different signal-transducing modules by positively or negatively selecting ligands could play a role in determining the fate of developing thymocytes remains an attractive but as yet unverified possibility.

Recently, an interesting new insight was obtained into the role of glucocorticoids. The observations suggest that endogenously produced steroids can antagonize TCR-mediated deletion. It was proposed that glucocorticoids kill thymocytes whose TCRs are not engaged but protect those which interact with MHC ligands with moderate avidity. According to this scenario, deletion of thymocytes that engage TCRs at high avidity would result from overriding the steroid/TCR antagonism by strong TCR-mediated signals or from a synergistic effect of glucocorticoids above a certain threshold of TCR avidity.

A synergistic role of stromal cytokines released in response to TCR-mediated activation of immature thymocytes has been suggested by a recent study by Rheinherz and colleagues. They found that prior to undergoing apoptosis DP thymocytes secrete cytokines which activate the surrounding thymic stroma to produce factors (e.g. IL-1 and Mig) which may be required for apoptosis. This observation provides an interesting example for the involvement of thymocyte-stroma cross-talk during the negative selection process.

The products of several genes have been proposed to act as intracellular mediators of lymphocyte apoptosis including p53, nur77, *c-myc* and interleukin-1B-converting enzyme (ICE) but their role in mediating the physiological process of negative selection is poorly understood. The list of other genes and gene products which have been implicated in the intracellular propagation or inhibition of signals leading to lymphocyte death is presented in Table 1. Currently there is much interest in the proteins belonging to the Bcl-2 family but despite rapid progress in clarifying the intricacies of the interactions between Bcl-2, Bax, Bad, Bcl-x_L and Bcl-x_S molecules, the mechanism by which this family of proteins regulate the balance between death and survival is not yet understood. The results obtained so far suggest that multiple death pathways regulated by distinct molecular mechanisms may be responsible for elimination of immature self antigen-reactive T and B cells.

Table 1 An incomplete alphabetical list of genes and gene products implicated in the regulation of apoptosis in lymphocytes, which may play a role in establishing central tolerance

Central B cell tolerance

Although there were suggestions in the literature that there may be no need for the central B cell tolerance because without T cell help B cells cannot respond to the majority of antigens, the results of studies, which became possible mainly due to the introduction of BCR transgenic models, provided clear evidence that immature self antigen-reactive B cells are usually prevented from maturation into autoreactive cells.

Since, as in the case of T cells, normal development of immature B cells depends on the unperturbed expression of BCRs and the molecular mechanisms responsible for the generation of diversity of TCRs and BCRs are essentially similar, the basic questions concerning central B cell tolerance are very much the same as those discussed above in relation to central T cell tolerance. The developmental stage of the B lymphocyte, BCR affinity, the antigen valency, concentration and mode of presentation, all have been shown to play a role in determining the outcome of self antigen recognition, i.e. whether developmental arrest, anergy or deletion will ensue. In fact, the

intracellular molecular mechanisms preventing maturation of self reactive B and T lymphocytes may be to a large extent identical as suggested by the observation that many molecules implicated in the regulation of signals mediating negative selection (e.g. *c-myc*, Bcl- x_s , Bad, p53 and others) are active during development of both lymphocyte lineages. The main differences in the mechanisms leading to central tolerance of B cells and T cells seem to exist at the level of antigen recognition and reflect differences in the structure of the antigen receptor, the nature of the ligand and the nature of accessory molecules involved during interactions between developing B cells and stromal cells.

An interesting example of a mechanism which seems to be specifically responsible for central B cell tolerance is the phenomenon of receptor editing. It has been observed in some systems that self-reactive B cells may undergo additional immunoglobulin gene rearrangements in response to encountering self antigen in the bone marrow. Such secondary rearrangements, which usually occur at the light chain locus, rescue immature autoreactive B cells from death by replacing the original receptor with a new receptor of different specificity. Thus, receptor editing may provide an alternative to antigen-induced apoptosis, which is believed to represent the main mechanism of central tolerance.

It has been recently demonstrated that not only immature B cells in the bone marrow but also germinal center B cells can be negatively selected by ligands which bind to their BCRs. Interestingly, there is a striking similarity between deletion-sensitive germinal center B cells and immature bone marrow B cells, which is reflected by the expression of high levels of HSA molecules and re-expression of recombination activating (RAG) genes. This indicates that mechanisms responsible for central tolerance are not confined to the immature stages of lymphocyte development but may also affect naive mature lymphocytes, which as a result of antigen recognition change or refine the specificity of their receptors and in so doing increase the risk of autoreactivity.

TOLERANCE, MODELS

William O Weigle, Department of Immunology, The Scripps Research Institute, La Jolla, California, USA

Immunological tolerance defines a number of phenomena characterized by an antigen-specific unresponsive state. These unresponsive states are antigen driven in that they require exposure to antigen for induction and continuous presence of antigen for their persistence. Tolerance may be characterized by anergy (T or B cell), deletion or suppressor mechanisms. The latter results from regulatory mechanisms within the system rather than an inherent tolerant state and will not be discussed in this entry. Tolerance, in the form of immunological ignorance, may also apply to sequestered antigens which never contact the immune system in either a tolerogenic or immunogenic fashion. Models of primary importance are those induced in neonatal animals, mature (both conventional and transgenic) animals and *in vitro*. Induction of tolerance is most readily achieved in neonatal animals because of the lack of an environment which supports immune responses. That neonates lend themselves to the induction of tolerance to more complicated antigens such as cells is best seen following the injection of living hematopoietic cells, which results in the establishment of a chimeric state. Neonates are also readily tolerized with serum protein antigens and probably with any antigen that tolerizes mature animals. It has also been long known that neonatal lymphocytes are competent when presented with antigen in an adequate environment. Tolerance can be readily induced under the proper conditions in mature animals using either protein preparations that do not activate antigen-presenting cells or peptides that do not require antigen processing.

Induction in mature animals

Although it is well-established that a system of negative and positive selection occurs in the thymus, resulting in shaping of a nonself-reactive T cell repertoire, tolerance can also be induced to foreign antigens either in early or late life under the appropriate conditions. The finding that certain V_{β} specificities of the T cell receptors that are reactive *in vitro* to self antigens are absent in mice possessing these antigens has led to a number of recent and important studies that have given considerable insight to self-nonself recognition. Later studies using a variety of superantigens which activate an entire T cell population expressing the same V_{β} T cell receptor, irres-

pective of antigenic specificity, also demonstrated that *in vivo* exposure to these superantigens results in the elimination of these cells. The models resulting from such studies yield valuable information concerning immunogenetics of tolerance induction, possible mechanisms of negative and positive selection within the thymus and T cell anergy.

These latter models, however, do not readily lend themselves to understanding the mechanisms of tolerance induction involving the cytokine cascade, antigen presentation, roles of activation events and intracellular biochemical processes as well as the role of antigen processing. Another model, the unresponsive state induced in adult mice to monomeric forms of mammalian gamma globulin, more readily lends itself to the investigation of these latter events. An *in vivo* model of a central unresponsive state is presented in this review to delineate the conditions required for the induction and maintenance of self tolerance and the role of such induction and maintenance on susceptibility to autoimmunity.

A classical *in vivo* model of tolerance which mimics a number of aspects of self tolerance has been studied in the past by several groups of workers using monomeric preparations of mammalian gamma globulin. In the model to be discussed below, tolerance is induced to human gamma globulin (HGG) by a single injection of adult mice with deaggregated (monomeric) HGG (DHGG). Furthermore, tolerance to HGG is also readily induced in neonatal mice. Adult treated mice fail to respond to a subsequent injection of aggregated HGG (AHGG) at both the T helper and B cell levels. However, as much as 2–3 logs less HGG are required to induce tolerance in T helper cells than in B cells (Figure 1). This observation suggests that tolerance to self antigens present in limited concentration may exist in only the T cell compartment, and, thus, has implications in antibody-induced autoimmunity. Although it is not known whether tolerance in this model is the result of anergy or deletion, it is independent of both suppressor cell activity and Fc γ receptor expression. Of particular interest is that antigen-specific T cell proliferation, T helper function, antibody production and cytokine release are tolerized by prior injection of DHGG. This tolerance is independent of the thymus, since it can be induced in adult thymectomized as well as normal mice. Fol-

Figure 1 Effect of deaggregated human gamma globulin (DHGG) dose on the induction of tolerance to aggregated HGG (AHGG) in mouse T helper cells and B cells.

lowing a single injection of the tolerogen, tolerance to immunogenic challenge is induced in B cells and all subsets of T cells capable of releasing cytokines upon *in vitro* stimulation. The down side of this model is that purified preparations of HGG (immunoglobulin G1, IgG1) rendered monomeric by ultracentrifugation (at 4°C) are required. These preparations are relatively unstable and aggregate over a relatively short period of time.

Antigen presentation in tolerance induction

It is most likely that the nature of the antigen-presenting cells plays a critical role in the induction of tolerance as it does in the immune response. It is well accepted that resting B cells are very poor antigen-presenting cells (APCs) and readily lend themselves to the induction of tolerance in both *in vivo* and *in vitro* models. The targeting of antigen to B cells with Fab fragments specific for B cell receptors leads to a sound induction of tolerance in the T cell compartment. However, it is unlikely that resting B cells are obligate APCs, while macrophages and/or dendritic cells (and antigen-activated B cells) can present antigen only in an immunogenic fashion. It has been recently demonstrated that tolerance can readily be produced in all T cell subsets in B cell-deficient (knockout) mice tolerized with DHGG or superantigens. These findings argue that every APC has the ability to present antigen either in a tolerogenic or immunogenic fashion depending on such factors as form of the antigen, route of antigen administration and the presence of cytokines released by activated APCs. It is likely that the APCs that initiate T cell activation are dendritic cells with macrophages and B cells participating in the expansion of T cell subsets.

Role of antigen (tolerogen) dose on the immune status of T helper and B cells

The differential effect of tolerogen dose on T helper and B cells is reflected in the duration of tolerance induced with a given dose of DHGG. Thus, T cells remain tolerant for a considerably longer period of time than do B cells, probably because of the dependency of the tolerant state on the continued presence of DHGG tolerogen in both cell types. Following injection, DHGG equilibrates in equal concentrations between the intra- and extravascular fluid spaces of mice and is catabolized with a half-life of approximately 8 days. After an appropriate decrease of DHGG resulting from catabolism, there is a period of time when tolerance exists in the T helper cell after competent B cells have reappeared. This suggestion is supported by the ability to induce an anti-HGG response in mice late in tolerance at a time when T helper cells are tolerant but competent B cells are present, with injections of lipopolysaccharide along with aggregated HGG (AHGG). Using multiple injections of bovine serum albumin (BSA), a dual dose tolerance has been reported in which low doses of BSA induce a state of tolerance, an intermediate dose induces immunity, with tolerance reappearing at higher doses. This phenomenon has been explained by the following mechanism: At low doses of antigen the specific B cells would preferentially pick up antigen through high-affinity binding by antigen-specific surface Ig. Because resting B cells do not express appropriate costimulatory signals, any interaction with an antigen-specific virgin T cell would be tolerogenic. At an increased antigen concentration uptake by other MHC class II-positive cells would occur. These cells of the so-called professional antigen-presenting cells would present antigen to the virgin T cells in an immunogenic fashion. At high antigen concentration all B cells would take up antigen by pinocytosis. Since B cells far outnumber other MHC class II-positive cell types, the results would again be tolerance of the virgin T cells. This explanation presumes that 1) only B cells are able to induce T cell tolerance; 2) B cells are tolerogenic even in the presence of specific antigen; and 3) all non-B cell antigen-presenting cells activated virgin T cells constitutively. These assumptions provide a firm framework explaining the midrange, immunogenic dose of antigen and imply that a B cell-deficient animal would not be able to induce T cell tolerance. However, the fact that T cells from B cell-deficient mice given DHGG are tolerized rather than activated indicates that tolerance cannot be explained by the above hypothesis. Actually there is no evidence for two zones of tolerance to HGG over a wide range

of tolerogen doses (10 mg per mouse to 5 µg per mouse).

Modulation of tolerance by cytokines

It is well-established that lipopolysaccharide (LPS) and other activators of interleukin-1 (IL-1) production injected along with the DHGG convert a tolerogenic signal into an immunogenic signal as well as inhibit the induction of tolerance, resulting in both T helper cell activity and antibody production. Similar modulation of tolerance with LPS has been suggested with superantigens. Furthermore, with the HGG-mouse model, *in vitro* exposure of antigen-presenting cells with AHGG (immunogen) results in aggressive processing and secretion of IL-1, whereas *in vitro* presentation of monomeric HGG fails to result in aggressive processing and cytokines are not released. Thus, it seems reasonable to suggest for the HGG-mouse model that tolerance results in a failure to activate APCs and cytokines are not released and the lymphokine cascade is not activated. Whether inhibition of induction of tolerance with IL-1 (and tumor necrosis factor α , TNF α) results from direct interaction with T cells or their precursors or whether such cytokines upregulate costimulatory molecules is unknown at the present time.

Clonal deletion versus anergy

Although it is firmly established that anergy occurs *in vitro* in both B cells and antigen-specific T cell lines, the nature of the tolerant state induced *in vitro* is still debatable. Original studies using double transgenic mice, transgenic for both the antigen and the antigen-specific antibody (targeted to the B cells), suggested anergy as a mechanism of B cell tolerance. However, in later experiments in which the endogenous/transgenic ratio of B cells was increased, transgenic B cells were competitively deleted in the T cell area of the follicles. Similarly it was demonstrated that in transgenic mice in which a large (70%) portion of the B cells carried IgM rheumatoid factor (IgM-RF) specific for human IgG, injection of DHGG resulted in deletion of the IgM-RF⁺ B cells with the same kinetics as for antigen-specific B cell function deleted in conventional mice tolerized with DHGG. Antigen-specific T cell receptor (TCR) transgenic mice have also lent themselves to the question of deletion or anergy. Although some of these models have not been adequate to answer this question, others have given considerable insight into the roles of anergy and deletion in tolerance induced to peptide antigens. Although it is not clear whether

deletion is the only mechanism in tolerance, the most recent studies suggest that following injection of peptide, deletion occurs in the thymus without T cell activation, whereas T cell activation may precede deletion observed in peripheral T cells. Although deletion appears to be a major form of tolerance induced to superantigens, such deletion may be preceded by T cell expansion.

Generation of effective immune responsiveness requires professional antigen presentation to T cells and cross-talk between helper cells and B cells. In each of these steps, the interacting cells both deliver signals and receive back-stimulation. Simply stated, this view of the immune system provides an overview not only for the generation of positive immune responsiveness (antibody formation, delayed hypersensitivity), but also for unresponsiveness or tolerance. As summarized in current versions of the two-signal hypothesis of Bretscher and Cohn, both recognition of antigen (signal one) and a second, costimulatory signal (signal two) are required for a positive immune response. Lacking such a second signal, the antigen-recognizing cells are rendered unresponsive. This may reflect the deletion of these cells via programmed cell death (apoptosis) or their anergy (functionally unresponsive but still alive).

Moreover, lymphocytes must be both positively and negatively selected in the thymus in terms of self-reactivity. Purging of the immune repertoire in the thymus is the first step in the process of tolerance. Thus, during the development of the immune system both *in utero* and after birth, T cells in the thymus are exposed to a variety of (self) peptides in conjunction with self histocompatibility (MHC) antigens. Peptides that do not appear in the thymus or fail to bind to self MHC do not participate in this process. Such peptides are either ignored by the immune system, stimulate an immune response if costimulation is provided, or induce tolerance peripherally if signal two is lacking. The ultimate result of this process also may be apoptosis or anergy.

History of tolerance

The ability to distinguish self from nonself (tolerance) is one of the basic tenets of immunology. As early as in the 1900s, Paul Ehrlich recognized the importance of this concept when he coined the term 'horror autotoxicus' (fear of poisoning oneself) to indicate the potential results of making an immune response against self components. However, it was not until four decades later that an experiment of nature provided a theoretical basis and explanation for this 'self-tolerance'. Thus, Ray Owen demonstrated that dizygotic (fraternal) cattle twins, which shared a blood supply *in utero*, possessed and tolerated red cells from their nonidentical twin. Sub-

sequently, it was shown that skin grafts could be reciprocally exchanged between these twins. It was suggested that the critical exposure to 'nonself' antigens during development (and their persistence as a chimeric state) led to tolerance to these antigens. Indeed, Burnet originally proposed in 1949 that any clones exposed to their specific antigen during this time would be eliminated.

Experimental verification of these predictions came in 1953 through the classic experiments of Billingham, Brent and Medawar. They demonstrated that perinatal exposure of mice to allogeneic lymphoid cells led to subsequent acceptance (tolerance) of skin grafts from the same strains that the mice were exposed to at birth; these animals still rejected skin grafts from other strains. Thus, this tolerance is *learned* and is *specific*. This phenomenon has been repeatedly confirmed and has led to a definition of tolerance as 'a specific unresponsive state induced by prior exposure to an antigen'.

Properties of unresponsiveness

Further analysis of experimental tolerance systems with a variety of antigens has verified that tolerance is not only specific, but is also dose-dependent and of finite duration. Indeed, early attempts to induce tolerance with nonreplicating antigens failed in part because the initial dose of antigen did not establish a persistent state of chimerism as in the Medawar experiments or the dose of antigens was insufficient to render the host unresponsive.

Tolerance, as such, generally represents a central failure of the immune system (with the exception of active suppression) and can be transferred with lymphocytes from unresponsive hosts to irradiated recipients just as secondary responsiveness can be adoptively transferred with primed lymphocytes. This unresponsive state is manifested in both T and B lymphocytes; indeed, Chiller and Weigle in now classic experiments showed that the kinetics, dose requirements and persistence of tolerance for T and B cells were different. For example, T cell unresponsiveness is more readily induced than B cell tolerance in terms of more rapid induction kinetics and lower dose requirements. Moreover, T cell tolerance lasts longer. This may, in part, be due to the relatively shorter half-life of B cells versus the time requirements to generate mature T cells from the thymus.

We will return briefly to (central) tolerance induction within the thymus later.

In addition, in experimental systems of tolerance induction, a small, detectable response is often obtained. When examined carefully, this response is often of low affinity for the tolerated antigen. Such a result is not surprising since the cells which would be most likely to be rendered tolerant would be those with the highest binding activity for antigen; thus, only the least avid cells would be spared. Therefore, it is not surprising that low-affinity autoantibodies can often be detected in normal human serum. These are usually of no pathological consequence and probably represent stimulation of cross-reactive clones against some extrinsic antigen that leads to a response with a low affinity for self.

It is assumed from the foregoing that tolerance represents the functional, if not physical, deletion of specific lymphocytes and that the waning of tolerance reflects the generation of new B and T cells in the absence of sufficient antigen to tolerize newly developing lymphocytes. Evidence supporting this notion has come from manipulation of either the amount of available antigen or the ability to generate new cells via the thymus.

Factors affecting tolerance

From the foregoing, it is clear that tolerance is a process that continues throughout life but begins during fetal development. Hence, experimental induction of unresponsiveness is easiest in fetal, neonatal or perinatal animals. Why? One theory is that these cells are the most immature and do not possess the appropriate costimulatory signals to become activated for a productive immune response. Any antigen to which these immature cells express receptors, upon exposure, will cause them to become tolerant. Thus, in some views, this is an obligate stage for tolerance induction. An alternate view is that, while highly sensitive to tolerance at this stage, there is little chance to receive 'signal two' in this milieu. The nature of these signals in the thymus is a source of great debate, but recent developments suggest that some of the normal signal-transducing mechanisms are involved (see below).

The conditions which favor tolerance not only shed light on the manipulation of responsiveness in disease states, but also provide insight into the multiple pathways employed in avoiding the horrors of 'autotoxicus' and regulating the level of responsiveness to extrinsic antigens *per se*. For example, while tolerance as stated above is more readily induced in immature lymphocytes, it can be induced experimentally in adult animals. It is most effectively induced

with systemic exposure to an antigen; this allows sufficient antigen to reach all antigen-specific B and T cells rapidly. Local administration, as in a natural exposure via the skin to the draining lymph nodes, instead stimulates priming for an immune response perhaps due to the nature and strength of costimulation on the antigen-presenting cells and the available inflammatory cytokines. Similarly, deaggregated antigens and those epitopes coupled to known self carriers, especially gamma globulins, also favor tolerance induction, even in adults. Whether these conditions also preclude costimulatory signals or promote inhibitory pathways like Fc receptor feedback remains to be resolved.

Mechanisms of responsiveness

Four broad-spectrum mechanisms have been proposed over the years to account for T and B cell tolerance (Figure 1): *deletion* of reactive clones; *clonal anergy*, in which specific lymphocytes are present but functionally inactive; T cell-mediated *suppression* of T or B cell responsiveness; and finally, *ignorance* of certain antigens that may be sequestered from the immune system. These mechanisms need not be mutually exclusive; however, no direct evidence for any of these was available for self-tolerance until recently. Transgenic models have been critical in unraveling these pathways.

In order to understand these mechanisms, one must first appreciate the developmental stages in lymphocyte maturation, especially since immature cells appear to be the most tolerance susceptible. Both B and T cells arise from pluripotential stem cells in the fetal liver and later from stem cells in the bone marrow. Stem cells (prethymocytes) migrate to the thymus (Figure 1) where they undergo a series of maturational steps, the most important of which is the rearrangement of the α and β chains, for example, of the T cell receptor (TCR). These T cells must be positively selected for self-MHC restriction and negatively selected for tolerance.

What happens to these cells as they are 'negatively selected'? Evidence from both normal and transgenic mice suggests that clonal deletion is one of the primary mechanisms for immature T cell tolerance. For example, in mice lacking the class II MHC antigen I-E, approximately 15% of the T cells in the thymus express an $\alpha\beta$ TCR using a specific V_β gene segment (designated $V_{\beta 17a}$). Strains of mice that express the I-E antigen lack the idiotype formed by this $V_{\beta 17a}$ in their mature T cells, but express it at low density in their immature $CD4^+$, $CD8^+$ thymocytes. Interestingly, F1 hybrids of I-A⁺ and I-E⁻ strains, which will codominantly express I-E, are also $V_{\beta 17a}$

Figure 1 Schematic representation of the pathways of B and T cell tolerance. Once rearrangement of Ig genes occurs in pre-B cells in the bone marrow and IgM is expressed, these early IgM-positive B cells are sensitive to tolerance via both deletional and anergic mechanisms, depending on the nature of the antigen. Following maturation, lymphocytes migrate to the periphery (lymph node and spleen), where anergy, deletion and perhaps suppression act as tolerance mechanisms. In both cases, cognate interaction with T cells and the deliverance of costimulation and lymphokine signals may overcome tolerance induction and lead to antibody formation, including autoantibodies. Similarly for T cells, maturing CD4⁺, CD8⁻ immature T cells are deleted in the thymus, but peripheral T cells may undergo a tolerogenic mechanism leading to an anergic state of apoptosis when exposed to peptides in the absence or costimulation.

negative in the mature T cell pool, but possess V_{β17a}-positive immature lymphocytes. This suggests that expression of I-E leads to deletion of T cells bearing a particular TCR-V_β as they transit to a mature stage.

In analogy to this process in T cells, the B cell repertoire is generated by V gene arrangements during development. Thus, immunoglobulin H and L chains rearrange in pre-B cells in the marrow to give clones of antigen-specific B cells expressing, initially, immunoglobulin M (IgM). In B cells, however, it has been harder to obtain direct evidence for a deletional event for tolerance since there is no predominant usage of a particular V region in these cells. Nonetheless, it has been assumed that immature B cells with rearranged receptors binding self antigens with high affinity are clonally deleted based on data from three systems: the elimination of B cells by anti-IgM treatment of neonatal mice, the antireceptor-induced death of immature B cell lymphomas and a loss of specific B cells in transgenic mice expressing IgM receptors for self MHC antigen. In the last system, Nemazee and colleagues created transgenic mice in which a large number of the B cells bore IgM receptors which were specific for the membrane class I histocompatibility antigen, H-2K^k. When bred to an H-2^k mouse to induce tolerance in these anti-H-2K^k-specific B cells, the IgM-transgenic cells were deleted at an immature stage. It is worth noting that this deletional mechanism may depend on the nature of the antigen (membrane versus soluble) or on the maturity of the B cells when first exposed to tolerogen (see below).

Further data from the laboratories of Nossal and Scott and their colleagues showed that mice rendered

tolerant as adults still possessed B cells with free receptors for the tolerated antigen. These were not cells of low affinity, as is often observed with anti-self-reactive B cells in humans. Rather, these were high-affinity cells which were simply anergic to stimulation by antigen and appeared to be blocked at the G₁/S boundary of the cell cycle. More definitive evidence came from another transgenic model, this time one in which all B cells expressed IgM and IgD receptors for a peptide from hen egg lysozyme (HEL). When these mice are bred to lysozyme-transgenic animals, tolerance to HEL is produced. Interestingly, normal numbers of lysozyme-reactive B cells were still present in these double transgenic mice. However, their now anergic (tolerant) B cells had an altered phenotype: they had lost most of their IgM yet retained membrane IgD. This system differs from the deletional model above in terms of both the nature of the antigen and the fact that target B cells express both IgM and IgD, that is, they are mature B cells. More recent experiments suggest that a membrane form of lysozyme causes deletion in anti-HEL transgenics, regardless of IgM/IgD isotype expression, and that this can occur as anergic B cells traverse into the follicles of the nodes. Additional data with another transgenic model suggest that supercrosslinking of transitional cells with IgM and little or no IgD led to deletion. Thus, it appears that multiple pathways for B cell tolerance are probably due to the diversity of antigens that can be considered 'self' and the fact that cells may be exposed to tolerogens at different maturational stages.

Furthermore, there must be mechanisms to assure that potential antiself activities that arise from

somatic mutation during an immune response are silenced. Evidence from Klinman's laboratory suggests that secondary lineage B cells indeed pass through a 'tolerance susceptible window' after the initiation of an immune response. This would ensure that potentially high-affinity cells were eliminated from the repertoire, either functionally or physically.

Additional experimental data suggest that a form of clonal anergy may also be induced in T, as well as B, cells. Schwartz and his collaborators demonstrated that interleukin 2 (IL-2)-producing CD4⁺ T cell helper (T_H1) clones were rendered anergic if exposed to an 'inert' antigen-MHC complex such as fixed macrophages, presumably due to the lack of costimulatory second signals provided by viable, professional antigen-presenting cells (APCs). These anergic T cells fail to produce IL-2 when subsequently appropriately stimulated. Similar results have been reported by Gilbert and Weigle for T_H2 helper cells treated in the same way and later measured for their functional capacity to help B cells produce antibody.

How do we explain these disparate results in terms of anergy versus deletion? As stated above, one possibility with respect to B cell tolerance is that different antigens were involved, some soluble and others membrane bound. Alternatively, the maturity of the target B cell (IgM expressing B cells are deleted versus IgM + IgD-bearing cells are rendered anergic) could be an explanation. Indeed, with respect to T cell tolerance, there are clear differences in mechanisms and maturational states between double-positive immature thymocytes and mature T_H1 clones, the former being 'deletable', the latter becoming anergic. Moreover, further control pathways for clonal expansion may result in deletion of reactive clones via a Fas-dependent pathway. Thus, the mechanism of tolerance may depend both on the maturity or subset of target cells, as well as the nature of the antigen.

In all cases, therefore, one unifying tenet occurs: exposure to antigen at an inappropriate stage of development or in the absence of costimulation leads to tolerance. Provision of a positive costimulatory signal often overcomes the initial negative signal.

Where does suppression fit into all of this? Fifteen years ago, the activity of suppressor T cells in experimental tolerance systems was under intense investigation. The difficulty in cloning these T cells, as well as the lack of strong molecular evidence on the nature of their TCR, has made it difficult to analyze the activity of these cells. Recent data suggest, however, that at least some cells with suppressive properties bear a normal CD3-linked TCR complex. Indeed, it appears that under certain circumstances normal T

cell clones can effect suppression of B cell differentiation or other T cell activity. Thus, T_H1 cells secreting interferon γ or lymphotoxin (TNF β) may inhibit B cell differentiation whereas T_H2 clones may be directly cytotoxic for antigen-presenting cells displaying peptide + class II MHC on their surface. However, it is now clear that not all self antigens are tolerated via the same mechanism, a conclusion which makes teleological sense due to the variety of antigens and their distribution and concentration in the body.

Sites of peripheral tolerance induction

It is clear that the B cell repertoire is generated in two phases and that tolerance induction must occur at both levels: that of the immature B cell in the bone marrow and later in the periphery in the lymph nodes and spleen. Indeed, this can occur in the latter case both at initial antigen contact (in the absence of costimulation), as well as in the germinal centers during somatic hypermutation before a secondary response (see below). Similarly, while T cell repertoire development goes through positive and negative selection in the thymus, there must be some degree of regulation as peripheral tolerance in various nodes in the body.

The lack of costimulatory molecules on certain cells in the periphery that may be induced to express class II MHC antigens (e.g. by viral infection and interferon production) and present endogenous peptides makes these cells excellent candidates for tolerogenic APCs. Such 'nonprofessional' APCs could present antigenic peptides to T cells virtually anywhere they arise in the body, assuming a reasonable lymphatic or capillary access to those tissues. It is most likely, however, that this presentation occurs in the lymph nodes especially if resting B cells are the presenting APCs. In some cases, immature (less differentiated) dendritic cells could subserve this same function in the white pulp periarteriolar lymphatic sheaths (PALS) in the spleen or the paracortex of the peripheral nodes. It is not clear whether this process occurs elsewhere (such as in mucosal tissues). Suffice it to say that oral exposure to antigens leads to presentation in the gut and preferential skewing of responsiveness to T_H2, due for example to local production of transforming growth factor β (TGF β). At the systemic level, this may be expressed as peripheral T_H1 tolerance or even suppression. It is likely that this reflects differential cytokine profiles as a consequence of alternative antigen presentation pathways, although the mechanism is not known. In addition, the potential for peripheral deletion to occur in tissues with high levels of Fas ligand (FasL;

such as in privileged sites such as the eye or testis) needs to be considered.

An elegant model system to examine specific niches in which peripheral tolerance occurs was described by Goodnow and colleagues, using the HEL/anti-HEL transgenic model system. In one situation, they used heavy-chain-only transgenic mice so that the rearranged heavy chain could pair with endogenous light chains in the peripheral pool. This gave rise to HEL-binding B cells of various affinities but at a high enough frequency to be detected *in vivo*. By crossing these Ig receptor transgenic animals with HEL-producing mice, they could determine the relationship between affinity, antigen concentration and the fate of these HEL-specific B cells in the periphery. Their studies not only confirmed this relationship, they also showed that there was a competition between the transgenic 'autoreactive' B cells and the endogenous repertoire for space. That is, if mice contained 100% transgenic B cells, their tissue distribution was similar to B cells in normal mice even when the autoantigen (soluble HEL) was plentiful. But if normal B cells were in excess and antigen was present, these cells failed to enter the follicles in the lymph nodes. Thus, there is a gate, so to speak, that prevents autoreactive B cells (exposed to antigen) from entering the follicles and forming germinal centers. This makes sense since the germinal centers are sites of extensive proliferation and the potential to undergo somatic hypermutation, would be a dangerous event for the host in terms of forming high-affinity autoantibodies.

How does the 'gatekeeping' occur? One likely mechanism is via Fas and Fas ligand. Data from the same group show that FasL on T cells may be acting to delete those B cells that have upregulated their surface expression of Fas, for example by CD40 interaction. Curiously, binding to membrane immunoglobulin M has been shown by Rothstein's group to block susceptibility of those B cells in terms of their susceptibility to undergo a FasL-mediated death signal. This creates a dynamic battle in which antigen-specific and nonantigen-specific signals determine the fate of B cells to survive in a peripheral tolerance pathway depending on which signals predominate, as well as when and where they are delivered as antigen-specific cells sojourn in a lymph node.

Signals for anergy and apoptosis

What is the nature of the negative signals for tolerance? Initial stimulation of both T and B cells involve receptor coupling via Src family protein tyrosine kinases (PTKs), e.g. to phospholipase C and the production of inositol phospholipids, some of which

lead to calcium mobilization, and other products cause activation of protein kinase C and subsequent phosphorylation of critical substrates leading to gene transcription. Other downstream substrates involve MAP kinase activation and both common and alternative transcriptional events. Studies in T cell clones suggest that if the initial calcium signal is given alone or abortively, then the T cell is rendered anergic. Whether this process can be mimicked in B cells remains to be determined although the idea that abortive stimulation of B cells in the absence of costimulation via T cell help is not only appealing, but consistent with several models. One paradigm that has developed is that there is great commonality between negative signals for tolerance (growth arrest, anergy, apoptosis) and the initial positive signals in lymphocyte stimulation. The two-signal hypothesis indeed proposes that it is the second signal that is the determining factor.

Therefore, what is the nature of positive costimulation? As summarized in Figure 1, T cells recognize costimulatory molecules of the B-7 family via the CD28 and CTLA-4 receptors. Blocking these interactions can modulate a stimulatory response towards tolerance; indeed, clinical trials in this direction are in progress. For B cells, the CD40 receptor can positively signal for their growth and differentiation via T cell CD40L and can overcome tolerogenic (signal 1) stimuli. The precise nature of the biochemical signals is unclear, but is likely to involve kinase activation and a balance of interacting transcription factors. Understanding this balance will provide new approaches for clinical tolerance induction.

Loss of unresponsiveness: role in autoimmunity

It is important to consider that tolerance, once induced, may not persist forever and can be broken. Some source of persisting antigen must continue to render newly emerging B and T cells tolerant. Indeed, it is likely that T cell tolerance is more critical since most protein antigens require T cell help in order to activate a humoral immune response. Nonetheless, as already mentioned, it would be undesirable for B cells not to be tolerant and to mutate toward high-affinity antiself receptors. It is also conceivable, under conditions of acute or persistent viral infection, that nonspecific T cell help may be generated that could activate any nontolerant antiself B cells.

One possibility is that tolerance to self antigens is broken because available antigen is modified (e.g. via viral infection that creates new epitopes or induces class II MHC markers via interferon γ or other inflammatory cytokines). A novel concept recently

put forth by Matzinger and her colleagues is that there is no real distinction between 'self' and 'non-self', but only a response to 'danger', which is clearly present during inflammation or at other sites of non-apoptotic cell death. Any self peptide presented (with costimulation) in the presence of inflammatory cytokines would then be reacted against as violently as would a viral invader. This has been referred to as 'signal three'. It is also possible that autoreactive B cells may be generated in the absence of sufficient self antigen to tolerize. Alternatively, a mutation to a high-affinity antiself receptor could occur in developing B or T cells in the absence of tolerizing signals, especially in later life. Note that these hypotheses are not mutually exclusive.

Induction of class II MHC antigens on cells which normally do not express these determinants, can lead to T cell recognition (since they may never have been rendered tolerant to tissue-specific antigens if they are not expressed on class II-positive APCs). This inappropriate activation may lead to tissue-specific autoimmunity, but it is not clear whether class II expression in these diseases is the result rather than the cause of autoimmunity. Indeed, experiments in transgenic mice with class II expression under the control of the insulin promoter, so that I-E is expressed on pancreatic β cells, showed that these β cells were tolerogenic rather than immunogenic, arguing against aberrant expression of MHC class II as a trigger of autoimmunity.

TOXINS

John Stephen, School of Biological Sciences, The University of Birmingham, Birmingham, UK

The development of antitoxin therapy stemmed from observations by Loeffler, Roux and Yersin on diphtheria, Behring and Kitasato on tetanus, and Ermengen on botulism. These diseases were demonstrably caused by potent toxins that could be produced *in vitro* and which, when introduced into

experimental animals, reproduced the main features of the disease caused by live organisms. By 1892, Behring had discovered antitoxins. In his search for antibacterial substances, he injected tetanus-infected animals with iodoform. This spared the animals but did not kill the organisms. He reasoned that the

effect, therefore, must be on the toxin. Transfer of serum from animals so treated to fresh animals rendered the recipients resistant to the effects of toxin and led to the discovery of antitoxins, later recognized as proteins belonging to the immunoglobulin class of serum proteins.

The impact of these discoveries was enormous and stimulated much toxin-oriented research during the next 25 years. Serum therapy for diphtheria and tetanus was successfully developed using mainly horses for large-scale production of antitoxin. Such success prompted further searches for similar substances to explain the principal features of other bacterial infections, and against which antitoxins could be generated for therapeutic use; but, there were many fruitless searches and progress was less dramatic. During the First World War gas gangrene was added to the small number of diseases in which a toxin played a significant if not overriding role. Another development was the production in the 1920s, by Glennie in Britain and Ramon in France, of toxoids that are stable, chemically detoxified toxins safe for use in human prophylaxis.

During the late 1920s to the late 1930s several species of *Clostridium*, important in veterinary as well as human disease, were shown to produce a range of soluble antigens, some of which were toxic to experimental animals, and successful vaccines were developed. Serological analysis led to the recognition of additional extracellular antigens, some of which were of potential relevance in the establishment and/or spread of infection. It is important to note that many bacterial toxins (and other soluble antigens) were first recognized either by their biological activity or as serological entities. In many cases they were arbitrarily assigned a letter of the Greek alphabet. Thus we have α toxins of *Clostridium perfringens*, *Clostridium novyi*, and staphylococci, which are completely unrelated to each other in any way other than that they are designated α . Even more confusing is the fact that some toxins bearing different Greek symbols were subsequently shown to be serologically and/or biochemically related.

The onset of the Second World War stimulated further research into toxigenic anaerobes. The α toxin of *C. perfringens* – important in gas gangrene – became the first toxin for which a biochemical mode of action was recognized in 1941; Macfarlane and Knight showed it to be a phospholipase C enzyme (lecithinase in older literature). However an intriguing observation was the fact that not every bacterial species that produced phospholipase C was necessarily pathogenic, nor were all such enzymes equally toxic. Explanations for this can now be given (see below).

In the early 1950s Smith and Keppie and their

numerous colleagues at the Microbiological Research Establishment, Porton, UK launched a series of studies on pathogenic bacteria and their products derived from *in vivo* sources. The prevailing climate was the threat of biological warfare and how to combat it. One organism with perceived military potential was *Bacillus anthracis*, an aerobic sporer. The Porton group discovered anthrax toxin(s). Another very important observation was made in 1953 by De and his collaborators. They injected cell-free filtrates of *Vibrio cholerae* into rabbit ileal loops and demonstrated the accumulation of fluid. The active factor was a heat-labile protein, fittingly described as an enterotoxin.

During the 1960s the mode of action of diphtheria toxin was elucidated by several groups. It was the first of several A–B toxins shown to consist of two types of fragment: fragment B ('binding') somehow facilitates entry of fragment A ('active') into the cytoplasm of susceptible cells.

The 1970s were a period of intense activity, during which enterotoxins were examined in great detail. The initial surge came from the need to develop more effective vaccines to control outbreaks of cholera in areas where it was (and still is) endemic or in areas where natural disasters or the ravages of war create conditions conducive to the spread of the disease. Attention was focused on the enterotoxin discovered by De in 1953. This led to the evolution of the currently widely held view that cholera toxin acts by biochemical perturbation of transport processes in epithelial cells of the small intestine giving rise to a cAMP-mediated watery diarrhea. This became the paradigm used to explain other toxin-mediated water diarrheas.

From the 1980s to the present, several developments have occurred. First, work on toxin A of *Clostridium difficile* (the causative agent of pseudomembranous colitis) disproves totally that the cholera toxin-based paradigm for watery diarrhea is of universal applicability: *C. difficile* toxin A is a histotoxic hemorrhagic toxin (i.e. it destroys tissue architecture and induces hemorrhage) which causes bloody fluid secretion in ileal loops but clear 'cholera-like' fluid from the colon of experimental animals; in the latter case, the hemorrhage remains tissue-localized as the basement membrane underlying the colonic epithelium is not breached. Second, the cAMP-mediated mode of action of cholera toxin has been shown by Lundgren's group in Sweden to be too simplistic; any satisfactory model must embrace a role for the enteric nervous system and (almost certainly) a colonic component.

The third development concerns the applications of modern molecular genetics to solve some extant problems in pathogenicity and in the development of

attenuated vaccine strains. Deciding the role played by a toxin in the causation of disease by organisms where virulence is manifestly multifactorial is sometimes very difficult. The construction of mutants in which toxin genes have been mutated or deleted has greatly helped in solving such problems; one example is the demonstration that Shiga toxin only exacerbates but is not necessary for the induction of dysentery caused by *Shigella dysenteriae*. Alternatively, the transfer of toxin (and other) genes to isogenic non-virulent strains is being used. Molecular genetical approaches are also being used in the construction of live vaccine strains.

Finally, many toxins have been cloned, sequenced and mutated. Three-dimensional structures have been inferred from modelling or, in the case of some toxins, by resolution of crystal structures. These approaches have led to the recognition of functional domains in toxin molecules. Knowledge of such structure/function relationships have in turn led to exciting therapeutic developments, such as the exploitation of botulinum toxin in the treatment of muscle dystonias, or the synthesis of chimeric toxins (e.g. diphtheria toxin/IL-2 fusion proteins) for the treatment of interleukin 2 receptor (IL-2R)-expressing cancers.

Toxins that act on noncellular/extracellular elements

Pseudomonas aeruginosa elastase and one (only) of at least six proteases of *Legionella pneumophila* both induce fibrinopurulent exudation (influx of fibroblasts and leukocytes) in the rat lung (a model for *P. aeruginosa*-induced pneumonia in human cystic fibrosis) and the guinea pig lung (a model for legionnaires' disease) respectively. These characteristic pathological features almost certainly arise from the release of oligopeptides (from extracellular matrix substances) which are chemotactic for leukocytes and fibroblasts. The hemorrhagic aspects of these diseases may be interpreted in terms of the effect of such proteases on protein components of type I alveolar epithelial and endothelial cells. *L. pneumophila* protease, the 'major secretory protein' (38 kDa zinc metalloprotease) is also involved in survival within macrophages.

The proteolytic activities of the gas gangrene group of *Clostridium* species are not primary virulence determinants but a priori one must regard them as aggressins or auxiliary factors. Similar considerations apply to the hyaluronidase family of enzymes produced by streptococcal and clostridial species which act on the hyaluronic acid component of extracellular tissue matrix. *Neisseria gonorrhoeae*, *Streptococcus pneumoniae*, *Streptococcus mitis* and

Streptococcus sanguis produce immunoglobulin A (IgA) proteases, which could be important in establishing infections of mucosal surfaces.

Staphylococcal exfoliatin(s) – a family of toxins important in staphylococcal scalded skin syndrome – cause cleavage of desmosomes in the stratum granulosum. Whether the primary site of action is external, i.e. on desmosomal proteins, or internal on cytoskeletal proteins is not clear. The toxins have demonstrable esterase activity and amino acid sequence analyses predict 'active serine' protease activity. They bind selectively to an intracellular skin protein, profilin, but there is no evidence of ability to enter intact skin cells. Purified exfoliatin will split the skin but does not *per se* cause the erythema associated with the disease. This suggests a role for other factors such as staphylococcal δ -hemolysin.

Toxins that act on membranes without internalization

Enterotoxigenic *Escherichia coli* elaborates families of low molecular weight heat-stable (ST-I_a (porcine), ST-I_b (human), ST-2 (porcine)) as well as the heat-labile cholera-like toxins (LTs; see below). ST-1 binds to its receptor – membrane-bound guanylate cyclase – which is then activated, thereby elevating cGMP levels; ST-2 (active only in weaned pigs) acts via a second messenger which is not cGMP, cAMP or Ca²⁺. The result in each case is efflux of ions, and hence water, into the gut lumen.

Toxins that traverse cell membranes and either kill or deregulate cells

We know that these toxins are able to traverse membranes since their targets are intracellular. These proteins have common features: one component (usually described as the B fragment or subunit) binds to and interacts with a cell receptor and promotes the uptake of an active component (A fragment or subunit) in which resides the biological activity which confers toxicity. There are several ways in which one can subgroup these toxins.

1. Biologically, some kill cells (cytotoxic toxins) whereas others (sometimes called cytotoxic toxins) 'deregulate' cells.
2. Some belong to a well-defined biochemical group recognized by their ability to cleave NAD⁺ into nicotinamide and ADP-ribose moieties. They are designated ADP-ribosyl (ADPR) transferases since they transfer ADPR to different target proteins.
3. The third possibility reflects the genetic origin of

these toxins: (a) production from a single gene of a single peptide which undergoes post-translational modification into A and B fragments that are covalently linked; (b) production from separate genes of A and B subunits which non-covalently associate into stable complexes, and (c) production from separate genes of different proteins which do not associate into stable complexes but which must act in concert to express toxicity. These are known as binary toxins.

Cytotoxic toxins

The classic example is diphtheria toxin (DT) made by *Corynebacterium diphtheriae*. This is the product of the *tox* gene (a constituent gene of β -phage) whose expression is regulated by [Fe]; the latter is a co-repressor of the *tox* gene. The processing, internalization and mode of action of DT is outlined in Figures 1–3.

A new and very exciting development is just beginning. For decades attempts have been made to make immunotoxins by coupling to native toxins antibodies specific to some surface antigen on tumor cells with as yet little practical success. However, Murphy's group in Boston, USA, have genetically engineered DT by substituting that portion of the DT structural gene encoding the native toxin receptor-binding domain with modified cDNA encoding one of a variety of cytokines and growth factors including IL-2, IL-4, IL-6, epidermal growth factor (EGF)

and α -melanocyte stimulating hormone (α -MSH). The resultant fusion toxin bears a new 'cellular address', but retains all of the other biological properties of the native DT molecule as well as a three-dimensional structure nearly identical with native DT. The IL-2 receptor fusion toxin has undergone phase I/II clinical trials for the treatment of IL-2 receptor-positive hematological malignancies (and other IL-2-related conditions) and has been shown to be safe and well-tolerated. A new era of 'magic bullets'?

Pseudomonas exotoxin A (PsA) acts in a near identical manner to DT on NAD^+ and EF2, despite the fact that there are no sequence homologies or serological cross-reactivities between DT and PsA. For DT, HeLa cells are more susceptible than mouse cells; the converse is true for PsA.

Other ADP-ribosylating toxins and their targets are: *Pseudomonas* exotoxin S (erythrocyte proteins – not necessarily the main target); cholera and *E. coli* LT toxins (α_s subunits of G-regulator proteins); pertussis toxin (not the invasive adenylate cyclase described below – α_i subunit of G-regulator proteins); botulinum C2 toxin (not a neurotoxin; nonmuscle actin). Shiga toxin (*Shigella dysenteriae*) has an AB_5 (B_5 is a homopolymer)-type structural arrangement similar to cholera toxin. Certain biotypes of *E. coli* make Vero toxins (VTs; or Shiga-like toxins (SLTs)) which are identical (SLT1) or near identical (SLT2) with Shiga toxin. The role of Shiga

Figure 1 Diphtheria toxin production and post-translational modification. The toxin is synthesized as a single polypeptide but is cleaved (nicked) by proteases into two fragments designated A and B, held together by a disulfide bond. The latter is reduced probably during translocation of the A fragment into the cytosol. (Reproduced with permission from Mims *et al*, 1995.)

Figure 2 DTA fragment entry. (A) Toxin binds via B fragment to a glycoprotein receptor in the cell membrane. (B) These complexes migrate to clathrin-coated pits. (C) This gives rise to acidified endosomes which facilitate the escape of A fragment into the cytosol. (Reproduced with permission from Mims *et al*, 1995.)

Figure 3 Protein synthesis: inhibition by DT, *Pseudomonas aeruginosa* exotoxin A (PEA), Shiga toxin (ShT), *E. coli* Shiga-like toxins (SLTs). The schema shows a round of peptide elongation and illustrates the key role played by two enzymes EF1 and EF2. DTA and PEA each ADP-ribosylates diphthamide (a modified histidine) in EF2-GTP which can no longer translocate the newly elongated peptide from the A site to P site. ShT A fragment is a specific *N*-glycosidase which cleaves an adenine residue from near the 3' end of the 28S ribosomal RNA. This depurination results in failure of EF1-dependent binding of aminoacyl-tRNA to site A and hence inhibits protein synthesis. EF1 α , nucleotide-binding protein; EF1 $\beta\gamma$, nucleotide exchange protein (Reproduced with permission from Mims *et al*, 1995.)

toxin in bacillary dysentery is to exacerbate but not to initiate disease. SLT-producing strains of *E. coli* are responsible for hemorrhagic colitis and hemolytic uremic syndrome. Crystallographic studies have shown a remarkable similarity in organizational structure of the B subunits of Shiga toxin and those of the cholera toxin despite the near complete absence of sequence homology. The B subunits attach to a ganglioside structure Gb3 or 4 (cholera toxin attaches to GM1) on susceptible cell surfaces. Shiga toxin A fragment is a specific *N*-glycosidase which cleaves an adenine residue from near the 3' end of 28S ribosomal RNA. This depurination results in failure of EF1-dependent binding of aminoacyl-tRNA to site A and hence inhibits protein synthesis; this perception comes from studies on cultured cells. How such cytotoxic activity gives rise to the enterotoxic activity – watery diarrhea seen in cases of dysentery preceding the bloody phase of the disease and attributed to the action of Shiga toxin on the small bowel – is not at all clear. Neither is there a clear explanation of the neurotoxic effects seen in severe dysentery (caused by *Shigella dysenteriae*) which definitely can be produced by administration of Shiga toxin.

Cytotoxic toxins

Vibrio cholerae attaches to enterocytes of the proximal small bowel and is capable of producing at least three toxins: classical cholera toxin (CT); a toxin that disrupts the zonula occludens tight junction (designated ZOT); and another less well-defined, auxiliary cholera enterotoxin (designated ACE). CT (an AB₅ toxin; B₅ is a homopolymer) is the classic example of a cytotoxic toxin and activates membrane-bound adenylate cyclase. The enzyme complex consists of several components: specific receptors for stimulatory (R_s) and inhibitory (R_i) hormones; the catalytic protein (C) responsible for the conversion of ATP to cAMP; and regulators of stimulation (G_s) and inhibition (G_i) comprising $\alpha_s\beta\gamma$ and $\alpha_i\beta\gamma$ subunits, respectively. See Figure 4 for mode of action of CT, LT and pertussis toxin (PTx). Phosphorylation by cAMP-dependent kinases of membrane proteins then occurs which perturbs ion transport – inhibiting absorption and stimulating secretion – and hence water. The biochemical data were derived mainly from studies on cultured cells (or isolated cell membranes) and the transport data from gut mucosal epithelia in Ussing chambers.

Figure 4 Mode of action of cholera toxin, LT toxins and pertussigen. There are five main features in this diagram:

1. cAMP is an important second messenger involved in the intracellular amplification mechanism of many cellular responses to external signals including hormones. The nature of the physiological response reflects the biochemical differentiation of the cell responding to the stimulus. For example, in gut cells the response would be altered ion transport and hence fluid secretion; in muscle cells it would be glycogen breakdown in response to the call for more energy. The production of cAMP is controlled both positively and negatively at two different levels. The central cycle represents a normal membrane-bound hormone receptor and the heterotrimeric ($\alpha\beta\gamma$) G protein regulator complex which is activated upon binding of hormone to the receptor. There are two receptors, each with regulatory G proteins: one system responds to stimulatory and the other responds to inhibitory stimuli; only one system is shown. In gut cells these receptors would be on the basolateral (nonluminal) side of enterocytes enabling responses to stimuli from the circulation or neuroactive hormone-like substances of which there are quite a few.
2. The endogenous GTPase properties of both stimulatory (α_s) and inhibitory (α_i) subunits of the G protein regulator may be outlined as follows. *Stimulation*: Stimulation of receptor results in the dissociation of the $\alpha_s\beta\gamma$ G protein from the receptor and of the subunits from each other, and the binding of GTP to α_s . α_s -GTP will productively interact with the catalytic unit of adenylate cyclase (not shown) and stimulate the production of cAMP from ATP. Endogenous GTPase activity in α_s results in a delayed conversion of α_s -GTP to inactive α_s -GDP which can no longer stimulate the cyclase but allows the reassociation of the trimeric G protein and loss of GDP. *Inhibition*: Stimulation of receptor results in an analogous situation for inhibiting cyclase activity via α_i ; inhibitory α_i -GTP inactivates the cyclase; α_i -GDP does not inactivate the cyclase.
3. The level of cAMP may be affected by physiological stimuli (which stimulates removal and modification of the G protein complex) or by intoxication which results in the perturbation of the normal regulatory cycle as illustrated for cholera toxin (CT) or pertussis toxin (PTx, pertussigen).
4. CT acts first by interacting (via CTB) with its receptor resulting in the internalization of the active A1 subunit. A1 ADP-ribosylates α_s -GTP which promotes continued dissociation of the heterodimer; also the endogenous GTPase is no longer functional hence the stimulation of the cyclase continues. LT toxins act in a similar manner. In the case of the enterotoxins the receptors are on the brush border membranes, i.e. on the luminal apex, of enterocytes.
5. PTx acts first by interacting (via PTxB) with its receptor resulting in the internalization of the active S1 subunit. S1 ADP-ribosylates the α_i -GDP $\beta\gamma$ heterodimer, which can no longer associate with the receptor (or lose GDP) to undergo another cycle of GTP activation; activated cyclase can no longer be turned off. (Reproduced with permission from Mims *et al*, 1995.)

This description (Figure 4) is correct but too simplistic. Studies by Lundgren's group in Sweden using gut preparations *in situ* have shown that up to 60% of CT-induced secretion is dependent on a functional enteric nervous system (ENS). Earlier studies by American workers (which have never been refuted) had shown that up to 60% of CT-induced secretion in ligated rabbit ileal loops was suppressed by cycloheximide, which inhibited protein synthesis and

mitotic activity (presumably in crypt cells), without affecting the elevation of levels of adenylate cyclase and cAMP. More recently, the colon has been implicated in CT-induced secretion via the ENS. The effect of ZOT has been demonstrated by electron microscopy in human biopsies but the relative importance of ZOT and ACE in human disease has not been quantified.

E. coli produces LT-I, and LT-II whose structure and mode of action is similar to CT. LT_h (human),

LTp (porcine) are minor variants of LT-I differing only by one amino acid in the A subunit and four amino acids in the B subunit. LT-I is plasmid encoded. LT-II (isolated from water buffalo) is chromosomally encoded, exists as IIa or IIb (which show partial serological identity), is a major variant of LT-I and is not neutralized by antisera to LT-I or CT. LT-II shows biological activity similar to LT-I, except that it does not cause secretion in ligated rabbit ileal loops, and (unlike LT-I) does not bind to ganglioside GM1. LT-IIb requires trypsin treatment for Y-1 adrenal cell assay.

CT and LT toxins are among the most potent antigens known and are also powerful adjuvants.

Bordetella pertussis produces several toxins including a heat-labile toxin, tracheal cytotoxin, endotoxin, adenylate cyclase-hemolysin (AC-Hly), and pertussis toxin (pertussigen). The latter has many biological activities (histamine sensitization, leukocytosis promotion, islets of Langerhans activations and adjuvanticity), is believed to be the most important but by no means the only virulence determinant of *B. pertussis*, and forms the basis of the vaccine against whooping cough. It is an AB₅ toxin in which the B₅ pentamer consists of four peptides comprising two heterodimers (S2, S4; S3, S4) held together by a fourth peptide (S5); A subunit is designated S1. The mode of action of A subunit is to ADP-ribosylate the α_1 -GTP complex of adenylate cyclase; this can no longer inhibit cyclase activity, thereby elevating cAMP. It is not yet clear how such biochemical activity relates to the clinical syndrome.

Clostridium tetani and *C. botulinum* both produce neurotoxins. Recently huge strides have been made in our knowledge of the structure and mode of action of these toxins (see Figures 5 and 6). There is very little overall sequence homology between BoNTs and TeTx; this could account for their immunological characteristics and the animal types normally affected. However, there is one structural feature common to all these neurotoxins located in the middle of the light chain and that is a zinc-binding motif. In fact it has now been formally proven that these neurotoxins are zinc endopeptidases. Their targets are protein constituents which comprise the synaptic fusion machine responsible for the exocytotic release of neurotransmitters. The intracellular target cleaved by BoNTs B, D, and F and TeTx is synaptobrevin (VAMP, vesicle-associated membrane protein) present in small synaptic vesicles. BoNTs A and E cleave SNAP-25 (synaptosomal-associated protein of 25 kDa) a highly conserved protein known to be involved in exocytosis. BoNT C acts on syntaxin, a synaptic membrane protein also involved in exocytosis.

Figure 5 Structure/nomenclature of tetanus and botulinum toxins. sc-TeTx, single chain non-cleaved tetanus toxin; TeTx, tetanus toxin after proteolytic activation; L and H, intact light and heavy chains respectively; L-H_{N(458-864)}TeTx, intact L chain linked to a fragment of H chain (from residue 458 at the N-terminal end to residue 864); H_N and H_C, N-terminal and C-terminal parts respectively of the H chain. The corresponding nomenclature for botulinum toxin type A is BoNT/A, and for type B, BoNT/B, etc. (Reproduced with permission from Mims *et al.*, 1995.)

Binary toxins

Bacillus anthracis produces two binary toxins: edema factor (EF) and lethal factor (LF). For both toxins, protective antigen (PA) is required for activity by promoting entry of either EF or LF (but not both simultaneously) into the cytosol of susceptible cells. (Historically, these proteins were first described as factors I (EF), II (PA) and III (LF) and perceived as forming a tripartite synergistically acting toxin. (Current usage favours EF, PA, LF and a duality of binary toxins: PA+EF; PA+LF.) Current perceptions on the mode of action of these binary toxins are based on effects seen in cultured cells. PA binds to cell membranes, undergoes proteolytic activation by furin and internalization into an acidified endosome. Activated PA oligomerizes into a heptameric ring structure to which either EF or LF will bind in a competitive manner. The heptamer acts as a pore-forming complex aiding the translocation of EF or LF into the cytosol. EF is an inactive adenylate cyclase which becomes activated by calmodulin, leading to supraphysiological levels of cAMP. The known secretagogue activity of cAMP (can induce fluid secretion) could explain both the edematous reaction evoked in skin tests and the lethal systemic effects of anthrax. In guinea pigs, lethality was shown to be due to secondary oligemic shock. The action of anti-PA (PA is a protective immunogen) may be interpreted in terms of antibodies preventing the initial binding of PA, or the binding of EF or LF to PA. The binding of EF is

Figure 6 Sites of action of TeTx and BoNTs. This figure has three main features:

1. Reflex arc. Mechanism for inhibiting the antagonists to a muscle contracting in response to stretch. Muscles are reciprocally innervated with sensory and motor neurons, although for clarity this is shown only for the protagonist muscle. On stretch, the stretch receptors generate an impulse which is transmitted along the afferent sensory (S) neuron (SP) of the protagonist muscle. This SP enters the spinal cord by the dorsal root and synapses with the motor neuron (MP) supplying the protagonist muscle and with an interneuron (I) which in turn synapses with the motor neuron (MA) supplying the antagonist muscle. At the SP/MP synapse an excitatory transmitter is released that induces an impulse in MP which leads to contraction of protagonist muscle. However, excitation of I causes release of an inhibitory transmitter at the I/MA synapse which leads to relaxation of the antagonist muscle. Note that the basic reflex arc has been shown for simplicity but TeTx acts mainly on voluntary muscles.
2. A simplified version of the biochemical events occurring in synapses. Excitatory and inhibitory synapses, neurotransmitter release and action. Gly, glycine; R, receptors of neurotransmitters; X, hitherto uncharacterized (candidates include glutamate, dopamine, ATP, substance P, and somatostatin).
3. Sites of neurotoxin action. The predominant site of action of TeTx is the intermotor neuron synapse; the exocytotic machine is interfered with by the endopeptidase action of TeTx on VAMP. BoNT acts at the neuromuscular junction inhibiting the release of acetylcholine (ACh) by its proteolytic action on VAMP (types B, D and F) or SNAP (types A and E) or syntaxin (type C). (Reproduced with permission from Mims *et al*, 1995.)

depressed by prior binding of LF and this could explain the depression of edema produced by LF when added to EF and PA. The cell model does not explain or predict the increase in lethality resulting from addition of LF to EF and PA. However, it is now known that in high doses PA+LF is cytolytic to murine macrophages but that in very small sublytic doses it will stimulate expression of IL-1 and tumor necrosis factor (TNF). Protection of mice against LF is possible using passive transfer with anti-IL-1 or injection of IL-1 receptors, implying that, in mice at least, death could be due to the overstimulation of cytokines, particularly IL-1. LF is a putative Zn metalloprotease.

Other binary toxins

Clostridium botulinum C2 toxin (Figure 7) is not a neurotoxin but belongs to a family of cytotoxins. (*C. perfringens* iota toxin, *C. spiroforme* toxin, *C. difficile* ADP-ribosyltransferase) whose common features are that they are binary toxins and that they target cytoskeletal actin. Of these *C. botulinum* C2 is the best studied at present. Component C2I is the equivalent of the A subunit and C2II, the B subunit. Both are produced in parallel although different strains produce different ratios. C2 is produced more during sporulation than in the vegetative phase of growth.

Figure 7 *C. botulinum* C2 toxin component 2II is activated by proteolysis and binds to the cell membrane followed by C2I. The latter is internalized and upsets the equilibrium between polymerization and depolymerization of actin. ADP-ribosylation of monomeric actin inhibits its polymerization and turns G-actin into a capping protein which binds to the fast-growing (barbed) ends of actin filaments. Capping of the barbed ends increases the critical concentration for actin polymerization. Since the slow-growing (pointed) ends of actin filaments are free, depolymerization of actin occurs at these ends. Released actin is substrate for the toxin and will be withdrawn from the treadmilling pool of actin by ADP-ribosylation, i.e. trapped. Both reactions will finally induce the breakdown of the microfilament network. The substrate specificity is high. The toxin will modify a specific arginine residue (177, present in all isoforms) in β and γ nonmuscle actin and γ smooth muscle actin but not in α isoforms of actin, which is surprising in view of the high degree of homology between the various isoforms of this protein. Neither component is toxic on its own but together the LD₅₀ dose for a mouse is about 5–50 ng. The two components may be injected into different sites or by different routes but toxic effects always occur at the site of injection of C2II. (Reproduced with permission from Mims *et al*, 1995.)

The other three form an iota subgroup in that antibodies will cross-react within this group but not with *C. botulinum* C2 toxin. Only within the iota group are the binding components interchangeable. The iota group will also modify all mammalian actin isoforms.

Other examples of binary toxins are staphylococcal leukocidin and staphylococcal γ -hemolysin.

Membrane-damaging toxins

Proteins, lipids and sterols are all known to be involved as targets for membrane-damaging toxins. Perhaps the best example of a toxin whose target is a membrane protein is the protease of *L. pneumophila* described earlier: this enzyme also induces the hemorrhagic response seen in experimental infections. Since the membranes of endothelial and type 1 alveolar epithelial cells undergo pathological changes, it is reasonable to ascribe these to the proteolytic activity of this toxin.

Phospholipases

There are many bacterial enzymes that act on phospholipids, of which the best known is the α -toxin of *Clostridium perfringens*. *C. perfringens* α -toxin is a

phospholipase C (PLC) which removes the head group, phosphorylcholine, from phosphatidylcholine and from sphingomyelin. It is of undoubted importance in gas gangrene. There are several reasons why all enzymes with such biochemical specificity are not equally toxic or important in determining virulence. By the combined use of monoclonal antibodies and molecular genetic analyses we now know that there are at least two functional domains in *C. perfringens* α -toxin. If one compares *C. perfringens* α -toxin with the phosphatidylcholine-preferring, nontoxic phospholipase of *Bacillus cereus*, one finds that two-thirds of the N-terminal sequence shows homology with the entire sequence of *B. cereus* PLC. This portion of *C. perfringens* α -toxin retains its PLC activity but not its hemolytic and lethal activities. The C-terminal part is not hemolytic, not enzymatically active and not cytotoxic for mouse lymphocytes but is necessary for conferring toxicity on the N-terminal part of the protein. In fact, the C-terminus is a potent immunogen that will solidly protect mice – and hopefully humans – against experimental infection with *C. perfringens*. Surprisingly, the C-terminal domain of the non-toxic *C. bifermentans* enzyme shows sequence similarity with that of its *C. perfringens* α -toxin

counterpart. The nontoxicity of this enzyme is ascribed to its comparatively much lower turnover rate, i.e. it is a much less efficient enzyme.

Staphylococcal β -hemolysin (a sphingomyelinase) exhibits the narrowest of phospholipid specificities and kills neutrophils.

Pore-forming toxins

SH-activated cytolysins A family of thiol-activated cytolysins exists produced by at least 17 bacterial species belonging to several genera. Sterol is the primary target in susceptible membranes to which such proteins, initially secreted as water-soluble entities, bind. Arc/ring complexes are formed in membranes which do not contain cholesterol, are extractable, and comprise conformationally altered proteins which will bind nonspecifically to other membrane lipids; sterol is only a primary anchor. Gross amino acid compositions of these proteins differ widely but serological cross-reactivity indicates at least some conserved epitopes. The majority are known not to be primary determinants of virulence. However, streptolysin-O (*Streptococcus pyogenes*) and listeriolysin (*Listeria monocytogenes*) are definitely produced *in vivo* and damage/kill neutrophils, causing their granules to discharge their degradative enzymes to kill the pathogen (or harm the host). Listeriolysin is also important in mediating escape of *L. monocytogenes* from vacuoles in nonphagocytic cells. Pneumolysin (*Streptococcus pneumoniae*) has definitely been implicated in experimental murine infections. Immunization of mice with pneumolysin toxoid prolongs the life of mice in an otherwise rapidly lethal respiratory infection with *S. pneumoniae*. Pneumolysin is also the primary ototoxic agent causing deafness in experimental meningitis in guinea pigs and rabbits.

RTX toxins These are a group of toxins whose common feature is the presence of an array of nine amino acid repeats; they have been designated RTX (repeats in toxin) toxins. The prototype is the hemolysin of *E. coli* which is important in extraintestinal infections caused by this organism. Other toxins of this group include hemolysins from *Proteus vulgaris*, *Proteus mirabilis*, *Morganella morganii* and *Actinobacillus pleuropneumoniae*, the leukotoxins from *Pasteurella haemolytica* and *Actinobacillus actinomycetemcomitans* and the adenylate cyclase-hemolysin (AC-Hly) of *Bordetella pertussis*. *E. coli* hemolysin is synthesized as an inactive precursor and actively secreted. The repeat domain is a Ca^{2+} -binding site needed for membrane recognition. *B. pertussis* AC-Hly, which is known to be produced early in infection in children (based on antibody detection), protects mice against colonization by

B. pertussis, and is a fascinating molecule having two functional domains. One confers adenylate cyclase activity and another hemolytic activity. It is possible to obtain Hly as a separate fragment from AC. It is 'anthrax-like' as far as being an adenylate cyclase is concerned. Its hemolytic activity arises from its pore-forming properties in cell membranes, the latter probably being responsible for the translocation of the AC portion of the complex. AC-Hly is also known as cyclolysin (or invasive adenylate cyclase).

Other pore-forming toxins Staphylococcal α - and δ -toxins act in a manner similar to that described for thiol-activated cytolysins with the exception that no known specificity for initial binding has been demonstrated. Based on studies using liposomes (artificial membranes), the size and orientation of the protein-lipid micelles generated by staphylococcal δ -toxin is concentration dependent: in larger concentration the effect is detergent-like. The genesis of pore-like structures is similar to what happens when the terminal C5b-9 complex of complement binds to membranes. It is also similar to the perforin-mediated killing mechanism whereby cytotoxic T lymphocytes kill target cells. The pore diameters for streptolysin-O, C5b-9, and staphylococcal α -toxin are 30, 5–10 and 2–3 nm respectively. These water-soluble entities undergo conformational changes and oligomerization on binding to membranes to form supra-molecular channels with the hydrophobic surfaces of the constituent proteins facing outwards and the hydrophilic surfaces facing inwards.

Toxic structural components of gram-negative bacteria: endotoxin

Endotoxins are well-recognized structural entities possessing microbial functions; they are lipopolysaccharide (LPS) in nature and are located in the outer membrane of gram-negative organisms (Figure 8). (The only lethal membrane-associated protein toxin is the complex guinea pig toxin of *Yersinia pestis*.)

Endotoxins are not primary determinants in initiating infection. The guts of healthy animals, including humans, are full of gram-negative organisms and their components which are normally not absorbed in quantity; small amounts are detoxified by liver Kupffer cells. But they are important in diseases caused by invasive pathogens: typhoid, tularemia, plague, brucellosis, and a variety of hospital-acquired infections caused by opportunistic gram-negative pathogens which include *E. coli*, *Proteus*, *Pseudomonas*, *Enterobacter*, *Serratia* and *Klebsiella* spp. In addition, endotoxin has been extensively studied as a possible causative agent of shock arising from

Figure 8 General structure of *Salmonella* lipopolysaccharide. PG, peptidoglycan; PL, phospholipid; A–D, sugar residues; Glc, D-glucose; Gal, D-galactose; GlcN, D-glucosamine; GlcNAc, N-acetyl-D-glucosamine; Hep, L-glycerol-D-manno-heptose; KDO, 2-keto-3-deoxy-D-manno-octonate; AraN, 4-amino-L-arabinose; P, phosphate; EtN, ethanolamine; $\backslash\backslash\backslash\backslash$ hydroxy and nonhydroxy fatty acids. Ra–e, are incomplete forms of lipopolysaccharides. The structures indicated are typical of the Enterobacteriaceae and the Pseudomonadaceae. *Haemophilus influenzae*, *Neisseria meningitidis*, *Bordetella pertussis*, *Acinetobacter calcoaceticus* and *Bacteroides fragilis* have less complicated LPS structures in that they do not possess the equivalent of the O-somatic side-chains. Chlamydiae possess only lipid A and the inner core region comprising lipid A and KDO. (Reproduced with permission from Mims *et al*, 1995.)

postoperative sepsis or other forms of traumatic injury, in which the normal gut flora is regarded (at least by some) as the source of endotoxin. It is thought that accompanying changes in gut permeability allow absorption of higher levels of endotoxin.

The diversity and range of biological properties associated with endotoxin is quite bewildering and include pyrogenicity, induction of tolerance (totally unrelated to immunological tolerance), abortion (in

pregnant ungulates), the generalized Schwartzman reaction (giving rise to disseminated intravascular coagulopathy), hypotension, shock, effects on lymphoid cells, etc. Lethality is almost certainly the cumulative effect of many aspects of the endotoxin pathophysiological cascade. Lipid A is the primary toxiphore, but polysaccharide confers solubility and optimizes the size of micellar aggregates of LPS which affects biological activity. However, the

immune status of the test animal may affect toxicity: normal animals produce antibodies to epitopes on the surface of normal gut organisms (including O-somatic antigens). In such circumstances, the biological effects of endotoxin may be mediated by hypersensitivity mechanisms.

Strategies for preventing or neutralizing the effects of LPS with reagents other than expensive partially effective anti-lipid A antibodies are being developed and include exploitation of LPS-binding protein, the bactericidal/permeability increasing protein, the CD14 LPS receptor, nontoxic lipid A and lipid A analogs.

TOXOCARIASIS

Malcolm W Kennedy, Division of Infection and Immunity, Institute of Biomedical and Life Sciences, University of Glasgow, Glasgow, UK

Characteristics of the organism and its antigens

The causative agent of toxocariasis is the nematode, or 'roundworm', parasite *Toxocara canis*. Infective eggs are released by sexually reproducing adult worms which parasitize the intestines of domestic dogs and related carnivores. The eggs are not initially infective, but require a period of 2–3 weeks for the development of infective larvae. These are contained within characteristically pitted eggs which are extremely resilient, and viable eggs can persist in soil for many years. Infection is initiated by ingestion of these eggs, and the release of the tissue-invasive larvae. This can occur in almost every species of mammal tested, and even some birds. The parasite will only develop to maturity in canids, but in other species will persist in the body, and remain infective to the definitive host through carnivory. The larvae remain dormant in the tissues of female dogs until pregnancy, whereupon they migrate to the uterus and invade the fetus. It has been reported that this results in a near 100% rate of infection in newborn pups, which can

also be infected by the transcolostral route. This complex and opportunistic life cycle is detailed in **Figure 1**.

Toxocariasis is not a significant veterinary problem and the main interest lies in its impact on humans. The tissue-invasive larvae of the parasite migrate throughout the soft tissues of the body, including the liver, musculature, brain and the eye, and give rise to symptoms which have been used to divide the condition into two main syndromes (**Figure 2**). The first of these is visceral larva migrans (VLM) which can present with high eosinophilia, high specific and nonspecific immunoglobulin E (IgE) responses, leukocytosis, hypergammaglobulinemia, hepatomegaly, pulmonary infiltration and pyrexia. The first two of these are characteristic of nematode infections. VLM is a chronic condition since the larva can persist in humans for up to 7 years, although it will gradually fade so long as new infections are prevented. The second syndrome is ocular larva migrans (OLM), in which the eye is invaded. This is associated with few systemic symptoms, and is thought to occur at lower levels of infection than VLM, and patients can be seronegative. OLM is, however, often the occasion upon which toxocariasis is first suspected. The granuloma produced in the

Figure 1 The life cycle of *Toxocara canis*, showing the various means by which the parasitic larvae can gain entry to the canine final host, and in which the human becomes an accidental host. *T. canis*, like all nematodes, undergoes a series of molts during its development to adulthood. These define four different larval stages, termed L1 to L4, which occur as detailed in the figure, beginning with the L2 stage which is in the egg and is infective to mammals. (Courtesy of Professor RM Maizels, University of Edinburgh and © Taylor & Francis.)

retina is sometimes misdiagnosed as retinoblastoma, which is also commonest in childhood, and unnecessary surgical removal of the eye can result. It can, however, be distinguished from the neoplasm by careful ophthalmoscopy or biopsy. The latter is clearly not always an option, and methods for the detection of parasite antigen in vitreous fluid are probably the only immunological means of diagnosis, in view of the lack of a detectable serological response in OLM, which would not be definitive anyway.

The antigens of *Toxocara* are amongst the best characterized among nematode parasites. This is chiefly because of the remarkable ease with which the infective larvae can be maintained *in vitro*; they can survive for up to a year in defined, serum-free medium, during which time they remain under developmental arrest, and release copious quantities of antigens into the medium. These are presumptively termed excretory/secretory (ES) antigens, and have become the most widely used preparation for the immunodiagnosis of toxocarasis. ES antigens are heavily glycosylated proteins, some of which are associated with enzymatic activity, e.g. proteinases, and have been detected in the circulation of infected humans and experimental animals. ES contains about eleven major components, ranging from 32 to 400 KDa. Monoclonal antibody analysis of ES has shown that there are both carbohydrate and peptide epitopes present, and that some of the former can be distributed among several otherwise unrelated

components. Moreover, certain of the glycoproteins bear epitopes similar to human ABO blood group substances. Recent analysis of the carbohydrate moieties in *T. canis* ES has revealed some structures which might explain the ABO blood group cross-reactions. Most monoclonal antibodies raised to *T. canis* also recognize the antigens of the closely related (and potentially hazardous) parasite of cats, *Toxocara cati*. However, one antibody is specific to

Figure 2 Scanning electron microscope picture of two infective larvae of *Toxocara canis*. The parasites were mounted on a membrane with pores of approximately 10 µm in diameter. (Courtesy of Dr L Tetley, University of Glasgow and Dr HV Smith, Scottish Parasite Diagnostic Laboratory and © Taylor & Francis.)

T. canis and is of some interest since it represents an example of a species-related carbohydrate epitope.

In common with a number of other nematode parasites, *Toxocara* is known to shed antigens rapidly from its surface and thereby contribute to ES. Utilization of monoclonal antibodies to surface and ES antigens has provided strong indications that they derive from the oesophageal gland which is ducted to the buccal cavity of the parasite, and the mid-body secretory gland which is directly connected to the cuticle by a duct opening at the secretory pore. Monoclonal antibodies to ES will bind to detergent-solubilized surface antigens, but few of them bind to the surface of intact, living, larvae. There are, therefore, cryptic epitopes, probably indicative of the orientation of glycoproteins in the surface layer of the parasite. The genes encoding two surface and/or ES antigens of the parasite have been cloned and sequenced; one encodes a phosphatidylethanolamine-binding protein and another a mucin-like protein. The latter might relate to the rapid shedding of surface antigens by *T. canis* and to the parasite's migratory propensity.

Humans are subject to infection with a number of nematodes that are antigenically cross-reactive with *Toxocara*, the most important of which is *Ascaris lumbricoides*. This could compromise specific serodiagnosis, but the significance of this problem remains to be established. However, with the availability of species-specific monoclonal antibodies and molecular cloning of ES antigens, which is now in progress, there is the potential for the development of specific serodiagnostic methods.

Immune responses of the host

Toxocariasis is a covert parasitism in humans, and immunodiagnosis remains the principal means by which infection can be detected. Seroprevalence rates in the general population are 2.8% and 2.0% among healthy adults or blood donors in certain areas of the USA and UK, respectively. Children have higher rates, for example, 23.1% and 14.3% in children under 10 years old in the USA and UK, respectively. A recent study in the Republic of Ireland also revealed alarmingly high seroprevalence rates amongst children. This increased prevalence among the young also occurs in less developed countries in which levels as high as 86.6% have been recorded in children under 6 years old in the Caribbean.

The other major aspect of the immune response in toxocariasis is eosinophilic granulomata which can occur throughout the body, with the apparent exception of the brain. Larvae can be found entrapped within liver granulomata, and there is some experi-

mental evidence that larvae can be killed within them. Granulomata can be found without larvae, and it seems that the parasite can escape entrapment, or deposited antigens stimulate a reaction to migratory tracks. ES materials have been shown to contain factors that stimulate eosinophilia *in vitro*, and at least one allergen whose activity is lost after treatment with a reducing agent.

T. canis infection elicits a strong T_H2-dominated response in experimental animals, and it was the analysis of the response of T cells to *T. canis* antigens which provided early evidence for the T_H1/T_H2 divide in humans.

Evasive strategies by the organism

T. canis clearly evades the immune response very successfully, but the means by which it does this are a matter of debate, and there are an increasing number of possible explanations. First must be the active shedding of surface antigens which has been observed *par excellence* in this parasite. Such a process could lead to a loss of bound antibody, complement and cells. Second, the release of enzymes. *T. canis* larvae are known to secrete proteases which could cleave bound antibody and complement, or aid in escape from granulomata. Acetylcholinesterase is also secreted, and this might serve to deplete local levels of acetylcholine which is known to enhance mediator release by mast cells, neutrophils, lymphocytes, and the release of interferon γ by T cells. *Toxocara* would be unusual amongst helminth parasites if it did not release enzymes capable of disarming the host's reactive oxygen defense mechanism, but these have not yet been described. Lastly, ES activates complement, which could lead to local depletion. The larval surface will, however, also activate human complement by both pathways, culminating in the deposition of C9, although this occurs without apparent damage to the parasite *in vitro*.

Vaccines

There is no immediate prospect of a vaccine. ES antigens have been shown to contain protective antigens in mice, and molecular cloning of some of the parasite's major ES components is encouraging. In common with other nematodiasis, most effort in vaccine development is aimed at surface and/or secreted antigens, and this is particularly appropriate to toxocariasis in which there is a vigorous response to surface and ES, but a poor response to internal components.

TOXOPLASMOSIS

Yasuhiro Suzuki and Jack S Remington, Research Institute, Palo Alto Medical Foundation, Palo Alto, California, USA

Toxoplasmosis is a disease of mammals and birds caused by the coccidian protozoan *Toxoplasma gondii*. It can be transmitted to humans via undercooked meat, contaminated soil and food, and by organ transplantation. The organism exists in three forms: tachyzoites, tissue cysts (which contain bradyzoites) and oocysts (which contain sporozoites). Tachyzoites are crescentic or oval shaped, 2–4 µm in width and 4–8 µm in length. They are seen during the acute stage of the infection and invade all types of mammalian cells except non-nucleated red blood cells. The tissue cyst and oocyst are the principal forms of the parasite involved in transmission. The tissue cyst is formed within the host cell cytoplasm and may vary in size from those containing relatively few organisms to those that are more than 100 µm in size and contain several thousand bradyzoites. Cysts are demonstrable as early as the first week of infection in experimental animals and probably persist throughout the life of the host. Although cysts may persist in virtually every organ, the brain and skeletal and heart muscle appear to be the most common sites of latent infection. Oocysts have been described only in members of the cat family. Schizogonic and gametogonic stages are found in the epithelium of the small intestine and culminate in the development of oocysts which are excreted in the feces of the cat.

Twenty-eight genes of *T. gondii* have been cloned. Based on the pattern of restriction fragment length polymorphisms of certain of these genes, strains of *T. gondii* have been classified into genotypes. The

highly virulent strains were found to have an essentially identical genotype whereas the less virulent strains were moderately polymorphic.

The presence of antigens specific for each form of the parasite has been reported, although each form shares common antigens. Tachyzoite antigens have been used for serodiagnosis of toxoplasmosis. Recently, tachyzoite antigens were reported to have a superantigen activity on murine lymphocytes.

Immune responses of the host

Infection with *T. gondii* induces both humoral and cell-mediated immune responses. The latter plays the major role in resistance to infection, although both are responsible for resistance.

Antibodies activate the classical pathway of complement to lyse extracellular parasites. Tachyzoites survive within normal macrophages, but are killed if coated with specific immunoglobulin G (IgG) antibody. Monocytes and neutrophils can rapidly kill tachyzoites. The protective effect of antibodies is only partial against challenge infection in laboratory animals. The cell-mediated immune response appears to be essential for survival of the host during the acute infection (Figure 1). Activation of macrophages by interferon γ (IFNγ), is a major effector mechanism against *Toxoplasma* infection. Macrophage killing of *T. gondii* is by both oxidative and nonoxidative means. Neutralization of endogenous IFNγ in mice by IFNγ-specific antibody resulted in a lack of macrophage activation during acute toxoplasma

infection; the mice died when infected with an avirulent strain which does not kill untreated mice. Tumor necrosis factor α (TNF α) plays an important role in IFN γ -mediated activation of macrophages. Natural killer (NK) cells and T cells are responsible for the efferent limb of the protective cell-mediated immune response. CD8 $^{+}$ T cells appear to be most important for induction of the protective effect. A major role of CD8 $^{+}$ T cells in this resistance appears to be production of IFN γ since an IFN γ -specific monoclonal antibody (mAb) completely ablated their protective activity in the acute infection. The role of CD4 $^{+}$ T cells is probably a production of interleukin 2 (IL-2) which augments IFN γ production by CD8 $^{+}$ T cells. NK cells are another important source of IFN γ . Production of IFN γ by NK cells appears to be important to activate macrophages in the early stage of infection prior to production of this cytokine by T cells. IFN γ produced by NK cells may play a critical role in induction of a T_H1-type response (IL-2 and IFN γ

production) of CD4 $^{+}$ T cells and augmentation of CD8 $^{+}$ T cell activity. IL-12, IL-15, TNF α and IL-1 β are important for activation of NK cells to produce IFN γ . *In vitro* production of IFN γ by spleen cells of SCID (severe combined immunodeficiency) mice (which lack T and B cells but have NK cells) following stimulation with *T. gondii* tachyzoites or antigens was enhanced by addition of antibodies against transforming growth factor β (TGF β) or IL-10. Thus, TGF β and IL-10 appear to play a role in downregulation of IFN γ production by NK cells during infection. IL-10 also downregulates IFN γ production by CD4 $^{+}$ T cells and inhibits IFN γ -mediated parasite killing by macrophages. IL-7 has enhanced the protective activity of NK and CD8 $^{+}$ T cells in a murine model. $\gamma\delta$ T cells are also involved in resistance against the acute infection and human $\gamma\delta$ T cells have cytotoxic activity against *T. gondii*-infected target cells and produce IFN γ , IL-2 and TNF α following stimulation with the infected cells.

Figure 1 During the early stage of infection with *T. gondii*, macrophages are stimulated to secrete IL-12, IL-15, TNF α and IL-1 β . These cytokines activate NK cells to produce IFN γ which then activates macrophages. Activated macrophages phagocytose tachyzoites and effectively kill the organisms by both oxidative and nonoxidative means. Activation of macrophages through this mechanism appears to be earlier than through production of IFN γ by $\alpha\beta$ T cells. Production of IFN γ by $\gamma\delta$ T cells may be involved in activation of macrophages in this early stage of infection.

During the later stage of infection, IL-12 produced by macrophages and IFN γ produced by NK cells induce differentiation of T_H precursor lymphocytes into T_H1 CD4 $^{+}$ T cells. T_H1 CD4 $^{+}$ T cells secrete IL-2 which enhances IFN γ production by CD8 $^{+}$ T cells and also produce IFN γ . However, CD8 $^{+}$ T cells appear to be more important than the CD4 $^{+}$ T cells as the source of this cytokine *in vivo*. Macrophages activated by IFN γ kill tachyzoites through the mechanisms described above.

Downregulatory cytokines: TGF β and IL-10 appear to play a role in downregulating IFN γ production by NK cells. IL-10 also inhibits IFN γ -mediated killing of tachyzoites by macrophages. IL-7 is not included in this figure but has been reported to enhance the protective activity of NK and CD8 $^{+}$ cells. However, the sources and target cells for this cytokine in *T. gondii* infection are unclear.

The frequent occurrence of toxoplasmic encephalitis (TE) in patients with the acquired immune deficiency syndrome (AIDS), due to recrudescence of the previously latent (cyst form) infection, indicates the importance of cellular immunity in maintaining the infection in its quiescent form. Injection of chronically infected mice with mAb to IFN γ induced remarkable encephalitis along with evidence of cyst disruption. Impaired production of IFN γ in AIDS patients is probably a major reason for the occurrence of the encephalitis and dissemination of the organisms to other tissues. Genetic regulation associated with the major histocompatibility complex (MHC) is operative in resistance/susceptibility against development of TE in humans and mice. HLA-DQ3 was found to be significantly more frequent in North American Caucasian AIDS patients with TE than in the general Caucasian population or randomly selected control AIDS patients who had not developed TE. HLA-DQ3 thus appears to be a genetic marker of susceptibility to development of TE in AIDS patients.

Evasive strategies by the organism

Cysts persist in tissues of immunologically normal hosts without any evidence of inflammation around them. The immune response seems to be only partially effective in removal of parasites before they can form cysts. Tachyzoites, present in the acute stage of infection, are the main target for the protective immune response. Following invasion of tachyzoites into host cells, the organisms form parasitophorous vacuoles that act as a protective interphase which prevents fusion of the vacuole with lysosomes or acidification of its contents. However, when murine macrophages or human monocyte-derived macrophages are activated by IFN γ , the parasite is efficiently killed by those cells after its invasion. It has been reported that tachyzoites induce both antigen-specific and nonspecific suppressor cells to inhibit induction of the immune responses to the parasites. The effector cells of the antigen-specific suppression are CD4⁺ and CD8⁺ T cells; the cells inhibit proliferation of lymphocytes to toxoplasma antigens *in vitro*. The activity of the suppressor cells was remarkable only in symptomatic patients with acute infection. The effector cell of the antigen-nonspecific suppression is the macrophage. The activity of the suppressor macrophages was much stronger in the susceptible than in the resistant strain of mice.

Vaccines

There is no vaccine against *T. gondii*. Recent studies demonstrate that administration of mAbs to *T. gondii* confers partial protection against mortality in mice. The antigens recognized by such protective mAbs may be candidates for vaccine development. The genes of certain of these antigens have been cloned, and the recombinant antigens are being examined for their efficacy in animals. The antigens which stimulate T cells to produce IFN γ would also be candidates for vaccine development. Use of live organisms of a mutant strain is also in trial. The mutant organisms can infect cats, but do not produce oocysts which is a principal form of the parasite involved in transmission. Immunization of cats with this mutant strain confers marked resistance against oocyst production following challenge infection.

TRANSFER FACTORS

Charles H Kirkpatrick, University of Colorado Health Sciences Center, Denver, Colorado, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Transfer factors are proteinaceous molecules that 'transfer' the ability to express cell-mediated immunity from sensitized donors to unimmunized recipients. Administration of a transfer factor does not activate antibody production by the recipient and does not prime the recipients for anamnestic responses when the appropriate antigen is administered. The immunologic activities of transfer factors are antigen specific.

Transfer factors may have applications in clinical medicine as a mechanism for inducing effective cell-mediated immune responses against infectious microorganisms and, possibly, tumor cells.

The phenomenon of transfer factors was first described by H. S. Lawrence in the mid-1950s when he reported that lysates of peripheral blood lymphocytes from donors who had delayed-type hypersensitivity to antigens such as tuberculin, streptococcal M protein or diphtheria toxoid could transfer delayed-type hypersensitivity to recipients who had been shown to be unresponsive to these antigens. Later, Lawrence and associates showed that the substance that was responsible for transferring the reactivities was dialyzable through membranes with a cut-off value of 12 kDa.

There were several reasons why Lawrence's experiments were questioned by other investigators. First, in his studies in humans the recipients were tested for delayed hypersensitivity to identify candidates for the study; there was concern that these skin tests could prime recipients to respond to the antigen after treatment with the transfer factor. Second, at the time, it was difficult to comprehend immunologic specificity of molecules with molecular weights of ≤ 12 kDa. Third, Lawrence's observations were in conflict with results of similar experiments in guinea pigs.

Although the mechanisms of action of transfer factors have not yet been defined, most of Lawrence's findings, including specificity, have been confirmed independently by subsequent studies.

Nature of transfer factors

A number of molecular models have been proposed through the years. On the basis of sedimentation properties, Gottlieb and coworkers proposed that transfer factors were nucleopeptides. Subsequent reports from Burger's group and by Padlock, Wilson and Fudenberg led to models in which

a peptide moiety was linked to an oligonucleotide by a phosphodiester bond. The presence of a nucleic acid or polynucleotide component in molecules with transfer factor activity has not been established conclusively. In contrast, the evidence for polypeptide is very good.

A major step toward definition of the molecular nature of transfer factor molecules was the discovery that there was a specific interaction between a transfer factor molecule and the antigen for which it was specific. This has allowed development of affinity purification techniques for isolation of individual transfer factors from mixtures of several transfer factors. The affinity purified materials have been processed further by high-performance liquid chromatography and gel filtration; the final products were virtually homogeneous. These materials had molecular weights of 4.9–5.4 kDa and retained the antigen specificity of the starting materials. The entire mass of the molecules could be accounted for by the amino acid composition; there were no detectable nucleic acid components. Subsequent studies of amino acid sequences have shown that a portion of transfer factor molecules is conserved irrespective of the specificity of the transfer factor or the species of origin of the transfer factor. Peptide mapping experiments have shown peptides that are identical in all transfer factor molecules (that have been studied so far) and other peptides that are unique to each transfer factor. The latter peptides are tentatively believed to be related to the specificity of the transfer factors.

Comparison of the sequence of the 'conserved' peptide with other sequences in the database did not reveal a relationship to any previously reported peptides.

Immunological activities of transfer factors

Specificity

A major concern in transfer factor research is how molecules with molecular weights of 4.9–5.4 kDa can transfer antigen-specific immune responses. The mechanism of this specificity has not been defined, but the evidence for specificity is so strong that it must be considered in formulation of models for transfer factor activity. For example, Maurer prepared lysates of leukocytes from human donors who had received ethylene oxide-treated human serum.

These lysates would transfer delayed-type hypersensitivity to recipients that had not received the modified serum. Burger and associates examined transfer factor activity in blood leukocytes of donors both before and after they were sensitized with keyhole limpet hemocyanin (KLH). The preimmunization specimens did not contain KLH transfer factor activity, while the postimmunization materials transferred delayed hypersensitivity to 25 of 26 recipients. Petersen and associates and Kirkpatrick and coworkers used a murine model to examine specificity of transfer factors, including preparations from donors that were immunized with synthetic antigens composed of amino acid random copolymers. Their results are summarized in Table 1. Taken together, the findings of these reports make it essential to consider specificity in formulating hypotheses for the mechanisms of action of transfer factors.

Interactions between transfer factors and antigens

At one time it was proposed that transfer factors were composed of highly immunogenic forms of antigen. This model would explain the specificity of transfer factors. To test this hypothesis, Petersen and colleagues mixed transfer factors with the immunizing antigen and tested the ability of the mixtures to transfer delayed-type hypersensitivity to unimmunized recipients. Their results disclosed that mixing

the transfer factor with the homologous antigen 'neutralized' the immunologic effects of the transfer factor. On the other hand, mixing the same transfer factor with a different antigen did not alter the activity of the transfer factor.

This observation provided evidence against antigenic units in the transfer factors. Of greater significance, it provided the basis for the affinity purification of individual transfer factors.

Transfer factors and delayed-type hypersensitivity

There are no *in vitro* assays for transfer factors. Therefore, the activity must be measured by *in vivo* assays such as transfer of delayed-type hypersensitivity to nonimmune recipients. In a murine system, the footpad swelling assay has been quantitated so that it can be used to follow changes in specific activity during purification.

Transfer factors and cytokine production

The immunologic consequences of administration of transfer factors have been described in clinical and experimental settings. The earliest reports concerned patients with the Wiskott-Aldrich syndrome, chronic coccidioidomycosis or chronic mucocutaneous candidiasis. Similar results were observed in each group of patients. The recipients acquired the ability to express the delayed-type hypersensitivity responses

Table 1 Specificity of transfer factors in assays of delayed hypersensitivity

Experiment	Donor sensitivity	Recipient		
		Antigen used	Footpad response (Δ mm $\times 10^{-2}$)	P
A	HRPO	HBSS	7.17 $\pm$ 3.87	
		HRPO	35.00 $\pm$ 6.09	<0.01
		Ferritin	5.50 $\pm$ 2.46	NS
B	Cytochrome c	HBSS	0.33 $\pm$ 2.22	
		Cytochrome c	22.00 $\pm$ 4.20	<0.001
		Ferritin	2.00 $\pm$ 3.08	NS
C	Ferritin	HBSS	3.50 $\pm$ 1.12	
		Ferritin	18.33 $\pm$ 1.84	<0.001
		Cytochrome c	1.67 $\pm$ 1.99	NS
D	GAT ¹⁰	HBSS	0.20 $\pm$ 2.27	
		GAT ¹⁰	34.40 $\pm$ 4.01	<0.001
		Cytochrome c	1.50 $\pm$ 1.31	NS
		GLA ⁵	4.20 $\pm$ 0.58	NS
E	GLA ⁵	HBSS	1.17 $\pm$ 2.36	
		GLA ⁵	67.33 $\pm$ 2.29	<0.001
		Cytochrome c	-0.67 $\pm$ 2.54	NS
		GAT ¹⁰	4.67 $\pm$ 0.95	NS

HBSS, Hanks' balanced salt solution; HRPO, horseradish peroxidase; GAT¹⁰, terpolymer of glutamic acid, alanine, and tyrosine; GLA⁵, terpolymer of glutamic acid, lysine and alanine; NS, not significant.

that were present in the transfer factor donors. Moreover, when blood lymphocytes from the recipients were examined for production of the lymphokine, macrophage migration inhibitory factor (MIF) *in vitro*, it was found that, in contrast to pretreatment results, the cells responded to antigen activation by secreting this lymphokine.

As with the studies of delayed-type hypersensitivity, acquisition of MIF production by recipients was closely correlated with the delayed hypersensitivity responses of the transfer factor donors.

Subsequent studies in mice have shown that recipients' spleen cells respond to antigen activation by secreting interferon γ (IFN γ).

Transfer factors and lymphocyte transformation responses

In normal subjects, there is a close correlation between antigens that evoke positive delayed hypersensitivity responses and *in vitro* lymphocyte transformation responses. However, this correlation is not common in recipients of transfer factors. Even though the recipients acquire strong delayed-type hypersensitivity, they usually do not have cells in their peripheral blood that proliferate *in vitro* in the presence of the same antigen (Figure 1).

The observations may indicate that the primary targets of transfer factors are IFN γ -producing effector T cells, and that transfer factors may not induce a population of antigen-specific memory T cells. This would be consistent with the observations that the best clinical results are seen in patients who are treated with repeated doses of the transfer factor.

Transfer factors and cytotoxic T cell activity

There have been fewer studies of cytotoxic T lymphocyte (CTL) activity in clinical or experimental situations. However, there are data in patients with malignant tumors and persistent viral infections that indicate that specific transfer factor therapy may activate CTLs.

Genetic studies of transfer factor production and activity

High- and low-responder mice were used to study genetic regulation of production of transfer factors. Donors were immunized with antigens such as amino acid terpolymers (GLA⁵ and GAT¹⁰) and ovalbumin in Freund's complete adjuvant. Spleen cells from high-responder donors were excellent sources of specific transfer factors. Low-responder donors did not express delayed-type hypersensitivity to the immunizing antigen, and their spleen cells did not contain detectable transfer factor activity. However, when the transfer factor from a high-responder donor was given to a low-responder recipient, the recipient acquired the ability to express delayed hypersensitivity to the test antigen that was comparable to the high-responder donor (Figure 2).

Thus, in this model transfer factor treatment changed the phenotype of the low-responder recipient to that of a high responder. This effect is similar to the immunological changes in patients with chronic or recurrent infectious diseases who are treated with specific transfer factors.

Figure 1 Effects of transfer factors on immune responses of recipients. These studies were conducted in patients with chronic mucocutaneous candidiasis. The transfer factor donor had positive delayed-type hypersensitivity (DTH) responses to candida and streptokinase-streptodornase (SK-SD) and a negative test with tuberculin (PPD). Note that before treatment the recipients were anergic, did not produce macrophage migration inhibitory factor (MIF) and did not have lymphocyte transformation responses in the proliferation assay. After treatment, the recipients could express DTH to candida and SK-SD and when their blood leukocytes were exposed to these antigens *in vitro* they secreted MIF. The treatment did not change the results of the lymphocyte proliferation test. The effect of the candida transfer factor was lost after 6 months but was restored by retreatment with the transfer factor.

Figure 2 Effects of transfer factors on genetically controlled immune responses. CBA and BALB/c mice were immunized with ovalbumin (OVA) in Freund's complete adjuvant. After 3 weeks some animals were tested for DTH with the footpad swelling assay; others were euthanized and the spleens were collected for isolation of the ova-specific transfer factor. The CBA mice did not develop DTH to ovalbumin and their spleen cell extracts did not contain OVA-transfer activity that would transfer DTH to CBA (low-responder) or BALB/c (high-responder) recipients. The CBA donors produced a transfer factor that was specific for tuberculin (PPD) indicating that failure to produce the OVA transfer factor was related to the low responder phenotype. BALB/c mice expressed DTH to OVA and their spleen cell extracts produced an OVA-specific transfer factor. Moreover, the same transfer factor could transfer the ability to express DTH to OVA to low-responder CBA recipients. Clinical studies with transfer factors

Several facts must be considered in discussing possible clinical uses of transfer factors. Many of the reports describe one or two patients in which transfer factor treatment was used in desperation; in most instances the long-term outcomes are not described. Second, all of the clinical trials have used leukocyte dialysates; no studies have used materials that were highly purified and it is possible that the immunological and clinical benefits that were observed were due to components other than the transfer factors. The recent demonstration of immunological specificity in highly purified transfer factors, and the close concordance of clinical responses to immunological reconstitution make this explanation less likely.

Several placebo-controlled clinical trials have shown that treatment with specific transfer factors may endow recipients with immune responses that are beneficial. In patients with frequent recurrences of herpes simplex type 1 or type 2, many patients have had complete or nearly complete remissions while on treatment with a herpes-specific transfer factor. Relapses occurred when treatment was stopped or when patients were treated with a similar preparation from a donor who lacked cellular immunity to herpes simplex. Remissions occurred when the patients were retreated with the specific transfer factor.

A placebo-controlled study of a transfer factor preparation from leukocytes of coccidia-immune calves has shown benefits in AIDS (acquired immune deficiency syndrome) patients with intestinal cryptosporidiosis. Long-term remissions of chronic muco-

cutaneous candidiasis have been reported when the patients' immunological defects were corrected by administration of candida-specific transfer factor. A varicella zoster-specific transfer factor was active in preventing chickenpox in children with acute leukemia.

The studies indicate a need for further controlled clinical trials to define the diseases in which transfer factor therapy may be efficacious.

Future research

Important projects include completion of determination of the structures of molecules with transfer factor activity. This would be a significant step toward definition of the mechanisms of their effects on the immune system and why the effects appear to be confined to cell-mediated immunity. In addition, isolation of the appropriate cDNA and production of specific transfer factors *in vitro* will allow clinical studies with purified transfer factors.

TRANSFERRIN RECEPTOR (CD71)

Balbino Alarcón and **Manuel Fresno**, Centro de Biología Molecular Severo Ochoa, CSIC-Universidad Autónoma de Madrid, Madrid, Spain

The first evidence for the existence of the transferrin receptor (TfR) was found in 1963 when Jandl and Katz showed that binding of transferrin to immature red cells was a specific and saturable process. Since then it has been shown that the TfR is present in virtually all dividing cells, which require iron for heme synthesis as well as for the activity of enzymes involved in DNA replication. Independently, monoclonal antibodies (mAbs), such as OKT9 and B3/25, raised against activated T lymphocytes, were found to recognize an immunodominant proliferation-associated cell surface antigen in activated hematopoietic cells. This surface antigen was shown to be the TfR because the mAbs were able to coprecipitate transferrin, although they did not react directly with it. Although the TfR was not initially considered as a cluster of differentiation antigen due to its wide cell distribution, it was finally assigned as CD71 at the 4th International Workshop on Leukocyte Typing.

Structure

The availability of anti-TfR mAbs made possible the biochemical characterization of the TfR and the identification of its coding cDNA sequence. The TfR gene maps to a region of human chromosome 3 containing several genes involved in metal binding. It encodes for a type II membrane protein anchored via a stretch of 26 hydrophobic amino acids (Figure 1).

Figure 1 Structure of the transferrin receptor. The cartoon shows the positions of the phosphorylatable cytoplasmic tyrosine and serine residues, of a fatty acid residue, of the two disulfide bridges, as well as the positions of the three *N*-linked glycosylation sites (◊). At standard extracellular pH conditions, the TfR binds holotransferrin (iron-loaded) but not apotransferrin.

Human TfR has 760 amino acids, of which 672 are extracellular and the first 62 N-terminal ones are cytoplasmic. It forms a homodimer of two 95 kDa subunits which are disulfide-linked through cysteines

89 and 98. Each subunit is able to bind a molecule of transferrin. The protein has three sites for N-linked glycosylation but has no known O-linked sugars. Other post-translational modifications include the addition of palmitic acid at cysteine residue 62 and phosphorylation on serine 24, which appears to be the only site for protein kinase C (PKC). More recently, it has been shown that the TfR also becomes tyrosine phosphorylated.

Tissue expression

TfR-specific mAbs react with many cell types. Although it was originally thought that the TfR was a marker for proliferating cells because most express it, some resting cells can also express the TfR. Indeed, its expression is rather related to the intracellular iron levels, and it is because iron is essential for the activity of ribonucleotide reductase, which is required for DNA synthesis, that the TfR plays an important regulatory role in cell proliferation.

The TfR is broadly expressed in cells of hematopoietic origin (Table 1). In lymphoid tissues, it is present on germinal center cells and macrophages. Resting peripheral blood lymphocytes and monocytes do not express it, but its expression is induced upon activation.

During ontogeny, the TfR is expressed in the populations of cell precursors which are more actively proliferating and is downregulated as cells differentiate to a resting state. Thus, during T cell maturation, the TfR is only expressed in large-sized immature CD4⁺CD8⁻CD3⁻, CD4⁺CD8⁺CD3⁻ and CD4⁺CD8⁺CD3⁺ thymocytes of fetal as well as of

newborn and adult mice, and is subsequently gradually downregulated in the CD4⁺CD8⁺CD3⁻ population. Similarly, the TfR is also downregulated during granulocyte maturation.

Because the TfR is expressed by proliferating cells, it is not, therefore, surprising that it is broadly expressed on carcinomas and sarcomas of different origin as well as on hematopoietic cell tumors. Nevertheless, TfR expression does not seem to correlate with malignant phenotype because it is found, for instance, in low- as well as in high-grade lymphomas, although they may express qualitatively different TfR proteins. Thus, the epitope recognized by mAb Trump is expressed in high-grade but not in low-grade lymphomas.

TfR expression in rapidly proliferating cells makes it a possible target for antitumor therapy. For instance, it has been shown that treatment of bone marrow cells with an anti-TfR/toxin complex kills committed progenitors to CFU-GM and BFU-E but spares immature noncycling, TfR-negative progenitors. Such treatment has been proposed as a purging method for bone marrow autotransplants in leukemic patients.

Regulation of TfR expression

The mechanisms underlying endocytosis and recycling of the TfR have been extensively studied and indeed, the TfR constitutes the most accepted marker for recycling endosomes. Diferric transferrin binds to the TfR and this complex is rapidly endocytosed via coated pits and from there it is transferred via early endosomes to recycling endosomes (Figure 2). Here,

Table 1 TfR cell surface expression on nontransformed cells

Cell type	Expression	
	Unstimulated	Stimulated (stimulus)
Bone marrow		
CD34 ^{high}	++++ ^a	
CD34 ^{med}	+++	
CD34 ^{low}	+	
Cultured endothelial cells	++	+++ (TNFα) ^b
Peripheral blood T cells	+/-	++++ (PHA)
Peripheral blood B cells	+/-	+++ (SAC)
Peripheral blood NK cells	+	+ (IL-2)
Peripheral blood monocytes	+/-	
Peripheral blood eosinophils	-	
Peripheral blood neutrophils	-	- (fMLP)
Platelets	+/-	+/- (thrombin)
Cultured fibroblasts	++	+++ (IL-1)

^aExpression ranged from none (-) to all cells brightly stained with anti-TfR (++++).

^bStimuli used were: tumor necrosis factor α (TNFα), phytohemagglutinin (PHA), *Staphylococcus aureus* Cowan strain (SAC), interleukin 2 or 1 (IL-2, IL-1), formyl-methionyl-leucyl-phenylalanine (fMLP).

Figure 2 Endocytosis of the TfR. Upon binding, the holotransferrin/TfR complex is internalized in clathrin-coated pits (CCP) which detach completely from the plasma membrane (PM) as clathrin-coated vesicles (CCV), and then, become uncoated and fuse with a tubulovesicular compartment, early endosomes (EE). From early endosomes the complex is transferred to another tubulated compartment called recycling endosomes (RE) where under the low intraluminal pH conditions, iron is released to the cytosol to be captured by ferritin. The resulting apotransferrin/TfR complex remains associated and is recycled to the plasma membrane in exocytic vesicles. On the cell surface, under neutral pH conditions, apotransferrin dissociates from the TfR and both become ready to initiate a new cycle.

under low pH conditions, transferrin releases iron but remains associated to the TfR. The TfR/apotransferrin complex is recycled to the cell surface where, at neutral pH, apotransferrin dissociates from the receptor. Endocytosis of the TfR depends on a tetrapeptide sequence, YTRF, in its cytoplasmic tail. This sequence forms a tight turn and promotes endocytosis by binding to a complex of proteins known as adaptins which link the TfR tail to clathrin triskelions.

The expression of the TfR is also controlled at the translational level by the intracellular concentrations of iron. The 3' untranslated region of the TfR mRNA contains an iron-responsive element (IRE) which is also found in the 5' region of the ferritin mRNA. Under low intracellular iron concentrations, an IRE-binding protein (IRP) interacts with TfR's mRNA and inhibits its degradation, whereas the interaction with the 5' element in ferritin inhibits its translation. Both effects tend to increase the concentration of intracellular iron. Under high iron concentrations, IRP dissociates from IREs and the system is set for increased storage and reduced uptake of iron. In addition to iron concentration, other factors affect the level of TfR expression. In hematopoietic cells, interleukin 2 (IL-2), IL-6, cyclic nucleotides, phorbol esters, vitamin D and interferons regulate it. Thus, interferon γ (IFN γ) decreases TfR expression in macrophages; and IFN β , but not IFN γ , has been described to inhibit TfR expression during *in vitro* differentiation of monocytes to macrophages. Some of these cytokines (tumor necrosis factor α (TNF α), IFN γ) increase nitric oxide (NO) production that in turn may regulate TfR expression by increasing the

affinity of IRP for IRE, independently of intracellular iron concentrations.

Role of the TfR

Role in cell proliferation

The depletion of TfR membrane levels or the blockade of transferrin binding with TfR-specific antibodies inhibit cell proliferation probably due to inhibition of iron uptake. In addition, it has been shown that antisense oligonucleotides inhibited progression of mitogen-activated lymphocytes into the cell cycle, synchronizing the cells in G₁. Similar effects were produced by the serum immunosuppressive factor from patients with Crohn's disease that has been shown to inhibit progression of phytohemagglutinin (PHA)-stimulated peripheral blood mononuclear cells (PBMCs) beyond G₀/G₁. This inhibition correlated with downregulation of TfR from the cell surface, although IL-2 receptor expression and IL-2 secretion were not affected.

In addition to the role in iron uptake, several reports suggest that the TfR could have some role in cell proliferation independently of its ability to bind iron, probably involving some form of signal transduction. This effect has been shown especially in T cells which seem to be more sensitive to inhibition of proliferation by TfR-specific antibodies than B cells.

Role on T cell activation and T cell differentiation

Regarding the effect of TfR on T cell activation different results have been obtained depending on the nature of the stimulus used, holo(iron-loaded)-transferrin versus mAbs; and among these, on the mAb used. However, all these data point to a signaling capability by the TfR. Holotransferrin has been shown to activate PKC in the T cell leukemic line CEM, whereas it did not induce increases of intracellular Ca²⁺. However, the TfR-specific mAb J64 was shown to induce IL-2 production by the T cell leukemic line HUT-78 without apparent translocation of PKC. A different TfR-specific mAb, FG1/6, was shown to induce IL-2 secretion by PBMCs and the T cell leukemic line Jurkat, and to costimulate proliferation of peripheral T cells together with PKC activators. Interestingly, J64 was unable to induce Ca²⁺ fluxes in HUT-78, whereas in Jurkat, FG1/6 produced significant increases of intracellular Ca²⁺ of about one-third of those obtained with mAbs against CD3. FG1/6 has also been shown to stimulate the tyrosine phosphorylation of several protein substrates including the ζ subunit of the TCR/CD3 complex and vice versa, CD3-specific antibodies cause the tyrosine phosphorylation of the TfR.

Indeed, it has been suggested that the TfR is functionally and physically associated to CD3- ζ . Nevertheless, most of these experiments were performed with leukemic T cell lines and have to be contrasted with nontransformed T cells.

Consistent with the expression of the TfR in large immature thymocytes, incubation of fetal thymic organ cultures with TfR-specific mAbs blocks differentiation of CD44-CD25⁺ CD4-CD8-CD3⁻ to CD4⁺CD8⁺CD3⁻ whereas it did not affect the differentiation of earlier thymic precursors to the CD44-CD25⁺ population. Most interesting, anti-TfR did not affect development of γ/δ T cells, suggesting a differential susceptibility to iron depletion of both T cell lineages.

Additional roles for the TfR have been claimed: as a putative target molecule for natural killer (NK) cells, as a receptor that mediates uptake and presentation of hepatitis B virus by T cells, and as a receptor that can mediate locomotion of adherent cells.

TRANSFORMING GROWTH FACTOR β (TGF β)

Hans Link and **Bao-Guo Xiao**, Division of Neurology, Karolinska Institutet, Huddinge University Hospital, Stockholm, Sweden

Transforming growth factor β (TGF β) is a cytokine produced by a multitude of cells, including T and B lymphocytes and macrophages. T cells predominantly producing TGF β are both CD4⁺ and CD8⁺ T lymphocytes, and are sometimes termed T_H3 cells. The pleiotropic effects of TGF β include strong growth-enhancing as well as growth-inhibiting properties, depending upon the presence of other growth factors and the type of cells that it acts upon. TGF β is an important immunomodulator. The immunosuppressive property of TGF β was dis-

covered on characterization of a glioblastoma-derived T cell suppressor factor which, after cloning, was termed TGF β_2 . Mice deficient in the gene for TGF β_1 , generated by knockout technology, die from a wasting syndrome accompanied by inflammation in multiple organs. Although TGF β belongs to the group of cytokines with anti-inflammatory effects, it may under certain circumstances also exhibit proinflammatory activities. TGF β participates critically in mucosal tolerance to experimental autoimmune encephalomyelitis (EAE) and myasthenia gravis

(EAMG) induced by oral or nasal administration of autoantigens, and could represent a powerful tool in the future abrogation and prevention of autoimmune diseases.

Molecular structure

The TGF β superfamily consists of a number of structurally related regulatory proteins which, besides TGF β_1 to TGF β_5 , include the inhibins, activins, bone morphogenic proteins and related morphogenic proteins, which are all of importance in many areas of cell biology. The five isoforms of TGF β share biological activities. The prototype of this family is TGF β_1 , originally purified from human platelets. These represent the most concentrated natural source of TGF β . Only TGF β_1 , TGF β_2 and TGF β_3 have been identified and cloned in mammalian species, whereas TGF β_4 and TGF β_5 have been found only in chick and *Xenopus*, respectively. The genes for each of the mammalian isoforms are located on different chromosomes: TGF β_1 on chromosome 19, TGF β_2 on chromosome 1, and TGF β_3 on chromosome 14.

TGF β_1 is a disulfide-linked homodimer of the C-terminal 112 amino acids (12.5 kDa) derived from a 390 amino acid precursor peptide (Table 1). The processed mature TGF β homodimer (25 kDa) is biologically inactive or latent when noncovalently associated with the N-terminal part of the dimeric precursor, the latency-associated peptide (β -LAP), which is linked by disulfide bond(s) to a third molecule termed the latent TGF β -binding protein (LTBP). LTBP is a 125–160 kDa protein containing epidermal growth factor (EGF)-like repeats.

Activation of TGF β occurs by dissociation of the mature dimer from the β -LAP by exposure *in vitro* to pH changes, heat, urea or SDS. The mechanisms for activation *in vivo*, e.g. in the context of inflammation, are incompletely understood. There is evi-

dence suggesting that degradation with plasmin is involved. Retinoids also show a capacity to activate latent TGF β , possibly by increasing the levels of plasmin. Only activated TGF β binds to membrane receptors specific for TGF β . The latent form of the molecule circulates with a half-life of 90 min, whereas active TGF β_1 is removed from the circulation via the liver in 2–3 min.

The three mammalian TGF β isoforms are 25 kDa homodimers in their biologically active form, with 70–80% sequence identity. They exert similar but not identical biological activities *in vitro*, although certain cells respond selectively. The three isoforms are controlled by unique transcriptional regulatory elements and therefore are likely to have different functions *in vivo*. Recent studies using TGF β_1 and TGF β_3 knockout mice have, in fact, revealed functional specificities for each isoform. There are also quantitative differences in that TGF β_1 and TGF β_3 generally elicit their effects at about a 100-fold lower concentration than does TGF β_2 . Most studies to date have involved TGF β_1 .

Receptors and other binding proteins for TGF β

Low numbers of high-affinity receptors for TGF β are found on most normal resting and transformed mammalian cells. Two major receptor species (TGF β RI, 53 kDa, and TGF β RII, 70–80 kDa) are both serine/threonine kinases. Each has a small extracellular region, a single transmembrane domain, and an intracytoplasmic serine/threonine kinase domain. Almost all cells, regardless of their origin, express TGF β receptors and bind TGF β with high affinity. Signaling has been shown to require the formation of a trimeric complex consisting of both TGF β receptors I and II and TGF β . Betaglycan (type III receptor) is a third major cell surface protein with high binding affinity to TGF β . Other binding proteins for TGF β include α_2 -macroglobulin, fibronectin and β -amyloid precursor.

TGF β and the cytokine network

The role of TGF β in immune surveillance and immunotherapy must be conceptualized in the context of its role as a cytokine, participating in the cytokine network (Figure 1). This integrated network includes contributions made through all cytokines involved in inflammation and immunity. The outcome of an immune response is the result of the balance between synergy and antagonism of several cytokines, and dysregulation at any level can contribute to disease pathogenesis. Like other cytokines, TGF β is highly

Table 1 Physicochemical properties of human TGF β_1 , TGF β_2 and TGF β_3

active	2–3 min	—	—

Figure 1 TGF β and the cytokine network. T_H1 cell-derived IFN γ suppresses the activation of T_H2 cells. T_H2-derived IL-4 induces T_H3 cells to secrete TGF β which, in turn, has effects on T_H1 cells, B cells and macrophages. Up- and downregulatory influences are indicated by continuous and noncontinuous arrows, respectively.

potent, acting on cell surface receptors at femtomolar concentrations (10^{-15} M). Since different cell types possess receptors for the same cytokine, TGF β like other individual cytokines may have multiple effects on the growth, differentiation and function of many cell types.

Detection of TGF β

To detect the involvement and quantitative changes of TGF β in experimental and clinical situations, either mRNA or total TGF β activity obtained after acid activation is measured. Bioassays for TGF β are based on inhibiting growth of mink lung cell line MV-1-Lu. *In situ* hybridization to detect TGF β transcripts in, for example, blood mononuclear cells, is a useful approach. It bypasses many of the obstacles inherent to conventional determinations of the concentrations of circulating TGF β by, for example, ELISA. TGF β secreted around diseased

tissue or by circulating lymphocytes is probably quickly captured by receptors on nearby cells as a result of its paracrine actions. The half-life of TGF β is short (Table 1), and its clearance from the systemic circulation is rapid. These features explain why TGF β measurements (as with many other cytokines) by, for example, ELISA, performed on human body fluids in disease states, frequently give inconsistent or negative results. There are, however, some reports on the successful evaluation of TGF β , as in serum from psoriasis patients, who showed elevated TGF β levels compared to healthy subjects, and even a significant correlation with clinical severity.

Measurements of mRNA or total TGF β activity tell nothing about the relative production of active versus latent forms of TGF β by, for example, blood mononuclear cells. Furthermore, the intracellular localization of cytokine transcripts does not necessarily equate with patterns of cytokine secretion. A discrepancy may be due to post-transcriptional

regulation of cytokine mRNA, or post-transcriptional regulation of cytokine secretion. Translational control has been reported for TGF β .

TGF β and immune privilege

Recent evidence supports the view that immune privilege is an active process and that its creation results from local tissue factors that interact with and alter the functional programs of cells of the immune system. Locally produced and released immunosuppressive cytokines constitute, besides neuropeptides, factors which maintain immune privilege. Intraocular fluid contains significant amounts of TGF β , which accounts in part for the immunosuppressive activities of the fluid.

Immunoreactive TGF β has been identified in CSF and in amniotic fluid. As these fluids are also considered to represent immune privileged sites, the possibility exists that TGF β contributes to a common

strategy designed to modulate immunity at such sites. In culture, microglia express the immunosuppressive cytokines TGF β_1 and interleukin 10 (IL-10) to a greater degree than proinflammatory cytokines. High TGF β levels could reflect one mechanism for immune privilege within the brain. Stimulation with LPS or IFN γ led to shift toward proinflammatory cytokine mRNA profiles in microglia, providing insight into the mechanism by which LPS and IFN γ act in inflammatory diseases of the CNS.

TGF β and the immune response

TGF β exhibits bifunctional properties, depending on the type and state of cells as well as the presence of other cytokines (Figure 2). TGF β_2 has been shown to completely suppress the proliferative response of CD4 $^+$ or CD8 $^+$ T cell clones to IL-2 or phorbol ester/ionophore. TGF β blocks the generation of both cytotoxic T cells in allogeneic mixed lymphocyte cul-

Figure 2 The bifunctional properties of TGF β .

tures and IL-2-induced cytokine-activated killer cells and natural killer (NK) cells. It has become clear that TGF β downregulates both cell-mediated and humoral immunity. TGF β probably exerts its immunosuppressive effects by regulating the expression of other cytokines, e.g. interferon γ (IFN γ). TGF β inhibits the production of both IFN γ and IL-4 in mitogen-activated human blood mononuclear cells.

TGF β administered systemically has profound effects on models of organ-specific inflammatory diseases, including experimental autoimmune encephalomyelitis (EAE) and collagen-induced arthritis. The pronounced suppression of the localized immune responses is not associated with any significant generalized immune suppression. These observations could reflect resistance to suppression of resting lymphocytes, but increased susceptibility of activated T lymphocytes. This may also explain the apparently opposing effects of TGF β on cells at different times in their life cycle: TGF β is released early and functions in many capacities to promote inflammation based on its stimulating effects on immature monocytes and T cells. Once these cells differentiate and become activated, they become susceptible to phenotypic modulation and functional inhibition by TGF β . Under normal conditions, this transition from pro- to anti-inflammatory responsiveness occurs with minimal disruption of host cell and tissue homeostasis.

TGF β -dependent suppression of antigen-induced T cell growth involves several distinct pathways which include 1) the direct inhibition of mitosis in the late G₁ phase of the cell cycle, and 2) regulation of transcription of the early growth factor-dependent *c-myc* gene and of the transferrin receptor. TGF β may also suppress clonal expansion indirectly by inducing synthesis of IL-1 receptor antagonist that has the capacity to abort IL-1-dependent responses.

TGF β also influences maturation of T helper cells in different ways. TGF β suppresses the development of IL-4-producing T lymphocytes and stimulates the generation of IFN γ -secreting T cells *in vitro*. In contrast, in an *in vivo* murine model, administration of TGF β at the time of infection with *Leishmania amazonensis* or *L. braziliensis* induced increased mRNA levels for IL-4 and decreased levels for IFN γ .

CD4⁺ and CD8⁺ T lymphocytes are differentially susceptible to TGF β : inhibition of CD4⁺ T cells is nearly complete, whereas TGF β is considerably less inhibitory and may even promote CD8⁺ cell growth. Resistant CD8⁺ T cells synthesize cytokines including IL-4 and IL-10 which have additional immunosuppressive properties. Under appropriate conditions, TGF β appears to foster the generation of inhibitory feedback molecules and apparently works in concert

with them to reverse immune processes. TGF β contributes to the shift toward T_H2-type responses through direct and IL-10-mediated pathways. TGF β can induce apoptosis in cultured uterine epithelial cells, hepatoma cells, gastric carcinoma cells, myeloid leukemia cells, resting B cells and hepatocytes *in vitro* and *in vivo*.

TGF β can inhibit proliferation and immunoglobulin (Ig) production by B cells. However, in the presence of an adequate combination of activators, e.g. antigen and T cell help, the inhibitory effects of TGF β are abrogated and large numbers of IgA⁺ cells can be produced in Peyer's patches along the small intestine. Which cells produce the TGF β involved in regulation of IgA switching by inducing germline α -transcripts and how it is regulated remains to be settled.

TGF β is known to induce its own production and secretion. The autoinduction of TGF β ₁ transcription is mediated by AP-1 (Jun-Fos) binding sites in the TGF β ₁ promoter. By this mechanism, TGF β activity might become persistent, resulting in deleterious effects.

An inflammatory process in the brain requires bidirectional interactions of the immune and nervous system. Expression of TGF β is highly regulated in T cells and is probably an important component in the molecular interaction between the immune and nervous systems. Glucocorticoids cause a significant decrease of TGF β ₁ mRNA levels in glial cells but not T cells, indicating that TGF β ₁-regulatory pathways can be utilized to affect the functions of neural and immune cells. Microglia, the macrophages of the central nervous system (CNS), are positive for TGF β ₁ mRNA and release TGF β ₁.

TGF β has immunosuppressive functions within the CNS. The target cells of this action are still unknown. TGF β ₁ selectively induced apoptosis of microglia, but not astrocytes and oligodendrocytes. Bcl-2 oncoprotein was mainly expressed in microglia, indicating that TGF β ₁-mediated microglial apoptosis was regulated by a bcl-2-independent mechanism.

Overproduction of nitric oxide (NO) by glial cells, but not by infiltrating mononuclear cells, can be a major cause of target tissue damage in autoimmune diseases such as EAE and multiple sclerosis (MS). TGF β has been shown to inhibit NO production by microglia. Astrocytes secrete both the active and latent form of TGF β ₂. Exogenous administration of TGF β could beneficially influence the course of such diseases. TGF β has also been shown to suppress rat astrocyte autoantigen presentation, and antagonizes hyperinduction of major histocompatibility complex (MHC) class II antigen induced by IFN γ or TNF α .

TGF β and experimental infectious diseases

The immunoregulatory effects of TGF β_1 and TGF β_2 have been assessed in mice infected with lymphocytic choriomeningitis virus (LCMV). Intraperitoneal injections of 1 μ g per day of recombinant TGF β_1 and TGF β_2 prolonged the survival interval after LCMV infection, inhibited the footpad swelling after local LCMV infection and impaired clearance of LCMV in infected mice. In Borna disease, a sporadically occurring progressive encephalopathy of sheep and horses that can be induced in a wide range of animal species by infection with Borna virus, a single-stranded RNA virus, TGF β inhibited clinical disease and reduced the inflammatory reaction and MHC class II expression in the brain and the production of antibodies to the virus.

TGF β and experimental autoimmune diseases

The influence of TGF β on EAE as a prototype of organ-specific CD4 $^+$ T cell-mediated autoimmune disease has been extensively studied. TGF β strongly inhibits *in vitro* activation of T cells from Lewis rats with EAE. During recovery from EAE, CD4 $^+$ spleen cells produce TGF β and thereby regulate both the production of IFN γ and the encephalitogenicity of effector cells. Systemic administration of TGF β reduces the incidence and severity of EAE induced in the SJL mouse, without generalized immunosuppression. This observation is in line with the known resistance of resting lymphocytes, but increased susceptibility of activated T lymphocytes, to suppression. *In vivo* administration of antibody to TGF β worsened the clinical signs of monophasic EAE. Taken together, these observations suggest that endogenous TGF β has an important role in the natural recovery from EAE. The mechanisms of how TGF β acts in EAE are not yet fully understood but it can be assumed that the disease-limiting effects are at least in part mediated through suppression of autoantigen presentation. In addition, TGF β_1 inhibited MBP-stimulated glial cell proliferation, and down-regulated the expression of ICAM-1 on MBP-stimulated glial cells. TGF β_1 -mediated inhibition of proliferation and down-regulation of ICAM-1 on glial cells were interrupted by IFN γ , indicating that biological effects of TGF β_1 vary depending on the local microenvironment.

TGF β also has protective effects on other experimental models for human autoimmune diseases, such as T cell-dependent arthritis induced by immunization with collagen. However, the injection of

TGF β into the ankle joint cavity of Lewis rats induced synovial erythema and swelling similar to that observed in rheumatoid arthritis, although the process was self-limiting. Besides the different consequences between systemic and local administration of TGF β , several other factors determine its biological effects. The wide-ranging biological effects of TGF β are illustrated in Figure 3. Local administration of TGF β_1 accelerates the healing of various cutaneous wounds. An excess of TGF β_1 causes scar tissue formation. TGF β can actively regulate the rate at which CD4 $^+$ CD8 $^+$ thymocytes are generated from precursor cells. TGF β can counteract the rejection process and could be useful for new therapeutic approaches of allograft rejection. TGF β is also a switch factor for the IgA class.

Tolerance induction and TGF β

Oral administration of myelin basic protein (MBP) to rats effectively prevents EAE induced by immunization with MBP in Freund's complete adjuvant. Evidence has been presented that such tolerance is mediated by CD8 $^+$ T cells producing TGF β . TGF β is also strongly upregulated in DA strain rats treated with low doses of MBP by the nasal route. Nasal tolerization with MBP efficiently prevents the induction of protracted-relapsing EAE in DA rats. In the acute Lewis rat EAE model, nasal administration of MBP or MBP peptides 63–88 or 89–101 resulted in increased levels of TGF β mRNA-expressing immune cells. TGF β -mediated bystander regulatory mechanisms are thought to be important for nasal tolerance induction. High numbers of TGF β mRNA-positive mononuclear cells are also found in lymph nodes of rats tolerized to the mainly B cell-mediated experimental autoimmune myasthenia gravis (EAMG) by oral or nasal administration of the target antigen acetylcholine receptor (AChR). Such findings suggest that a nonspecific bystander regulation dominated by upregulation of TGF β is pivotal for induction of tolerance to autoimmune diseases.

Human autoimmune and infectious diseases

Patients with multiple sclerosis (MS) have dramatically elevated levels of TGF β mRNA-expressing mononuclear cells in blood and CSF. MS patients also have elevated numbers of circulating MBP- and proteolipid protein (PLP)-reactive TGF β mRNA-expressing cells. Interestingly, patients with severe MS had fewer cells expressing TGF β mRNA compared to patients with mild MS. In another recent study, patients with stable MS had higher levels of

Figure 3 Local effects of TGF β .

TGF β mRNA in blood mononuclear cells than patients with relapsing MS. The data support a disease-limiting role for TGF β in MS.

Patients with myasthenia gravis have elevated levels of AChR-reactive TGF β mRNA-expressing blood mononuclear cells. Levels of circulating TGF β mRNA-expressing cells increase after thymectomy. The relevance of TGF β in myasthenia gravis is unclear, but it may have therapeutic potential in this disease.

Elevated TGF β levels have been reported in serum in HIV infection and in cell supernatants after culture of blood mononuclear cells from human immunodeficiency virus (HIV)-infected patients. Levels of TGF β mRNA-expressing mononuclear cells are elevated in HIV-infected patients' blood. TGF β has been identified by immunohistochemistry in brain tissue of patients with the acquired immune deficiency syndrome (AIDS). It has been suggested that TGF β may play an important role in the spread of infection and/or disease progression by amplifying the existing viral load.

Femtogram concentrations of TGF β_1 suppresses *in vitro* myelin antigen (MBP, PLP)-induced upregulation of $\text{IFN}\gamma$, IL-4, IL-6, $\text{TNF}\alpha$ and lymphotoxin, and of perforin, in MS. TGF β also suppresses AChR-induced upregulation of the same proinflammatory

cytokines in myasthenia gravis. In contrast, TGF β has no corresponding effects on IL-10 or on TGF β itself. These selective suppressive effects of TGF β_1 on autoantigen-induced upregulation of proinflammatory cytokines makes TGF β attractive as a potential therapeutic agent in MS and myasthenia gravis.

TRANSFUSION

Willy A Flegel, Abteilung Transfusionsmedizin, Universität Ulm, Ulm, Germany

Transfusion medicine relates to substitution therapies with human blood in cytopenias, protein deficiencies, and blood loss during surgery. Peripheral blood cell and plasma collection, processing, storage, compatibility matching and transfusion are large scale procedures in blood centers and hospitals today. Initially, humoral alloimmunizations presented a serious obstacle to allogeneic transfusion. This was overcome by the discovery of red cell blood groups and the development of modern blood group serology and immunohematology covering the clinical aspects of allo- and autoantibodies to red cells. Later, bloodborne viruses were recognized as the pre-eminent risk of transfusion. In the last 15 years, major progress has been made in limiting the transmission rate of viral infections. The possible immunologic side-effects of transfusion are a major and still largely unsolved topic in transfusion medicine.

Blood components

Whole blood is separated into its different cellular and plasmatic components and processed within several hours of donation. Processing is being continuously improved in order to reduce contaminating cells and plasma. Numerous processing steps are applied which influence the purity, side-effects, storage time, etc. Preparation procedures, standard blood components and indications vary considerably among and within different countries. Because of considerable disadvantages associated with the transfusion of whole blood, its use has almost been aban-

doned. Blood components are often administered on empirical grounds, when clinical studies to validate their use are lacking, to substitute specifically those constituents of the patients' blood which fall below the minimal tolerable threshold. During hemorrhage or hemolysis the oxygen-carrying capacity of erythrocytes must be replaced first, in addition to intravascular volume. After further blood loss the substitution of plasma and platelets to restore plasmatic and thrombocytic coagulation activity may also be required (Table 1).

Hematopoietic stem cell therapy

After suitable stimulation by cytokines, such as granulocyte colony-stimulating factor (G-CSF), hematopoietic stem cells can be harvested from peripheral blood by cytapheresis in sufficient quantities for stem cell transplantation. This may supplant, in many clinical situations, the collection of stem cells from bone marrow. Applications are autologous stem cell therapy to promote rapid hematopoietic recovery after intensive chemo- and radiotherapy, and allogeneic bone marrow transplantation in hematologic failure and malignancy.

Autologous blood

The term allogeneic blood refers to that used in transfusion from donor to recipient. However, the patient's own (autologous) blood can be collected before an expected transfusion need and transfused during, for example, planned surgery. Many but not

Table 1 Blood components used in current transfusion and bone marrow transplantation practice

<i>Blood components used in substitution therapies</i>	
Erythrocytes	
	Buffly coat depleted with additive solution (standard)
	Buffly coat depleted (standard in some countries)
	Leukocyte and thrombocyte reduced (filtered)
	Washed (rarely indicated)
	Stored frozen at -80°C or in liquid nitrogen (rarely indicated)
Plasma	
	Quarantine stored (standard)
	Fresh frozen (standard in some countries)
	Virus inactivated (alternative to quarantined plasma)
	Lyophilized and virus inactivated
Platelets (thrombocytes)	
	Buffly coat-derived platelet concentrates (standard)
	Platelet-rich plasma (standard in some countries)
	Leukocyte reduced (filtered)
	HLA-matched single donor thrombocytophoresis preparation
Granulocytes	
	HLA-matched single donor granulocytophoresis preparation
Whole blood (obsolete in some countries)	
	Fresh blood
	Warm blood
	Pure blood
<i>Hematopoietic active tissue used in bone marrow transplantation</i>	
Stem cell preparations (CD34⁺ cells)	
	Peripheral blood stem cells induced by growth factors (G-CSF, GM-CSF)
	Bone marrow stem cells prepared from bone marrow tissue with/without T cell depletion
Bone marrow tissue	
	Without further processing
	T cell depleted
	Purged for malignant cells (in autologous transplantation)

all immunologic problems of transfusions may be avoided by this strategy. Endogenous and exogenous materials in autologous blood may still cause adverse effects. It is generally accepted that autologous blood should be used in all groups of patients and indications for which benefit and cost-effectiveness is established. Other options reducing for allogeneic transfusion are perioperative blood salvage, increase of endogenous red cell production by erythropoietin and control of blood loss by surgical/anesthetic techniques.

Screening for infectious agents

Since the 1970s donors have been screened for hepatitis B virus infection and for syphilis. Alanine aminotransferase is used as a surrogate test for early viral hepatitis A, B and C or non A, non B, non C hepatitis. Major improvements were brought forth by the introduction of testing for human immuno-

deficiency virus (HIV) in 1985 and for hepatitis C virus in 1990, rendering the blood supply today safer than ever. The rate of infectious units in the blood supply varies considerably among different populations and over time within a population. It depends on the endemic diseases, the selection of the donor populations and their epidemiologies, which need to be monitored on a continuous basis. Because infectious donors may be missed during the diagnostic window, both the incidence of infections and their prevalence are important parameters. Removal of white blood cells, which serve as a shuttle for some viruses, may limit viral transmission. Plasma is often quarantined for 6 months until the donor is retested, once the window period of virus infections has expired (Table 2).

Immunohematology

The natural occurrence and lifelong persistence of alloantibodies (isoagglutinins) to the ABO blood group antigens preclude all ABO-incompatible transfusions. For this reason transfusion became feasible only after the discovery of the ABO blood group system in 1900 using the erythrocyte agglutination technique. Clinically relevant alloantibodies to most other blood group antigens hardly occur before immunization by transfusions or pregnancies. Besides ABO, a few other antigens such as Rh D and Kell are always considered in transfusion practice in Caucasians, because of their prevalence and immunogenicity. The relative immunogenicity of antigens is determined by comparing the actual antibody frequency and the calculated frequency of the probability of exposure. The genes of almost all blood groups are cloned, allowing the molecular

Table 2 Infectious marker screening

<i>Routinely tested in many countries</i>	
HIV-1/HIV-2	HIV-specific antibodies, sometimes p24 antigen
Hepatitis B virus	HBsAg, sometimes HBc-specific antibodies
Hepatitis C virus	HCV-specific antibodies
HTLV-1	HTLV-1-specific antibodies
Syphilis	<i>Treponema pallidum</i> -specific antibodies (TPHA)

Other pathogens and diseases commonly transmissible by blood

Cytomegalovirus, parvovirus B19, Epstein-Barr virus, yellow fever, malaria, Chagas disease, toxoplasmosis, leishmaniasis, onchocerciasis

HTLV-1, human T cell lymphoma virus.

characterization of the allelic diversity. Recently, all authenticated blood group antigens were revised according to their genetic basis and may fall into one of four classifications: systems, collections, low incidence antigens (700 series), and high incidence antigens (901 series). A numerical terminology was devised. Systems are genetically discrete from each other and are represented by antigens controlled by one or more very closely linked homologous gene loci. Collections comprise antigens, which are related but do not meet system status criteria. Low and high incidence antigens that do not belong to systems or collections are grouped into series. The antigen structure is generally constituted either by carbohydrates or by proteins (Table 3).

Since about 1960, efficient antibody detection and cross-matching (compatibility testing between donor and recipient) have been routinely applied using the antiglobulin (Coombs) test. A serologic incompatibility causing immediate or delayed hemolytic transfusion should rarely be a serious threat today. The recent introduction of matrix (gel) and solid phase tests increased the sensitivity of antierythrocyte antibody detection and holds promise in respect to standardization and automation.

Immunomodulatory effect of transfusion

The transfusion of various allogeneic blood components is circumstantially linked with subtle immunosuppressive effects. Whole blood transfusions may enhance renal allograft survival and reduce relapse rates of Crohn's disease. In some murine models tumor growth and bacterial infection can be

increased by transfusion of fresh allogeneic whole blood, but not by that of prestorage leukocyte-depleted blood. Many observational studies in humans reported considerable increases in serious short- and long-term sequelae of allogeneic transfusions, but are known to lack control of important confounding factors (Table 4).

Current clinical studies

The combined results of the prospective, randomized, controlled clinical trials conducted to date do not prove a significant difference in cancer recurrence nor in postoperative infection. While the sizable effects reported in many retrospective studies may be incorrect, smaller clinical differences of great public health interest cannot be excluded. Buffy coat-depleted erythrocytes were mainly used in the controlled studies; they are assumed to have fewer immunosuppressive effects than whole blood. Deleterious transfusion effects are also missed if they occur equally with allogeneic and autologous blood, because some undesired compounds like cell debris and cytokines may not differ.

Possible mechanisms

While the clinical relevance of a possible transfusion-associated immunosuppression have not been shown unequivocally, several mechanisms affecting the recipients' cellular immunity have been reported, including T cell anergy and decreases in helper:suppressor T cell ratio, natural killer (NK) cell function or antigen presentation. Any immunosuppressive effect based on tissue type mismatches of the donor-recipient pair is expected to depend on the HLA

Table 3 Blood group systems, genes, structure and antigens

Common name	ISBT terminology ^a	Gene names	Null alleles	Chromosomal location	Important antigens ^b	Year of discovery

^bExamples for receptor functions of blood group antigens are: Le(b), *Helicobacter pylori*; Fy6, *Plasmodium vivax*, interleukin 8; P₁, parvovirus B19 (ISBT 209 GLOBO collection of antigens); AnWj, *Haemophilus influenzae* (ISBT 901 series of high incidence antigens). With the exception of Lewis antigens, all antigens are present on fetal red cells, albeit some antigens may be expressed with a reduced number of antigens per cell.

Table 4 Parameters relevant for the immunological consequences of blood transfusion

Blood component preparation technique
Content of therapeutically intended cellular and plasmatic components
Erythrocytes, thrombocytes, granulocytes and plasma
Contamination by constituents not intended for therapy
White blood cells (WBC) (in all blood components)
Plasma (in all cellular components)
Erythrocytes (in platelet and plasma components)
Number and viability of donor WBC
Preparation technique
Storage conditions (time, temperature)
Gamma or ultraviolet irradiation
Content of stem cells and T cells
Ratio of T cells/stem cells
Immunocompetence of recipient
Age of patient (fetus, newborn, elderly)
Underlying disease (lymphoma, immunodeficiency diseases)
Concurrent therapies (chemotherapy, bone marrow depletion, immunosuppressive therapies)
HLA-relationship between donor and recipient
Accidental similarity dependent on ethnic backgrounds
Intended similarity in organ transplants contaminated by WBC and HLA-matched blood components
Immunohematological differences between donor and recipient
Dependent on the degree of blood group matching
Accidental similarity dependent on ethnic backgrounds
Allo- and autoantibodies in plasma
Endogenous materials released after blood donation
Cytokines (IL-1, IL-6, IL-8, TNF α , etc.) from WBC
Proteolytic enzymes (elastase, cathepsins, etc.) from WBC
Metabolic products from erythrocytes and platelets
Soluble antigens from erythrocytes, platelets and WBC
Cellular debris from erythrocytes, platelets and WBC
Exogenous materials, processing steps
Bacterial and viral contamination
Storage conditions (time, temperature, agitation)
Stabilizers, anticoagulants and preservatives (adenine, glucose, sodium citrate, sodium dihydrogen phosphate, citric acid, mannitol)
Leaching of plasticizer from the plastic containers
Chemicals used for viral inactivation (methylene blue)
Cellular damage by gamma or ultraviolet irradiation

haplotype profiles and thus may vary between different populations.

Mononuclear cell microchimerism

The fate of transfused leukocytes is essentially determined by the balance of three factors: 1) the dose of allogeneic leukocytes; 2) the immunocompetence of the recipient; and 3) the antigenic differences between donor and recipient, which are mostly due to HLA mismatches. Generally leukocytes transfused by buffy coat-depleted erythrocyte preparations are rapidly cleared, with almost no persistence beyond 1 week, if donor and recipient were HLA unmatched.

HLA immunization usually occurs only after repeated or high-dose leukocyte exposure. However, leukocytes of fetal origin can circulate in the mother for months after delivery, and maternal leukocytes for years in the child. Lasting microchimerism is found in some HLA-matched solid organ transplant recipients, who may develop donor specific HLA tolerance. In the immunosuppressed patient prolonged leukocyte chimerism and life-threatening graft-versus-host disease (GVHD) may ensue, particularly if the HLA antigens are closely matched. In less well characterized instances microchimerism with lack of or subclinical GVHD occurs, possibly following induction of anergy or peripheral tolerance.

Transfusion-associated graft-versus-host disease

Transfusion-associated GVHD (TA-GVHD) in immunocompetent recipients may occur in transfusions of blood from HLA-homozygous donors to HLA-heterozygous patients who share an HLA haplotype. Because of a linkage disequilibrium, a few combinations of certain HLA antigens represent a large fraction of HLA haplotypes. Estimates for TA-GVHD-prone HLA constellations are calculated as a function of the HLA haplotype frequencies, which vary considerably among different populations (Table 5).

The actual occurrence of TA-GVHD is lower probably because of subtle HLA differences and because of HLA-independent elimination of T cells from the graft (for example by reduced viability after prolonged storage or prestorage leukocyte removal), which are not taken account of in current models. In transfusions between blood relatives the risk of TA-GVHD is considerably increased. In directed transfusions (i.e. blood donated for use in a specific recipient such as between blood relatives) gamma irradiation with a dose of 30 Gy (3000 rad) is mandatory for all blood components. The potential risk of TA-GVHD to the local population should be considered in directed blood donation programs.

Mediators in blood components

Mediators are produced and released during storage of blood components. Clinically relevant concentrations of pyrogenic cytokines (interleukin 1 (IL-1), IL-6 and tumor necrosis factor α (TNF α)) and histamine may occur. These cytokines – and not, as previously thought, the leukocytes themselves – are the cause of the high rate of febrile transfusion reactions experienced with platelet-rich plasma. Other blood components are less prone to mediator induction

Table 5 Frequency estimates for TA-GVHD-prone HLA constellations

Population	Estimate of frequency ^a		Relative increase in directed transfusions ^b
	Minimal	Maximal	
USA (Whites)	1:39 034	1:17 682	21-fold
Spain	1:175 296	1:10 595	23-fold
France	1:68 742	1:6 365	17-fold
Germany	1:48 583	1:6 903	18-fold
Japan	1:7 981	1:1 612	11-fold

^aIn nondirected transfusions.^bBetween parents and children or vice versa as compared to nondirected transfusions.

because of their smaller leukocyte content and lower storage temperatures. Evidence of clinical effects is lacking for the amounts of mediators occurring in most blood components.

Blood substitutes

The efficacy of synthetic blood substitutes as oxygen carriers has been known since the 1960s. Because of severe adverse effects, it is the improvement of biocompatibility rather than of oxygen-carrying capacities that is needed. Pharmacologic requirements are absorption and release of oxygen and carbon dioxide in physiologic conditions; oncotic, osmotic, rheologic and immunologic compatibility; lack of cell and tissue toxicity; limited resorption by the reticuloendothelial system; no effect on hematopoiesis; and sufficient but limited intravascular retention time.

Perfluorocarbon emulsions and modified hemoglobin solutions

Perfluorocarbons, which dissolve oxygen and carbon dioxide physically, are biologically inert fluorinated polycarbonates and can be excreted via the lung. They are oily liquids and need to be emulsified by tensids, which are often the cause of adverse effects. Because free hemoglobin is toxic, several modifications of hemoglobin, such as polymerization, conjugation, microencapsulation and S-nitrosylation, have been developed. After promising results in phase I studies, phase II trials are currently being conducted with both kinds of blood substitute.

Future prospects

Immunomodulation and blood component quality

Despite the large-scale use of blood substitution therapies for more than four decades, the immunologic sequelae of allogeneic transfusions are not fully understood. Improvement in transfusion medicine

will be achieved by enhanced preparation techniques, purer blood components, avoiding cytokine and leukocyte contamination, and consideration of the donor-recipient immunologic relationship. This development requires particular emphasis on quality assurance and transfusion management, which allows the better definition of trigger factors and exact indications for the different blood components. The characterization of mononuclear cell microchimerism may contribute to the understanding of peripheral tolerance induction. As our knowledge of the transfusion effects on the immune system increases, the importance of a more precisely defined blood component therapy will become more evident.

Stem cells, blood safety and substitutes

Major advances are currently being made in hematopoietic stem cell therapy. Many aspects of cell recovery by cytophoresis, progenitor cell processing and expansion, handling and storage are under investigation. Further advances in the safety of the blood supply are to be expected from improved screening methods for infectious agents, such as the polymerase chain reaction technique, and by the discovery of additional hepatitis viruses. Inactivation of viruses in cellular blood components is also being investigated. If the biocompatibility of artificial blood substitutes can be enhanced sufficiently, they may become useful in applications for which blood transfusion is not feasible.

Genotyping and recombinant technology

Blood group genotyping is already practised in prenatal diagnostics and may find much broader application in the future. Use of recombinant blood group proteins could improve antibody detection techniques. The large blood group databases may be utilized in the molecular genetic analysis of null mutations, silent mutations and gene hybridizations, elucidating the genetic diversity of alleles in natural populations.

TRANSGENIC ANIMALS

George A Kollias, Department of Molecular Genetics, Hellenic Pasteur Institute, Athens, Greece

Transgenic animals are those that, as a consequence of experimental DNA transfer application, have exogenous DNA integrated in their germ line. The integrated DNA may or may not derive from the same species as the host genome; it may or may not encode for a functional gene; and it may or may not be targeted to an intended site of incorporation in the genome. Although the term 'transgenic animal' fully represents all such cases, more specific terms such as 'knockout animals' or 'mutant animals' are used to notify the targeted disruption or mutagenesis of selected endogenous gene sequences in the germ line of animals. Most of what we know of transgenesis in animal species comes from experimental work on the mouse but transgenic technology has been also successfully applied in insects, domestic livestock, poultry and fish.

Historically, the first transgenic mouse was created by Jaenisch in 1976, by infection of preimplantation embryos with murine leukemia virus which resulted

in germline integration of the virus. Today, almost all transgenic mice are produced by pronuclear microinjection of DNA into fertilized eggs, a technique introduced in 1980 by Gordon and colleagues (Figure 1). One of the most important properties of transgenesis in animals is that the introduced transgenes usually retain their natural cell-type specificity of expression but show perturbed quantitative regulation. This selective perturbation of gene expression in whole animals allows us to interfere with physiological processes and thereby to reveal gene function. The use of transgenic animals in biological and biomedical research has increased dramatically during the last decade and has advanced greatly our understanding of gene structure and function in physiological and pathological processes. In addition, biotechnological applications of transgenesis in large animals have provided a potential for its commercial exploitation in agriculture and biotechnology.

Figure 1 Microinjection of DNA into one of the pronuclei of a mouse zygote. (Photo taken by Sally Hill, Department of Molecular Genetics, Hellenic Pasteur Institute).

Production techniques

Direct microinjection of DNA into one of the pronuclei of a zygote (Figure 1), has been the most rewarding technique for the production of transgenic mice, rats, rabbits and large domestic livestock such as sheep, pigs and cows. The technique (Figure 2) requires special equipment and technical skills but in comparison to other methods it remains the most straightforward and efficient way to produce transgenic animals. Briefly, the procedure as it applies in the mouse, consists of collecting a number of fertilized mouse eggs, visualizing their male and female pronuclei under appropriate microscope optics and injecting one of them with a DNA solution

(containing a few hundred copies of the gene of interest) using a fine glass needle prepared on specialized equipment (pipette puller). Injected eggs are then surgically transplanted into the oviducts of 'pseudo-pregnant' female mice (mice that have been mated with a vasectomized male) and left to develop to term. In general, it is expected that in skilled hands, as many as 90% of the injected eggs survive the microinjection, approximately 20% of these develop to term and approximately 20–50% of the latter are found to carry the injected DNA in their tissues. Integration of the transgene occurs apparently at a random site in the genome, either as a single copy or as a tandem head to tail array. In rarer cases, head to head arrangements and multiple integration sites should also be expected. In most cases transgene integration occurs in 100% of the animal cells, however, in as high as 30% of transgenic founder mice genetic mosaicism has been observed which means that only a subset of cells in the different tissues, including the germ line, carries the transgene. Subsequent derivation of transgenic progeny from such transgenic animals leads to the generation of fully transgenic animals that transmit their transgenes in a Mendelian fashion.

In addition to the microinjection procedure, there have been several alternative methods for introducing foreign DNA into the germ line of mice. Infection of preimplantation embryos with recombinant retroviruses offers a highly efficient route of single copy

Figure 2 Experimental scheme for the production of transgenic mice by the pronuclear microinjection technique. (Computer graphics by Katerina Akassoglou, Department of Molecular Genetics, Hellenic Pasteur Institute).

integrations into the mammalian genome; however, a main disadvantage of this procedure is that retroviral vector DNA usually interferes with the expression patterns of the genes that it carries. Yet another route to transgenesis employs the introduction of exogenous DNA into totipotent mouse embryonic stem (ES) cells and their consequent incorporation into the blastocyst of a developing mouse embryo. This is technically a very demanding procedure and it does not offer advantages over the direct pronuclear microinjection for transgenesis; however it has been so far a uniquely applied technique for the targeted disruption ('knockout') or mutagenesis of endogenous genes in mice.

Optimal transgene design

It is well known that transcriptional efficiency and tissue specificity of gene expression is mainly influenced by proximity to the gene *cis*-acting elements such as promoters and enhancers, and when desired such elements should be included in the transgene construct. To discriminate the transgene and the protein that it encodes, from that of the endogenous counterpart, the injected gene must differ in some way from the respective endogenous gene and this is accomplished either by using transgenes from different species or by using transgenes that carry diagnostic modifications. Since it has been shown that prokaryotic sequences inhibit the expression of some transgenes, inclusion of large prokaryotic DNA sequences such as plasmid vector sequences in the linear DNA fragment to be injected, should be avoided. When desired, 'minigenes', that is genes with some introns deleted (e.g. constructs containing cDNA sequences) may be used, but the presence of introns seems to facilitate expression and they are usually included in the transgene construct.

A major issue in attempting to generate correctly regulated gene expression in transgenic mice is the influence of the so-called 'integration position effects' on transgene expression. For example transgenes containing all proximal control regions are rarely expressed at the same level as their endogenous counterparts and almost always there is no strict correlation between transgene copy number and level of expression. Moreover, expression of the transgene also at ectopic sites is a common phenomenon. An additional phenomenon which seems to interfere with the correct expression of transgenes is what is called 'position effect variegation' of transgene expression. This phenomenon leads to the generation of a variable and mosaic pattern of transgene expression within cells of the same tissue. All this is found to be mainly due to the absence from the

transgene construct of elements which control the tissue-specific and developmentally regulated activation status of chromatin and which insulate such genetic loci from the effects of neighboring chromatin. When available, inclusion of such locus control regions (LCRs) in transgene constructs, guarantees a strictly tissue-specific, developmentally regulated, nonvariegating, position-independent and copy number-dependent transgene expression.

Transgenic mice have been routinely generated with DNA fragments ranging from a few to several tens of kilobase pairs. For some time this limitation reflected technical difficulties in isolating and preserving the structure of larger DNA fragments for microinjection. However, advances in the use of vector systems such as those based on P1 bacteriophages and yeast artificial chromosomes (YACs) which may carry cloned DNA fragments of several hundred kilobase pairs, have allowed the efficient generation of transgenic mice carrying and expressing such large DNA constructs.

Modulation of transgene expression

Manipulation of the developmental timing and the cell specificity of transgene expression is particularly valuable in the analysis of gene function. There are currently several approaches which are used successfully for the inducible control of transgene expression *in vivo*. One of these makes use of the antibiotic tetracycline and its property to bind to a repressor protein that sits on control sequences at the promoter of bacterial genes. When tetracycline is administered, it binds and removes this protein from the promoter, switching the gene on. A modification in this system allows its use in mammalian cells as a way to turn genes either on or off. Additional systems are also being developed that transfer hormone responsiveness to mammalian cells by the stable expression of modified receptors that regulate a responsive promoter. Modified receptors are necessary in these systems to confer a specificity for an externally applied hormone, avoiding at the same time background activities from homologous endogenous hormones.

A new generation of tools for temporal control of transgene expression was introduced by the use of the bacteriophage P1 Cre/loxP site-specific recombination system. Expression of a Cre recombinase transgene in animal tissues mediates the excision of DNA segments flanked by loxP sites (floxed DNA). Such Cre-mediated excision can function to activate or inactivate transgenes in a tissue-specific manner (Figure 3). In principle, inducible activation or inactivation of transgene expression may also be

Figure 3 Tissue-specific activation or inactivation of transgenes by the use of Cre-mediated recombination of engineered loxP sites. (Computer graphics by Katerina Akassoglou, Department of Molecular Genetics, Hellenic Pasteur Institute.)

engineered when a tetracycline or hormone-inducible system drives the activation of Cre recombinase. Transgene activation may thus be achieved by Cre-mediated excision of a floxed DNA fragment which is engineered to reversibly interrupt the coding sequence of the transgene (e.g. when it is inserted in its 5' untranslated region). Conversely transgene inactivation is achieved when loxP sites are engineered to flank an essential part of an active transgene.

Applications of the transgenic technology

Transgenic technologies form today the core of 'interventional genetics', a key methodology for analyzing and interfering with gene function in whole animals. In agriculture, transgenic animals are engineered to achieve better genetic characteristics such as increased production of dairy proteins for food, enhanced production of wool or enhanced disease resistance. In biotechnology, the use of large transgenic animals or 'bioreactors' has been attempted, e.g. for the cost-effective production of high-value pharmaceuticals in the blood or milk of transgenic sheep or cows. Another promising area for the

exploitation of the transgenic technology has been in the field of xenotransplantation, where transgenic pigs are engineered to express immunological characteristics that would make their organs well tolerated after transplantation into humans.

However, so far, the major contribution of transgenic technology has been in basic research, in studies of gene expression, gene function and disease processes. Targeting of genes encoding toxins to specific cell types in the mouse (specific cell ablation) has been a helpful tool to address questions of mammalian development and cell lineage analysis. Mutagenesis or disruption of the functioning of endogenous genes by insertion of transgenes (insertional mutagenesis) has also been used not only to identify but also to clone developmentally important genetic loci. Animal modeling of human disease is certainly the area where transgenic technology has made a serious impact. Applications in these fields have allowed research into pathophysiological mechanisms, the long-term consequences and possible deleterious side-effects of therapeutic approaches including gene therapy, and the pathological interactions between multiple genetic components and the environment.

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES, INFECTION AND IMMUNITY

CF Farquhar, Institute for Animal Health, BBSRC & MRC Neuropathogenesis Unit, Edinburgh, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Scrapie, the most studied transmissible spongiform encephalopathy (TSE), is a fatal neurodegenerative disease of sheep and goats. Cuille and Chelle reported the first experimental transmission of scrapie, by intracerebral inoculation of healthy sheep with suspensions of brain from affected cases, in 1936. Human TSEs were recognized in 1959 with Hadlow's observation of similar central nervous system (CNS) pathology in cases of kuru, and confirmed by Gajdusek with his transmissions of kuru to non-human primates. Other human variants are Creutzfeldt-Jakob disease (CJD), transmitted in 1968, and a number of familial forms, for example Gerstmann-Sträussler syndrome (GSS) and fatal familial insomnia (FFI). TSEs are characterized by long, largely asymptomatic, incubation periods which may last for months or years. Pathological changes are restricted to the CNS and include vacuolation, degeneration of neurons and gliosis in the absence of demyelination or inflammation. Public awareness of, and anxiety about, TSEs has increased since the mid-1980s with the outbreak of bovine spongiform encephalopathy (BSE) in UK cattle, an apparent result of their consumption of scrapie-contaminated feed, and the inadvertent transmission of CJD in humans by the use of contaminated growth hormone, dura mater, cornea or EEG electrodes. We now face the probability that BSE has crossed the 'species barrier' into the human population with the emergence of a new variant of CJD presenting in younger adults and having a different clinical onset and pathology.

The pathogen: slow virus, virino or prion?

In the late 1940s, Wilson at the Moredun Institute, Edinburgh, classified the scrapie agent as a virus, based on filtration studies through membranes, and, in 1954, Sigurdsson included rida (Icelandic scrapie) with maedi/visna and infectious adenomatosis in his group of slow virus diseases. These diseases were shown to be caused by conventional viruses but the molecular structure of the TSE pathogen remains a subject for debate. While it has some of the properties of a conventional virus, such as strain variation and mutation, others, such as surviving virucidal

procedures, lend credence to the hypothesis that a host protein, PrP or prion protein, may be transformed into the infectious particle. Prion, slow virus and virino are all used as synonyms for the causative agent of TSE diseases: a virino is a composite structure of host protein (possibly PrP) and a host-independent molecule (possibly nucleic acid) which determines the strain of scrapie; a slow virus is a conventional structure of host-independent protein and nucleic acid; and one version of the prion structure has some form of PrP as the sole component of the scrapie pathogen. In all of these diseases PrP accumulates abnormally in the brain and this isoform (PrP^{sc} or PrP-res) copurifies with infectivity. In some TSEs, PrP^{sc} can also be identified in extracts from peripheral tissues (e.g. spleen, lymph nodes). Anti-PrP antibodies do not neutralize infectivity and no autoantibodies to PrP have been detected in the sera or cerebrospinal fluid of affected animals or man.

Host genes control infection

The overall rate of replication of infectivity, and hence the incubation period of the disease, depends primarily on the interaction between the strain(s) of pathogen and the genotype of the affected animal. The mouse has a single genetic locus, *Sinc*, with two alleles s7 and p7, which is the major determinant of its survival time when challenged by a standard dose of scrapie. Depending on the *Sinc* genotype, the incubation period can vary from a few months to beyond the lifespan of the mouse (>2 years). PrP is

Figure 1 Scrapie spread to the CNS.

likely to be the *Sinc* gene product. There are several similar linkages of the PrP gene with susceptibility to GSS and other diseases in humans and susceptibility and resistance to natural and experimental scrapie in sheep. Disease does not develop in mice in which the PrP gene is ablated.

Other loci have minor effects on incubation period, including the major histocompatibility complex (MHC) of mouse (in the region of H2D) and sheep (various OLA loci, although the linkage is disputed).

Spread of infection

Extensive studies by Hadlow, Eklund and colleagues from the late 1950s, and more recently by Kimberlin and Walker, have helped define the spread of pathogen within an animal following natural or experimental infection with scrapie. The dynamics of spread in the mouse are dependent primarily on the strain of pathogen and *Sinc* genotype. After peripheral infection in the mouse a very short viremic phase is followed by titer rising first in the spleen and lymph nodes followed by the thymus and submaxillary glands prior to neuroinvasion of the thoracic region of the spinal cord and thence into the brain. There is also evidence in other models of routes which bypass the spinal cord and these may be very important with TSEs such as BSE, which seems more neuroinvasive after oral infection than does scrapie. That spleen is an important, but not unique, early replication site has been established by splenectomy, which delays the incubation period in mice (but not in hamsters) although it does not affect the estimate of end-point titer. The cell type(s) of spleen in which the pathogen multiplies have not been identified, although several lines of evidence point to a central role for the follicular dendritic cell. SCID (severe combined immunodeficient) mice are relatively refractory to infection by a peripheral route and PrP^{Sc} does not accumulate in their spleens. Engraftment with bone marrow from immunocompetent donors renders them susceptible to infection. Evidence also exists that spread across a species barrier requires an intact immune system and that infection cannot spread from peripheral tissues into the CNS without PrP expression. Circulating lymphocytes express low levels of PrP.

Once established within the CNS, infection spreads via neurons to specific brain areas, depending on the strain of scrapie and route of infection. The host genotype appears to have a minor role in this targeting. Although there is no classical acute inflammatory response or perivascular cuffing, astrocytes and microglia are activated, and cytokines

released, after PrP^{Sc} begins to accumulate and before neuronal apoptosis. It is still uncertain as to whether neuronal death is caused by PrP^{Sc} neurotoxicity, local depletion of the normal cellular isoform, PrP^C, or perturbation of signals from other affected cells.

The immune system and scrapie: pharmacological strategies for control

A functional immune system is required for efficient experimental transmission of scrapie and for TSE agents to cross the 'species barrier'. Outram and Dickinson have shown that immunologically immature, perinatal mice are less susceptible to scrapie infection than their 3-week-old littermates, and SCID mice are relatively refractory to infection by peripheral, natural, routes of infection. Various immunomodulators can affect the incubation period of peripherally-routed scrapie if administered at the time of infection. Phytohemagglutinin and methanol-extracted BCG increase susceptibility to infection, while prednisone acetate, dexamethazone, arachis oil and the antiviral agent HPA-23 have the opposite effect. However, interferon, antilymphocyte serum, cyclophosphamide, neonatal thymectomy or whole body irradiation fail to alter incubation period. The polyanions, dextran sulfate and pentosan polysulfate, increase survival time considerably, even when administered weeks after peripheral infection, and can completely protect against disease in some cases. They reduce the effective titer of infectivity and inhibit PrP^{Sc} accumulation, most probably by removing PrP^C from the cell surface by stimulating endocytosis, and are therefore of potential therapeutic value. Amphotericin B, a polyene antibiotic, is unique in delaying scrapie replication and PrP^{Sc} accumulation in some models infected by an intracerebral route. It is, however, highly toxic and has to be administered daily throughout pathogenesis. Safer derivatives are being developed.

TRANSPLANTATION

Peter J Morris, Nuffield Department of Surgery, University of Oxford, John Radcliffe Hospital, Oxford, UK

No area of medicine has developed so rapidly in the past 40 years as that of transplantation. From the early pioneer attempts at renal transplantation in the 1950s, renal transplantation has now become the therapy of choice for the vast majority of patients with end-stage renal failure. So too have liver and cardiac transplantation in selected instances of end-stage disease of those organs. Combined heart and lung and single lung transplantation are being performed with increasing success and the pancreas is being transplanted into the insulin-dependent diabetic in the hope of halting the progression of the microangiopathic complications of diabetes. Corneal grafting is a routine procedure in the treatment of corneal opacification, while skin allografts have been used in the treatment of burns. As immunosuppression becomes more specific as well as more potent, not only will the short-term results of transplantation improve, but more importantly so too will the long-term results which still are generally poor.

Historical background

Experimental organ transplantation was reported at the beginning of this century, the most illustrious of

these early pioneers being Alexis Carrel who published extensively on renal allografts in dogs and cats. Skin allografts had been performed over the centuries with alleged success on occasions. However, the first human kidney transplants were performed by the Russian, Voronoy, in 1936, who carried out six such transplants in total but none probably functioned.

In the early 1950s renewed experimental interest in kidney transplantation by Simonsen in Denmark and Dempster in London led to a series of human cadaver transplants in Paris by Kuss, Servelle and Dubost and in Boston by David Hume. Some of these kidneys functioned for some weeks without immunosuppression. The first live related transplant, from mother to son, was reported from Paris in 1953 but the kidney was rejected at 3 weeks. And then in 1954 in Boston, Murray (awarded the Nobel prize in 1990 for his pioneer work in transplantation) performed a renal transplant between identical twins, one of whom had renal failure. Needless to say rejection did not occur, but this did also show that a transplanted kidney could function in a normal physiological manner. Total body irradiation was the only form of immunosuppression available at that time and, if given in sufficiently large doses to be immunosup-

pressive it inevitably resulted in pancytopenia and death from infection. In 1959 the immunosuppressive effect of the anticancer agent 6-mercaptopurine (6MP) was reported by Schwartz and Damashek from Boston, and soon after Calne in London and Zukoski, Lee and Hume in Richmond, Virginia showed that it suppressed rejection of kidney allografts in dogs. Elion and Hutchings of Burroughs Wellcome then developed a derivative of 6MP, azathioprine, which was perhaps less toxic, and this ushered in the modern era of transplantation.

In 1963 Starzl began the first liver transplantation program in Denver, Colorado, a field in which he, now in Pittsburgh, has continued to dominate. The first cardiac transplant was performed in 1968 by Barnard in South Africa, which was associated with a good deal of unfortunate publicity thereafter and led to many premature attempts all over the world at cardiac transplantation. Nevertheless Shumway at Stanford who had pioneered the experimental work in this field quickly entered the clinical arena and restored an air of respectability to the whole field in a program which established cardiac transplantation as a genuine therapy.

During that time immunosuppression was dependent essentially on azathioprine and prednisolone with the development of antilymphocyte globulin to treat resistant rejection; but then the arrival of cyclosporine, a new potent immunosuppressive agent, at the beginning of the 1980s, led to an explosion in organ transplantation. Today several new drugs – FK506, mycophenolate mofetil and rapamycin are available or about to come available, further enhancing the immunosuppressive armamentarium available to the clinician.

Donors

In general, the majority of donors of organs for transplantation are cadaveric donors, and the general acceptance of the criteria of brainstem death allowed hearts and livers to be removed before irreparable damage occurred from ischemia.

However, in the case of a paired organ, such as the kidney, donors from within the family of the patient may be used. Living related donors have the attraction of providing a better chance of long-term graft survival than a cadaver kidney, but do expose the donor to the risk of a major operation. More recently the use of living related donors of a segment of liver (for children) and of lung is being explored by a number of units.

Organ preservation

In the early days of kidney transplantation, the organ once removed, had to be implanted immediately. However, the development of first machine preservation and then later preservation by flushing the kidney with solutions of an intracellular electrolyte composition with storage in ice allows kidneys to be stored for up to 48 h. More recent developments in preservation solutions also allow livers to be stored in ice for up to 24 h, and similarly hearts and lungs can be preserved for up to 6 hours.

Matching for HLA (the MHC in humans)

Within a family the matching of a living related donor and recipient of a kidney is very precise and there is a good correlation between matching and graft outcome. However in cadaver renal transplantation the role of matching is controversial. Nevertheless there is considerable evidence that better graft survival is achieved by better matched kidneys, especially for HLA-DR, and more recently similar observations have been made in cardiac and pancreatic transplantation. Part of the matching of donor and recipient involves the detection of specific sensitization in the recipient against the donor, as evidenced by the presence of donor-specific cytotoxic antibodies. However, there are exceptions to this dogma that a positive cross-match between donor cells and recipient sera precludes transplantation when this is due to non-HLA antibodies.

Renal transplantation

There are virtually no contraindications to renal transplantation today and both the very young and the elderly may be transplanted successfully for all causes of end-stage renal failure. The kidney is generally placed in the iliac fossa retroperitoneally, the renal vessels being anastomosed to the iliac vessels and the ureter implanted into the bladder. The results of renal transplantation are excellent in the short-term with a 1-year patient and graft survival of 95% and 85% respectively being achieved. However, although 5-year patient survival is still around 90%, graft survival is only around 70%, there being a steady attrition of grafts from chronic rejection.

Liver transplantation

The major indications in the adult are the non-alcoholic cirrhoses while in the child biliary atresia is the most common indication. An increasing number of liver transplants are performed for acute

fulminating hepatitis while successful correction of metabolic defects, e.g. α_1 -antitrypsin deficiency, may also be achieved by liver transplantation. Technically liver transplantation is the most difficult of the organ transplants, the liver being placed in the bed of the patient's own liver which is first removed (orthotopic transplant). However, most of the technical problems have been resolved and 1-year graft survival both in adults and children is around 65%, with full rehabilitation of patients with a successful transplant being achieved.

Cardiac transplantation

Cardiac transplantation is performed for terminal heart disease in patients less than 55 years of age when the estimated life expectancy would be 6–12 months. The two major indications for cardiac transplantation are idiopathic cardiomyopathy and ischemic heart disease with left ventricular failure. The heart is placed orthotopically in the chest after removing the recipient's heart but leaving the back wall of the right and left atria with the atrial septum to which the appropriate part of the donor atria is anastomosed followed by the pulmonary artery and aortic anastomoses. The results of cardiac transplantation are very similar now to those of the kidney with around 80% 1-year graft survival and 60% at 5 years. Chronic rejection manifest by coronary atherosclerosis is a major problem in the medium term for many patients.

Combined heart-lung and lung transplantation

Combined heart-lung transplants are performed for intractable disease of the lungs either with or without associated cardiac damage. The commonest indications are Eisenmenger's syndrome, cystic fibrosis and primary pulmonary hypertension. In cystic fibrosis the heart is often not damaged and this does allow the recipient heart to be used for a patient needing just a cardiac transplant while the recipient is given a combined heart and lungs transplant (domino procedure). The other reason for using combined heart and lung transplants, even where the heart did not need to be replaced, was the unsatisfactory results of single or double lung transplants. However, more recent developments have led to very successful results of single lung transplants in patients with bilateral lung disease, e.g. end-stage obstructive airways disease. This approach represents a much more efficient use of organs and if successful in the medium term, the indications for combined heart and lung transplants will be con-

siderably reduced. However obliterative bronchiolitis, a manifestation of chronic rejection, is a major problem in some 30% of patients with a lung transplant.

Pancreas transplantation

The rationale of transplantation of the pancreas is to replace the endocrine pancreas, namely the islets of Langerhans, in insulin-dependent or type I diabetes with the expectation that this would halt the progress of the secondary microangiopathic complications of diabetes, e.g. retinopathy, nephropathy, peripheral arterial and ischemic heart disease. The pancreas is transplanted as a vascularized organ, either using the whole organ with the celiac artery and portal vein or a segment of the pancreas (tail and body) with the splenic vessels, the vessels in both instances being anastomosed to the iliac vessels of the recipient. The major problem of this procedure has been the exocrine drainage of the pancreas which has been dealt with by drainage of the pancreatic duct into the bladder or the small intestine, the former being now the most widely used technique.

The results have improved in recent years and some 70–80% of grafts are functioning at 1 year (as judged by insulin independence). However the procedure is associated with a high morbidity and so far there is little convincing evidence that the microangiopathic complications improve, perhaps because the procedure is only performed at a very advanced stage of the disease, generally in patients requiring a renal transplant for diabetic nephropathy at the same time.

A more attractive approach would be the transplantation of isolated pancreatic islets only. This has been performed successfully in experimental models of diabetes in the rodent for many years but a major obstacle to human application has been the lack of a satisfactory technique to prepare isolated islets from the large mammalian pancreas, including humans. However, these problems have been resolved to a large extent and clinical trials have commenced in several centers. The islet preparation is implanted in the liver via the portal vein, although the spleen or the kidney capsule may be alternative sites as demonstrated in experimental models. Although functional islet transplants have been achieved, as judged by normal C peptide levels, only a handful of patients have been rendered insulin independent.

Cornea

The major indication for corneal grafting is corneal opacification due to such problems as postinflam-

matory scarring, corneal dystrophies and endothelial dysfunction. It is performed as often or more than kidney transplantation. The cornea is a privileged site, presumably due to the lack of lymphatic drainage. For this reason primary grafts in a nonsensitized recipient fail only for technical reasons and immunosuppression is not required. However, in patients sensitized by a previous failed graft, the failure rate is high. Better results are achieved with secondary grafts in the presence of good HLA matching of donor and recipient or low doses of immunosuppressive drugs.

Skin

Skin allografts have been performed in patients with severe burns where inadequate donor skin sites are available. Although rejection does occur, it is delayed presumably because of the severity of the injury. Immunosuppression has also been used to prolong skin allograft survival in burn patients with some success but this adds to the risks of infection in severely injured patients who are already at risk.

Immunosuppression

Immunosuppression is used in clinical transplantation both to prevent rejection and also to treat rejection. Preventive immunosuppression therapies today are based on cyclosporine which may be used alone, with steroids, or with both azathioprine and steroids (triple therapy). Another very powerful induction therapy includes a course of a heterologous antilymphocyte globulin (ALG) or a pan T cell monoclonal antibody (e.g. OKT3) with azathioprine and prednisolone, introducing cyclosporine after 7 days (sequential therapy). Certainly in renal transplantation there is no convincing evidence in terms of graft survival that one immunosuppressive protocol is superior to another, although there is a lower incidence of rejection in sequential therapy protocols.

An acute rejection episode is treated with high-dose methylprednisolone, but if the rejection proves resistant to steroids then either ALG or OKT3 is generally introduced. Some 75% of steroid-resistant rejection episodes can be reversed with ALG or OKT3.

New immunosuppressive agents, FK506 (tacrolimus) and mycophenolate mofetil, have now undergone extensive investigation in large multicenter trials which have proven their value in liver and renal transplantation respectively. FK506, a macrolide antibiotic, has a very similar mechanism of action to cyclosporine and inhibits the activation of T lympho-

cytes and in particular the transcription of the genes for a number of cytokines, especially interleukin 2 (IL-2). However, it is a more potent agent on a weight basis, and does seem at least as effective as cyclosporine in liver transplantation and indeed may rescue livers that are being rejected on treatment with cyclosporine. Mycophenolate mofetil is an antiproliferative agent. It has been tested in renal transplantation as a replacement for azathioprine in association with cyclosporine and steroids, where it has been shown to reduce the incidence of acute rejection episodes substantially in the first 6 months after transplantation. Another new agent, rapamycin (sirolimus), also a macrolide antibiotic, which inhibits proliferation of activated T lymphocytes by a mechanism as yet unclear, is undergoing phase II trials at present in renal transplantation. Early results suggest that it is a potent immunosuppressive agent.

The development of monoclonal antibodies against various leukocyte subpopulations also provides the possibility of more specific immunosuppression. So far the only monoclonal antibody used extensively in clinical practice is OKT3, a pan T monoclonal antibody directed against the CD3 molecule. Trials of monoclonal antibodies against the IL-2 receptor (CD25), LFA-1, ICAM-1, CD4 and the T cell receptor have been, or are being, carried out using murine or humanized monoclonal antibodies. So far results available are disappointing, but expectation remains high that such antibodies will allow more specific immunosuppression and hence less of the potent nonspecific immunosuppressive drugs to be used. Certainly a number of very promising protocols have been developed in experimental models of transplantation which allow tolerance to be produced and which may be applicable in the clinic.

Complications

The complications of transplantation of all organs are either technical or related to the immunosuppressive therapy. Technical complications are relatively uncommon in renal and cardiac transplantation, but still are a feature of liver and especially pancreatic transplantation. The major complications related to immunosuppression, either directly or indirectly, are infection, ischemic heart disease and cancer. Viral infections, particularly cytomegalovirus (CMV) infection, remain the most prominent of the post-transplant infections, but more exotic infections are seen from time to time, e.g. *Aspergillus*, *Pneumocystis carinii*, tuberculosis, and clinicians must be aware of this possibility in these immunosuppressed patients.

Most types of cancer show a modest increase in

frequency in patients after transplantation but there is a marked increase in the frequency of lymphomas, cervical cancer, squamous cell cancers and Kaposi sarcomas, all tumors with a putative viral etiology. Ischemic heart disease is the major cause of death in patients with long-term functioning transplants. Hyperlipidemia and hypertension, two major risk factors associated with ischemic heart disease, are common in transplant patients and are probably related to the immunosuppressive drug therapy.

Xenografts

The possibility of transplanting organs from other species to humans in order to meet the unmet demand for organs remains an area of considerable research interest. However, a major immunological obstacle to xenografts is the presence of natural cytotoxic antibodies in humans directed against most species that might be used as a donor of organs, e.g. pig. Although kidney xenografts from chimpanzee to human were performed in the 1960s by Reemstma with function persisting for weeks to months with azathioprine/prednisolone, it is doubtful whether the use of chimpanzees would be ethically acceptable today (humans do not have natural cytotoxic antibodies reactive with chimpanzee). The natural cytotoxic antibodies in humans are, on the whole, directed against a xenoantigen, galactose ($\alpha 1,3$) galactose, which is expressed on most tissues in all species except humans and the Old World primates. Transplantation of an organ from a species such as a pig into a human would result in immediate hyperacute rejection mediated by a classical complement-dependent destruction of the target tissue by antibody. A variety of approaches to this problem have been investigated, e.g. depletion of antibody and/or complement, but one of the most promising has been the development of transgenic pigs expressing human complement inhibitors on endothelium as well as

other cells. In experimental models organs from such animals have been shown to be resistant to the immediate antibody and complement-mediated destruction. However, even if this approach proves to be successful, many other problems remain to be resolved such as suppression of the cellular immune response, both specific and nonspecific, the possibility of transferring potential pathogenic organisms to humans, and the metabolic and physiological behavior of an organ from another species in a human.

TREPONEMA, INFECTION AND IMMUNITY

Konrad Wicher and **Victoria Wicher**, New York State Department of Health, Wadsworth Center for Laboratories and Research, New York, USA

The genus *Treponema* consists of pathogenic and nonpathogenic spirochaetes. Human diseases caused by the treponemes are syphilis (*Treponema pallidum* subsp. *pallidum*), endemic syphilis (*T. pallidum* subsp. *endemicum*), yaws (*T. pallidum* subsp.

pertenue) and pinta (*T. carateum*). While syphilis is a venereal disease, the remaining are nonvenereal diseases. These microorganisms are morphologically almost identical but exhibit different patterns of pathogenesis in humans and laboratory animals.

They cannot be detected in conventionally stained smears. They are visualized in wet films by dark-field microscopy, and in fixed preparations by immunofluorescent antibody technique or silver nitrate staining. The pathogenic treponemes are not cultivable *in vitro*, but can be propagated in animals (Table 1), with the exception of *T. carateum*. The nonpathogenic treponemes, which are numerous, can be cultivated *in vitro*. They colonize humans and animals.

Characteristics of *Treponema* and its antigens

Information on the morphology and molecular characterization were obtained using *T. pallidum* Nichols strain which is a reference strain of *T. pallidum* subsp. *pallidum*. Treponemes are spiral microorganisms ca. 0.1 μm thick and 5–20 μm long. They are helical in nature, having outer and cytoplasmic membranes, a thin peptidoglycan layer and periplasmic flagella. The latter are located between the cytoplasmic and the outer membranes. They extend from one to the other end of the microorganism allowing for the characteristic movements of the spirochetes. The flagellum consists of three structural components: the sheath, core and hook, and is composed of four major polypeptides. Treponemes also contain cytoplasmic filaments, which run in parallel to the periplasmic flagella. Their function is unknown. At least eight major membrane-associated lipoproteins have been identified in *T. pallidum*, but their precise location (internal versus external) has not been established. A unique structural feature of *T. pallidum* is the paucity of intramembranous protein particles in the outer membrane.

T. pallidum, *T. pertenue* and *T. endemicum* have over 95% homology by DNA–DNA hybridization. *T. pallidum* and *T. pertenue* vary at only one of 531 base pairs (bp), resulting in a single amino acid difference in the sequence. The DNA homology of *T.*

pallidum and nonpathogenic treponemes, e.g. *T. phagedenis*, varies from 20 to 80%, depending on the method used for comparison. *T. pallidum* has one of the smallest prokaryotic genomes (1000 kbp), which is in the form of a circular chromosome.

Twenty-seven polypeptides have been identified in *T. pallidum*. Those studied for potential practical use have a wide spectrum of molecular mass, representing surface-, membrane- and flagella-localized proteins. An increasing number of monoclonal antibodies to the various peptides are available but they are not species or subspecies specific.

Syphilis

In 1993 the World Health Organization reported 12 million new cases of syphilis worldwide. Of all known treponematoses, syphilis remains the focus of wide interest. Except for congenital syphilis, sexual contact accounts for virtually all syphilitic infection. The ID₅₀ for man is ca. 50 treponemes. The microorganisms enter the host through abraded skin or mucous membranes. Part of the inoculum spreads via lymphatics into regional lymph nodes, while the remaining organisms propagate at the site of entry, forming a characteristic lesion (chancre) in an average of 3 weeks (10–90 days). The course of infection in an untreated individual runs through stages: primary (6–8 weeks), secondary (a few weeks to a year), early latent (up to 2 years), late latent (several years) and tertiary (variable time). During primary and secondary stages the individual is infectious; in latent periods, except for a pregnant woman who can transmit the disease to the fetus, the individual is non-infectious. During spirochaetemia *T. pallidum* may invade many organs, including the central nervous system, causing a variety of neurologic symptoms. Clinical manifestations of tertiary syphilis occur in ca. 30% of untreated patients affecting various organs. Congenital syphilis is acquired by trans-

^cDoubtful results.

placental passage of *T. pallidum* from an infected pregnant woman to her fetus. Depending on the time of infection and maternal immune status, stillbirth may occur, or a newborn may demonstrate characteristic symptoms immediately or within 2 years (early congenital), or after 2 years of birth (late congenital), or the newborn may be free of syphilis.

Syphilis has been frequently associated with AIDS. Severe courses of syphilis, accelerated development of neurosyphilis and syphilis masquerading as AIDS have been reported.

The antibiotic of choice for treatment of syphilis and nonvenereal treponematoses is penicillin. Individuals allergic to penicillin are treated with tetracycline or similar antibiotics.

Immune response in syphilis

T. pallidum infection evokes cellular and humoral immune responses. The humoral response manifested by production of phospholipid and treponemal antibodies is the basis for serodiagnosis of syphilis. The phospholipid or cardiolipin antibodies are detected by a variety of flocculation tests using a defined mixture of cardiolipin–lecithin–cholesterol as antigen (Venereal Disease Research Laboratory, VDRL antigen or VDRL test). A second type of antibody, known as cardiolipin F (detected by immunofluorescence) and directed against host-cell mitochondrial cardiolipin (autoantibody), is also associated with syphilis, but is not used for serodiagnosis. Treponemal antibodies, once detected by the cumbersome *T. pallidum* immobilization test (TPI) are now identified by immunofluorescence (FTA-ABS) or microhemagglutination test (MHA-TP). Treponemal antibodies appear after infection almost simultaneously with the cardiolipin antibodies. The treponemal antibodies persist in the host for many years even after treatment, whereas the cardiolipin antibodies parallel the dynamics of the infection and are useful in interpreting the efficacy of treatment. Autoantibodies to tissue phospholipids and other tissue constituents, to blood cells and serum globulins are also produced by *T. pallidum*-infected hosts.

Cell-mediated immune responses to infectious organisms involve activation of macrophages and the induction of CD8 T cells and helper CD4 T cells. The various subsets of CD4 T cells, and the cytokines they produce, play a crucial role in determining the outcome of infectious disease in terms of both protective immunity and immunopathology. Although a switch from T helper T_H1 to T_H2 immune response has been observed in the rabbit experimental model of syphilis, this remains to be further studied.

Immunity in syphilis

Correlation of the humoral and cellular immune responses with clinical manifestations of the disease in both natural and experimental infection seems to favor a cellular rather than a humoral mechanism in the acquisition of immunity, as deduced from the following information: 1) primary and secondary syphilis progresses despite a profuse humoral response; 2) passive immunization with immune serum has had only limited success; 3) immunization with killed *T. pallidum* does not protect recipients despite development of antibodies; 4) delayed hypersensitivity appears late in the course of infection; 5) tertiary lesions have a granulomatous appearance; 6) lasting immunity has been induced in animals only by infection with live or immunization with γ -irradiated *T. pallidum*; 7) adoptive transfer of *T. pallidum*-immune T lymphocytes into syngeneic naive recipients prevented the development of lesions after challenge and the hematogenous dissemination of *T. pallidum*, providing a longlasting protection against reinfection; 8) treponemal antibodies, i.e. TPI antibodies, are not associated with the protective mechanism(s) operative after challenge in adoptively immune animals.

Evasive strategies of *T. pallidum*

A large number of host macromolecules appear to be avidly associated with the outer envelope of *T. pallidum*. The biologic importance of this association, between host proteins and pathogen, seems to be considerable, as it may decrease the immunogenicity of the latter, promoting its survival and induction of autoimmune responses. It is also speculated that the immunologically inert surface of the *T. pallidum* (paucity of intramembranous proteins) contributes to the organism's evasion of the host inflammatory response.

Vaccine

Immunization protocols in experimental syphilis failed to produce protection from infection.

Nonvenereal treponematoses

Yaws and pinta are restricted to tropical countries but endemic syphilis has, besides Africa and Middle East, also been reported in Europe and North America. The nonvenereal treponematoses have been nearly eradicated through an intensive campaign by the World Health Organization. Only sporadic outbreaks or cases were reported. These diseases usually

occur in children living in poor sanitary conditions, and infection is due to contact with fluid-exuding lesions, and through usage of common utensils.

These diseases have several features similar to syphilis, i.e. the morphology of the treponemes, antibody production (VDRL, FTA-ABS, TPI), lesions, and cell infiltration in secondary and late active yaws. However, differences in the mode and severity of infection, host susceptibility, cross-immunity and time of antibody appearance exist (Table 1).

TRICHURIASIS

Derek Wakelin, Department of Life Science, University of Nottingham, Nottingham, UK

Trichuriasis is caused by infection with the nematode *Trichuris trichiura*, one of a group of worms, the soil-transmitted nematodes, that includes some of the commonest parasites of humans. Globally, some 800 million people harbour *T. trichiura*. The existence of such widespread and long-term infections raises a number of interesting questions about host resistance and susceptibility, some of which have been answered by studies in laboratory models.

Characteristics of the organism and its antigens

T. trichiura is a relatively long worm, measuring about 2 cm. It lives in the large intestine, occupying a superficial tunnel on the surface of the mucosa. The smaller larval stages live completely within such tunnels, which are produced as the worm moves through the epithelial cells, but at the adult stage only the anterior half of the body is embedded, the posterior lying free. The species has both males and females. When mature, the females release very large numbers of eggs, which pass out with fecal material, becoming infective after a period of development in the soil. Hosts are infected by accidental ingestion of eggs containing fully developed infective first-stage larvae, which then hatch in the small intestine.

Trichuriasis is common in countries where climatic and socio-economic conditions favor the survival

and transmission of infective eggs. Infections are most prevalent in children, where heavy infections may cause chronic diarrhea, anemia and retarded physical and educational development. Other *Trichuris* species occur in many animals. *T. suis*, for example, can cause a severe disease in pigs. *T. muris*, which infects mice, provides a useful experimental model for studying the immunobiology of this group of worms.

Trichuris worms belong to the same group as *Trichinella* and the body has the same overall organization. The anterior esophagus lies within glandular stichocyte cells, which are one of the major sources of antigens. Antigens are synthesized in the stichocytes, released into the esophagus and pass out of the mouth. Many are enzymes, which presumably facilitate feeding or mucosal penetration. The most important antigens are between 40 and 60 kDa, but certain molecules (47 kDa in *T. trichiura* and 43 kDa in *T. muris*) are immunodominant. Major antigens are also present within the pseudocoelomic fluid. Surface antigens are present on the cuticle but play only a minor role in immunity.

Immune responses of the host

In humans, infection elicits specific immunoglobulin G (IgG), IgA and IgE antibody responses. Levels of IgG increase with levels of infection, but raised levels

of IgA may correlate with reduced worm burdens, i.e. with resistance to infection. To date cellular responses have been little studied. The large intestine shows macroscopic inflammatory changes, which are associated with local increases in macrophages and mast cells. Macrophage release of cytokines (especially tumor necrosis factor α , TNF α) and an IgE-mediated release of mast cell mediators contribute to the inflammation and protein-losing enteropathy that are associated with heavy infection.

The immune response to *T. muris* in mice has been studied in detail. Infections elicit strong T cell responses both locally and in the draining node, and these lead to the premature expulsion of worms from the intestine. Exposure to primary infections can stimulate complete resistance to reinfection. Immunity can be transferred between animals using CD4⁺ T cells or immune sera. An IgA monoclonal antibody specific for *T. muris* antigen is also effective. Inflammatory responses (e.g. mucosal mastocytosis) occur but do not seem to contribute to the expression of immunity. How immunity is achieved is uncertain. Antibodies may combine with released molecules and interfere with feeding or movement; the role of T cells is unknown.

Immune responses to *T. muris* show considerable genetically determined variation, both major histocompatibility complex (MHC)-linked and background genes being involved. Variation affects the onset and degree of immunity, the level and specificity of antibody responses and the T cell response. Mouse strains that respond well and eliminate infection produce responses mediated by T_H2 cells; susceptible strains, that are unable to eliminate worms, show a switch to T_H1 subset responses.

Evasive strategies by the organism

It is characteristic of human infections with *Trichuris*, as with all helminths, that the infections are aggregated within the population. A majority of individuals have low-level infections, a few are heavily infected; children are the most heavily infected age group. Although differences in environmental exposure could be a major determinant of variations in the levels of infection, there are reasons to believe that differences in immune-mediated resistance could also be involved. Studies in mice, in addition to demonstrating the existence of similar genetic variation, have shown that the later stages of infection may be powerfully immunosuppressive and responsible for the switch to a T_H1 response that prevents effective

immune control. Thus, if for genetic reasons a host fails to control the early stages of infection, the later stages may inhibit the subsequent development of immunity, leading to the establishment of a chronic infection. In mice, at least, chronic infections are associated with a long-lasting inability to respond protectively, even when the initial infection is removed. Chronicity of infection and frequent reinfection of susceptible individuals are characteristic of trichuriasis in endemic areas. Both may therefore reflect the success of an evasion strategy based on the parasite's manipulation of the host's response.

Vaccines

No vaccine is available against *Trichuris* or indeed against any soil-transmitted nematode. The data from experimental studies suggest that vaccination could be achieved relatively easily, given that, in mice, identifiable antigens elicit high levels of immunity. Modern techniques of antigen purification and production could make such antigens available (the major antigen of *T. trichiura* has been cloned) but it seems unlikely that there will ever be sufficient demand for a vaccine against trichuriasis to be produced.

TRYPANOSOMIASIS, AFRICAN

C Michael R Turner, Division of Infection and Immunity, Institute of Biomedical and Life Science, University of Glasgow, Glasgow, UK

Keith Vickerman, Division of Environmental and Evolutionary Biology, Institute of Biomedical and Life Science, University of Glasgow, Glasgow, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Characteristics of the organisms and their antigens

The tsetse fly-transmitted trypanosomes cause sleeping sickness in humans and a related disease, nagana, in domestic animals in Africa. These flagellated protozoan parasites multiply largely in the blood of the mammalian host but may invade extravascular sites (lymphatics, connective tissue, central nervous system), depending on the species of trypanosome.

Two types of sleeping sickness are recognized: a chronic West African form transmitted by riverine tsetse and caused by *Trypanosoma brucei gambiense*, and an acute East African form transmitted by savanna flies and caused by the morphologically identical *T. brucei rhodesiense*. A third 'subspecies', *T. brucei brucei*, cannot infect humans but causes nagana in animals. Other species of *Trypanosoma*, *T. congolense* and *T. vivax*, also cause nagana. All three species undergo a complicated cycle of development in the blood-sucking tsetse fly vector, details differing with the species. In all cases the end-result is the discharge of the mammal-infective metacyclic stage with the saliva when the fly takes a blood meal.

Sleeping sickness is usually fatal, unless treated with toxic drugs (e.g. suramin) and over 50 million people are at risk of acquiring infection. Cattle trypanosomiasis is widespread and has devastating effects on animal husbandry, preventing satisfactory stock rearing over 10 million km² south of the Sahara. Antelopes and other game animals serve as a reservoir of both human and animal trypanosomiasis, often showing no symptoms of disease. Outside the tsetse belt of Africa, *T. brucei* ('*T. evansi*') and *T. vivax* may be spread by tabanid and *Stomoxys* flies acting as flying syringes, transferring the infection directly from one host to another. The main victims of such mechanical transmission are the draught animals of unmechanized farming and transport in North Africa, South America and southern Asia – horses and camels in particular.

Because chemoprophylaxis has proved unsatisfactory and vector control raises major environmental problems, vaccination has long been regarded as a potentially ideal solution to the problem of African trypanosomiasis. Unfortunately it is an unattainable ideal, because although the antigen inducing a pro-

tective humoral response is well characterized as a surface glycoprotein covering the entire trypanosome, the parasite has the ability to change repeatedly the antigenic nature of this glycoprotein (the variant surface glycoprotein, VSG) and so avoid destruction by the host's immune response through antigenic variation.

The molecular basis of trypanosome antigenic variation has received a great deal of attention over the last 30 years so that we now know more about the trypanosome as antigenic challenge than we do about the response of the natural host to infection with the parasite. Most of our knowledge of immunity to trypanosomiasis is based on experimental infections in rodents. African trypanosomes usually infect laboratory animals readily, but repeated syringe passage results in increased parasite virulence with large numbers of trypanosomes in the blood, whereas in sleeping sickness patients and infected cattle or game animals, the parasitemia may be undetectable by microscopic examination of the blood.

In the mammalian host the VSG forms an enveloping 15 nm thick coat covering the entire trypanosome plasma membrane, body and flagellum, and is readily visualized by electron microscopy. In this monomolecular layer of a single species of glycoprotein (46–65 kDa, depending on the trypanosome species or variant), the immunogenic epitopes reside in the N-terminal domains distal to the membrane rather than in the C-terminal domains; each molecule is anchored to the membrane by a glycosylphosphatidylinositol (GPI) moiety at its C-terminus. Variant surface glycoproteins become N-glycosylated at one or more asparagine residues but the carbohydrate plays no part in the VSG immunogenicity. Dense packing of VSG homodimers in the exposed coat results in an effective macromolecular diffusion barrier and proteins as small as 50 kDa are unable to penetrate it. The coat thus protects the parasite against nonspecific attack by the alternative complement pathway. It also deters phagocytosis by macrophages. On entering the tsetse fly the VSG coat is shed and replaced by a different immunodominant protein called procyclin; by electron microscopy the various developmental stages in the tsetse gut and salivary glands or mouthparts appear uncoated, but

Figure 1 Blood smear showing trypanosomes undergoing antigen variation. (A) Three cells (two arrowed) are labeled with a VAT-specific antibody. (B) All parasites in the field of view are labeled, nucleus and kinetoplast, with DAPI.

the VSG coat is reacquired at the final metacyclic stage which is discharged in the fly's saliva. The metacyclic trypanosomes thus enter the mammal already protected against its host's nonspecific defences.

Antigen variation; the difficulties it poses for vaccine design

Only one VSG is expressed by a trypanosome at a time; trypanosomes expressing the same VSG are said to belong to the same variable antigenic type (VAT). In the blood of a chronically infected mammal, there is a hierarchical expression of VATs with some always being detected early in infection and others later. Protective immune responses of the host are VAT-specific and parasites expressing these VATs are cleared from the blood (through complement-mediated lysis and/or opsonization) and the parasitemia declines. Remission is invariably followed by recrudescence, however, as trypanosomes expressing other VATs multiply. Thus, the numbers of trypanosomes detectable in the blood fluctuate wildly such that the infection characteristically consists of a series of parasitaemic peaks.

Switching from one VAT to another occurs spontaneously; it is not induced by the host's immune response as it occurs in *in vitro* cultures of bloodstream stage trypanosomes. The rate of switching varies between 10^{-2} and 10^{-7} switches per cell generation and is higher in tsetse-transmitted than in syringe-passaged infections. Each VSG is encoded by a separate VSG gene and switching involves the expression of a different VSG gene at one of a few mutually exclusive chromosomal telomeric

expression sites. These are two principal mechanisms by which a VSG gene can be expressed: It can be activated *in situ* or a copy (the so called expression-linked copy or ELC) of a chromosomal internal gene (basic copy) may be inserted at a telomeric expression site, displacing the previously expressed gene. What controls the rate of switching or the order in which heterotypes grow up to become homotypes is not known.

Trypanosoma brucei appears to have about 1000 VSG genes underlying its VAT repertoire though *T. b. gambiense* and *T. vivax* may have a smaller number. Late in an infection new chimeric VSG genes may arise as a result of only partial replacement of the outgoing gene at the expression site by the incoming expression-linked copy. For a given trypanosome species or subspecies, a number of VAT repertoires (serodemes) can be discerned in different or in the same geographical areas. Despite the high immunogenicity of VSGs, the prospect of vaccinating potential hosts against all VATs in all serodemes is clearly hopeless. A more promising approach was thought to be to protect such hosts against tsetse-transmitted trypanosomiasis by rendering them solidly immune to the metacyclic VATs (M-VATs) that constitute a limited subset of the bloodstream repertoire (12 in *T. congolense*, ≤ 27 in *T. brucei*). Metacyclic VSG genes always reside at the telomeres of large chromosomes, are activated *in situ* and can be expressed at a lower temperature than bloodstream form VSGs. *T. brucei* has over 120 chromosomes, about 100 of which are 'minichromosomes' (average size 100 kb as compared with >1 Mb large chromosomes); the minichromosomes appear to house only VSG genes.

Although immunity against infection with metacyclic trypanosomes can be induced by allowing cattle to become infected by fly bites and then treating the resulting infection as soon as the parasitemia becomes patent, such immunity is usually short-lived. Breakthroughs in infection can occur as a result of replacement of a metacyclic VSG (M-VSG) gene with a bloodstream stage VSG as part of the process of antigenic switching occurring at a M-VSG gene expression site. The ability of the M-VAT repertoire of a given serodeme to evolve in this way ensures that hosts in a given area do not all become immune to a given serodeme. With the collapse of plans for vaccination based on M-VATs, attention has turned to the possibility of vaccination against nonvariable antigens of the parasite, that is those common to all trypanosomes irrespective of their VAT. Such common antigens are largely unexposed and so unable to react with host effector mechanisms, but the discovery that the trypanosome relies on receptor-mediated endocytosis to take up certain necessary host proteins (e.g. transferrin, low-density lipoprotein) from its flagellar pocket has raised hopes that the blocking of exposed receptors by host antibodies might halt or slow the infection. Alternatively, transmission blocking antibodies raised to procyclin or some other component of the trypanosome surface in early vector development might be used to limit the spread of trypanosomiasis by tsetse flies.

Immune responses of the host

Trypanosome infections elicit a strong humoral response. In the experimental mouse it has been established that the pronounced immunoglobulin M (IgM) and IgG responses which accompany the elimination of each VAT are responsible for killing of parasites and their clearance from the blood by two main effector mechanisms: activation of complement via the classical pathway and opsonization leading to uptake by Kupffer cells of the liver.

In bovines (including asymptomatic antelopes) IgM levels may increase ninefold over normal. This sustained macroglobulinemia is usually interpreted as being due to antibodies produced against successive trypanosome VATs, but heterophile antibodies have been demonstrated in trypanosome-infected hosts and taken to be a sign of polyclonal B cell activation. Elevated levels of IgM in the cerebrospinal fluid (5–10% of this IgM is 7S, possibly indicating failure to assemble the 19S product) is diagnostic of the disease.

The immune response in mice comprises both T-dependent and T-independent components. The classic evidence for the latter is the control of para-

sitemia in nude mice. With regard to T-dependent responses, there is no current consensus on either the nature of the T cells involved or the importance of their function. T_H1 type responses have been observed ($CD4^+$, $CD8^-$ cells secreting interferon γ ($IFN\gamma$) but not interleukin 4 (IL-4), antigen-specific, major histocompatibility complex (MHC) class II restricted) but these cells failed to mount proliferative responses and were found only in the peritoneum, not in the spleen or lymph node. $CD4^+$ knockout mice regulate parasitemias as well as control mice. Activation of $CD8^+$ cells secreting $IFN\gamma$ has also been reported but these cells unexpectedly, at least in some model systems, appeared to promote parasite growth and exacerbate infections. There is no evidence for $CD8^+$ cells modulating infections in bovines.

A profound depression of lymphocyte responsiveness is characteristic of trypanosome infections and, in mice, the onset of depression is very rapid – 5–7 days. This depression is caused in large part by suppressor macrophages which when elicited release nitric oxide and prostaglandins leading to a reduction in IL-2 production, IL-2 receptor expression and lymphocyte unresponsiveness.

Certain *Bos taurus* (humpless) breeds of domestic cattle, the N'dama and shorthorn (Muturu) of West Africa, are trypanotolerant, that is they can survive and be productive in tsetse-infected areas where other breeds succumb to trypanosomiasis in the absence of drug treatment. Trypanotolerance appears to be due largely to the superiority of the animal's acquired immune response, in ability both to respond to the trypanosome and to control the infection. The severity of the anemia, which often proves fatal, in cattle trypanosomiasis is broadly related to the level of parasitemia and its duration. Differences in anemia between N'dama and Zebu cattle appear to be due to the capacity to control parasitemia rather than differences in erythropoietic responsiveness. Other factors (food utilization, heat tolerance) may be important to innate trypanotolerance, and in game animals trypanocidal factors in the serum undoubtedly play a part. The inability of *T. brucei brucei* to infect humans is probably due to its susceptibility to lysis by human high-density lipoprotein; sleeping sickness trypanosomes resist such destruction.

Much of the pathology of African trypanosomiasis (anemia, circulatory disturbances, lymphoid cell proliferation, tissue destruction) has been attributed to the host's exaggerated response to the presence of the trypanosome. Trypanosomes expressing M-VATs multiply in the dermis at the site of an infected tsetse bite, inducing an inflammatory reaction (the chancre)

with redness, edema, and infiltration by neutrophils and small/medium lymphocytes. At the peak of the reaction, these cells are replaced by proliferating large lymphocytes and, progressively, plasma cells, numbers of the latter increasing as the chancre subsides in the third week. In sheep, T lymphocyte subpopulations (both CD4⁺ and CD8⁺) form a major component of the early mononuclear cell infiltrate, whereas after 5–7 days B cells dominate in the *T. congolense*-induced chancre. Another chancre does not form if the animal is challenged with the same trypanosome serodeme, suggesting immune neutralization of the challenge infections. Chancres never form in mice and rats.

Trypanosomes are found in the draining lymph of the chancre 6–7 days after infection and in the blood 3–5 days later. They switch from one M-VAT to another in the chancre: the first bloodstream VAT (B-VAT) to appear is that originally ingested by the tsetse fly (due to reactivation of the B-VSG gene *in situ*). After this the procession of B-VATs occurs as in syringe-passaged infections; early VATs appear to be coded by VSG-genes activated *in situ* at telomeric sites, later B-VATs the result of the ELCs of internal genes being transposed to an expression site.

The lymphoid proliferative phase of the disease starts with the first patent parasitemia and lasts for less than 2 weeks in mice, over 3 months in cattle. Enlargement of lymph nodes and spleen are striking, with a disproportionate increase in the size of B cell-dependent follicular areas, and germinal centers are usually well developed. After the proliferative phase a more protracted cellular depletion phase occurs in the lymphoid organs, supposedly due to clonal exhaustion.

Immune complex formation (especially due to the boosting of antibodies against common antigens as the infection advances) has been postulated to account for macrophage infiltration of tissues and Arthus reactions (tissue immune complexes), and anemia and kinin-induced vascular permeability (circulating complexes). These conclusions are based

on laboratory animals but the hematological changes observed in rodents appear similar to those in cattle where they pose the main clinical problem. In humans neurological changes are more prominent, hence the disease name 'sleeping sickness'. When trypanosomes invade the brain astrocytes assume an important role as antigen-presenting cells containing immune reactions to perivascular regions leading to vascular cuffing, the formation of a dense layer of lymphocytes, macrophages and plasma cells around blood vessels. Prostaglandin release by astrocytes may give rise to altered sleep patterns in advanced sleeping sickness patients. Intriguingly, the pathological symptoms of trypanosomiasis disappear rapidly after elimination of the parasite by drug treatment.

TUMOR ANTIGENS

The notion that tumor cells express target structures that can be recognized by the immune system was put forward a long time ago, but only recently was the molecular nature of tumor antigens rigorously defined, thanks to the tools of modern immunology combined with molecular biology.

Tumor antigens recognized by T cells

The study of animal models has clearly demonstrated that the immune system has the capacity to reject tumor cells and that T lymphocytes are instrumental in this rejection. In particular, the essential role of cytotoxic T lymphocytes (CTLs) was highlighted by adoptive transfer studies and by the analysis of tumor variants escaping rejection, which were found to have lost CTL epitopes. A number of mouse tumors were found to express one or several antigens recognized by CTLs derived from lymphocytes of mice having rejected these tumors. In humans, anti-tumor CTLs were obtained *in vitro* from the lymphocytes of cancer patients, and a number of antimelanoma CTL clones have been analyzed in detail. The study of melanoma variants that were resistant to some but not all of these CTL clones revealed that melanoma cells express several distinct antigens. The molecular definition of these antigens has afforded crucial insights into both the specificity of these tumor antigens and the mechanism of their expression by tumor cells.

The experimental approach that allowed the identification of most tumor antigens is a genetic approach aimed at cloning the gene that encodes the antigen. This is done by transfecting recombinant libraries into cells that are subsequently screened with the CTL for their expression of the antigen. As observed for viral CTL epitopes, most tumor antigens identified to date do indeed correspond to peptides derived from intracellular proteins and presented at the cell surface by major histocompatibility complex (MHC) class I molecules. Based on the pattern of expression of the parent protein, the antigens can be classified into four major groups: tumor-specific shared antigens, differentiation antigens, antigens resulting from mutations and viral antigens.

Tumor-specific shared antigens

These antigens are encoded by genes that are completely silent in most normal tissues but are activated in a number of tumors of various histological types. Prototype antigens of this group are those encoded by gene P1A in the mouse and by genes MAGE in humans. Additional human genes with a similar expression profile have been identified subsequently and are listed in **Table 1**. Antigenic peptides derived from the proteins encoded by these genes were defined and found to be presented to CTLs by specific MHC class I molecules (**Table 1**). With the exception of RAGE, the only normal cells where

^aAberrant transcript of *N*-acetylglucosaminyl transferase V (GnTV) that is found only in melanomas (50%).

significant expression of these genes was detected are testicular germ cells and placental trophoblasts. Since these cells do not express MHC Class I molecules, they do not present the peptide at their surface. Therefore such antigens can be considered as strictly tumor specific. The activation of the genes usually results from a demethylation of their promoter that correlates with a nonspecific genome-wide demethylation. Expression was detected in substantial fractions of human melanomas, head and neck, lung, bladder and breast carcinomas (Table 2). Because they are shared by tumors expressing the genes and bearing the appropriate MHC type, these antigens represent promising targets for cancer immunotherapy. About 60% of melanomas, 40% of head and neck tumors, 34% of non-small cell lung carcinomas and 28% of bladder tumors express at least one of the antigens identified to date.

Some CTLs-directed against breast, ovarian and pancreatic carcinomas recognize an epitope of mucin, a surface protein composed of multiple tandem repeats of 20 amino acids. Whereas in normal cells mucin is heavily glycosylated, in these tumors the peptide repeats are unmasked by underglycosylation, resulting in CTL recognition. Remarkably, this recognition, which depends on the presence of multiple repeats, occurs in the absence of HLA restriction. Mucin underglycosylation also occurs in breast duct epithelial cells during lactation, but only at the extracellular apical surface which normally is not accessible to T cells. These mucin antigens therefore appear to be very specific for tumor cells, and the lack of HLA restriction should facilitate therapeutic vaccination trials.

Lymphocytes infiltrating some HLA-A2⁺ ovarian carcinomas were found to recognize peptides derived from HER-2/neu, an oncogene expressed in normal

tissues at low levels and overexpressed in 30% of breast and ovarian carcinomas.

Differentiation antigens

A large number of CTLs directed against human melanoma were found to recognize not only a majority of HLA-A2⁺ melanomas but also HLA-A2⁺ normal melanocytes. The notion that such CTLs recognize melanocyte differentiation antigens was confirmed when the antigens were identified at the molecular level. Five genes encoding melanocyte differentiation antigens have been identified (Table 3). Most antigenic peptides are presented by HLA-A2, but other HLA-peptide combinations have been found. Two tyrosinase peptides are presented by HLA-DR4 to CD4 T cells. The gp75 peptide presented by HLA-A31 is peculiar in that it is translated from an open reading frame that is different from the one encoding the gp75 protein. Tyrosinase peptide 369–377 presents an interesting post-translational modification that was observed when the naturally occurring peptide eluted from an HLA-A2⁺ melanoma was analyzed (Table 3). The asparagine residue in position 3 is transformed into an aspartic acid residue, presumably because the asparagine was glycosylated and subsequently deglycosylated by an enzyme which removed the amino group with the glycan.

The role of CTLs against such antigens in melanoma rejection is not clear, but is supported by the reported association of vitiligo with prolonged survival and spontaneous regression of melanoma. Because melanocytes are also present in the choroid layer of retina, the potential ophthalmic toxicity of active immunotherapy targeted at these antigens needs to be evaluated.

Similar concerns about autoimmune side-effects

apply to carcinoembryonic antigen (CEA), an oncofetal protein expressed in normal colon epithelium and in most gut carcinomas, that was recently shown to contain a peptide epitope recognized by T cells from immunized patients.

B cell lymphomas are monoclonal tumors derived from B cells. They express the idiotype corresponding to the antigen specificity of the parent B cell. Idiotypic immunoglobulins therefore represent a particular case of differentiation antigens that are unique to individual tumors. Such antigens, which need to be prepared individually for every patient, are being evaluated as vaccines for B cell lymphoma.

Antigens resulting from mutations

Antigens of the third category correspond to peptides derived from regions of ubiquitous proteins that are mutated in tumor cells (Table 4). The mutation either generates a new epitope in the peptide or enables its binding to the MHC molecule. In most cases the mutation is unique to an individual tumor, and therefore the antigen is not shared. Other mutations occur in several tumors that may then share the antigen. The mutations may affect genes involved in cell regulation, such as p53 and CDK4, and thereby play a role in carcinogenesis. The great majority of mouse tumor antigens identified to date result from mutations. This may be due to the fact that many mouse tumors were induced with carcino-

gens or radiation. However, antigens of this category were also found on spontaneous mouse tumors and on human tumors. Although their tumor specificity is optimal, the fact that these antigens are often individually unique prevents their use as components of generic cancer vaccines.

Viral antigens

Antigens derived from oncogenic viruses constitute another category of potentially useful tumor antigens. A number of viral antigens have been studied in detail on virally induced mouse tumors and shown to be relevant for tumor rejection. In humans, the best example is oncoprotein E7 of human papillomavirus 16 (HPV-16), which is present in most cervical carcinomas. Peptides derived from this protein and selected for their high binding affinity to HLA-A2 were used to stimulate CD8⁺ lymphocytes from normal individuals. CTL clones obtained against three of these peptides were found to recognize not only peptide-pulsed cells but also a cervical carcinoma line expressing HLA-A2 and HPV-16 E7, demonstrating that these peptides indeed correspond to genuine cervical carcinoma antigens.

Clinical perspectives

The next few years will see the evaluation of new clinical trials using some of these defined tumor antigens. Progress at three different levels is anticipated.

^cThe peptide derives from the env gene product of MuLV that appears to be transcribed in several tumors.

^dPeptide selected from the ras sequence and used to stimulate CTLs *in vitro*.

^eThe mutation affects the HLA-A2 gene itself.

First, knowledge of the molecular nature of these antigens allows the selection of patients whose tumor actually expresses a given antigen. Secondly, it allows the rational design of highly specific vaccine preparations. These could consist of peptides mixed with appropriate adjuvants or used to pulse autologous antigen-presenting cells *ex vivo*. The availability of the genes encoding the antigens also allows the preparation of recombinant proteins that can be combined with adjuvants, the preparation of recombinant viral vectors that can be used for immunization, or the direct use of these genes in nucleic acid vaccination protocols. Thirdly, precise knowledge of the antigenic epitopes allows careful monitoring of the CTL response after vaccination. This should help to optimize the immunization procedure.

Since a number of tumors express several antigens, patients bearing these tumors could be immunized simultaneously against distinct defined antigens. In addition to being more effective at rejecting the tumor cells, this should reduce the emergence of escaping variants arising by loss of antigen expression, as it is unlikely that the same variant would simultaneously lose distinct nominal antigens.

Tumor antigens recognized by monoclonal antibodies

Considerable progress has been made in the identification of defined tumor-associated antigens recognized by monoclonal antibodies (mAbs). The process of identification and characterization of tumor anti-

gens recognized by mAbs involves careful serological analysis and rigorous immunohistochemistry screening of normal tissues and tumors. These methods differ from the genetic approach used to identify antigens recognized by CTLs, and the molecular nature of many of these antigens is therefore less well defined. Similarly, the function of many tumor-associated antigens (especially cell surface antigens in solid tumors) often remains poorly understood. The expression of antigens recognized by mAbs in tumors is often heterogeneous, and loss of expression may be observed in anaplastic transformation and as a result of immune escape. The classification of tumor antigens recognized by mAbs is generally performed on the basis of antigen structure, and the anatomical component that expresses the antigen within the tumor.

Differentiation antigens in hematologic malignancies

Leukemias and lymphomas are characterized by malignant cells that express immunophenotypes that are found in selected stages of hematopoietic differentiation. These antigens are usually associated with CD groupings, have a glycoprotein structure, but are not always strictly tumor specific or lineage specific. The ideal antigen target for mAb directed against leukemias or lymphomas has high expression in neoplastic cells, but not on normal cells or bone marrow progenitors. The antigens most successfully targeted by mAbs in clinical trials in leukemia and lymphoma are detailed in Table 5. The accessibility of leukemia

Mutated gene products	ΔEGFR	Glioblastoma multiforme, breast, lung cancer
Stromal/extracellular antigens	FAP α Tenascin Metalloproteinases	Epithelial cancers (breast, colon, lung) Glioblastoma multiforme Epithelial tumors
Endothelial/vascular antigens	Endosialin, VEGF, $\alpha_v\beta_3$	Tumor vasculature
Apoptosis	Apo-1	B cell neoplasms

and lymphoma cells to circulating mAbs provides distinct advantages in antigen targeting compared to solid tumors.

Cell surface antigens

Glycoproteins Glycoprotein antigens expressed on the cell surface of solid tumors are common targets for monoclonal antibodies. These antigens have variable expression patterns in normal tissues, ranging from extensive tissue distribution to restricted expression, and are predominantly found on tumors of epithelial origin (Table 5). The carcinoembryonic antigen (CEA), TAG-72 antigen, and the MUC1 gene product PEM (polymorphic epithelial mucin) have been the tumor antigens most studied in animal models and clinical trials with mAbs. All these antigens have variable expression in a broad range of epithelial tumors, and soluble forms of these antigens may be found in the serum of patients with these tumors. Both PEM and Ep-CAM (a 40 kDa glycoprotein targeted by the mAb 17-1A, and involved in cell adhesion) are expressed in epithelial tumors and a wide range of normal epithelial tissues. In most tumors expressing these antigens, downregulation of antigen in metastases compared to primary tumors has been reported. Glycoprotein antigens with distinct high tumor expression and restricted normal

tissue distribution include A33 and G250. The A33 antigen is a 43 kDa protein which has a restricted expression in human small and large intestine epithelial cells, and is expressed on over 95% of human colorectal carcinoma cells. Upon mAb binding to A33 antigen, the antibody-antigen complex is internalized and sequestered in vesicles. The unique structure of the A33 antigen has been shown to consist of a transmembrane glycoprotein with an extracellular domain structure related to the CD2 subgroup of the immunoglobulin superfamily. The function of this antigen is as yet undefined, but may be a novel cell surface receptor or involved in cell-cell adhesion. Another glycoprotein antigen with restricted normal tissue expression is G250, which is expressed in over 90% of clear cell renal carcinoma but not in normal kidney, and is also expressed in biliary epithelium. The precise structure of this antigen is undefined, but is thought to be related to carbonic anhydrase. mAbs directed against the A33 and G250 antigens have been studied in clinical trials, and have demonstrated excellent targeting characteristics indicating the suitability of these antigens for directed cancer therapy.

Glycolipids Gangliosides are glycolipids expressed in animal cells, and consist of a carbohydrate moiety

linked to a ceramide molecule which is anchored in the lipid bilayer of the cell surface membrane. Malignant transformation of cells may be associated with qualitative and quantitative changes in ganglioside expression on the malignant cell surface, which can be recognized immunologically. Ganglioside synthesis may be incomplete and result in precursor accumulation, e.g. GD2, GD3, GM2, GM3, which are found on tumors of neuroectodermal origin (melanoma, neuroblastoma, astrocytoma and small cell lung carcinoma). Modifications to the carbohydrate or ceramide portions may also be observed. The high expression of some gangliosides in tumor cell membranes may also lead to conformational changes of antigen epitopes which enhance monoclonal antibody binding. The function of gangliosides is unclear, but is thought to involve cell growth and differentiation.

Carbohydrates A range of carbohydrate determinants linked to either lipids or proteins have been identified by serological analysis of human cancer cells with mouse mAbs. Blood group-related antigens (e.g. Le^b and Le^y) have been the focus of much attention because of their high level of expression in epithelial tumors, although some expression in normal tissues is also present. The Le^y antigen is expressed in over 70% of epithelial cancers (including breast, colon, ovary and lung cancer), and is an attractive target for mAb-directed therapy. A number of mouse mAbs against Le^y antigen have been produced, although a consistent problem with these mAbs has been an element of cross-reactivity with Le^x and H-type 2 structures, and agglutination of human red blood cells. Meticulous serological analysis has been required to identify anti-Le^y mAb that have minimal or no cross-reactivity with other blood group-related antigens: a number have been studied in clinical trials and are the subject of ongoing research.

Growth factor receptors

Growth factors may be overexpressed in tumors, and the growth or survival of some tumors may partially depend on autocrine or paracrine production of epidermal growth factor (EGF) or transforming growth factor α (TGF α). These two factors share a common receptor, the EGF receptor, which is expressed in normal tissue (particularly the liver), but has increased expression in certain tumors (e.g. lung and breast). mAbs against the EGF receptor have been shown in *in vivo* models to inhibit growth of breast cancer xenografts, and clinical trials with anti-EGF receptor mAbs have also demonstrated specific targeting. A truncated mutant EGF receptor (δ EGFR) that contains a deletion of 267 amino acids from the

extracellular domain, and does not bind EGF, has also been identified in human gliomas. Expression of δ EGFR confers enhanced tumorigenicity to glioblastoma cells, and is associated with increased proliferation and reduced apoptosis. mAbs against the δ EGFR have been generated, and may represent an important new strategy for glioma therapy. An additional important receptor is the transmembrane glycoprotein receptor p185^{HER2} (encoded by the HER-2/neu oncogene). p185^{HER2} has partial homology with the EGF receptor, is overexpressed in 25–30% of breast cancers, and is associated with a worse prognosis in patients with primary disease involving axillary lymph nodes. mAbs directed against p185^{HER2} have been shown to inhibit the growth of tumors in animal models, and of transformed cells expressing high amounts of this receptor. Objective responses in patients with metastatic breast carcinoma overexpressing p185^{HER2} with mAbs directed against the extracellular domain have been reported, indicating the potential therapeutic use of growth factor-targeted therapy.

Stromal antigens

The human fibroblast activation protein α (FAP α) is a cell surface antigen expressed in reactive stromal fibroblasts of a number of epithelial cancers including colon, breast and lung. FAP α is absent or expressed in low levels in most adult tissues, but is seen in wound healing and transiently in some fetal mesenchymal tissues. FAP α has structural homology to CD26, but appears to be functionally distinct, and expression of FAP α can be induced *in vitro* on cultured fibroblasts by various growth factors (e.g. TGF β). The successful targeting of mAbs against FAP α expressed in tumor stroma has been demonstrated in clinical trials of patients with colorectal carcinoma. Another potential stromal antigen target is tenascin, an extracellular matrix glycoprotein present in developing tissue during the fetal period, and expressed in the stroma of many adult tumors, particularly glioblastoma multiforme.

Angiogenesis and apoptosis

Serological studies have identified a number of antigens expressed selectively on neovascular endothelium of tumors, including endosialin, vascular endothelial growth factor receptor (VEGFR), and the integrin $\alpha_v\beta_3$. Because of the restricted expression of these antigens in tumor vasculature, the potential anti-tumor effect of inhibitors of these antigens has been the subject of intense interest as a means of killing tumor cells without requiring specific tumor cell targeting. The role of apoptosis in mediating tumor

cell death is also being explored with mAbs against a variety of antigens including Fas (CD95, Apo-1).

Clinical perspectives

The clinical applications of tumor-associated antigens recognised by mAbs include both diagnosis and therapy. Diagnostic uses include serum detection of soluble antigen as a marker of disease activity (e.g. CEA, CA-125, PSA (prostate-specific antigen)), immunohistochemistry characterization of biopsy specimens for pathologic diagnosis, and the use of radiolabeled mAbs for tumor detection *in vivo* (e.g. anti-CEA, anti-TAG-72, anti-PSMA (prostate-specific membrane antigen) mAbs). Perhaps the most promising area of clinical development, however, is in mAb-targeted therapy. Based on the experience of clinical trials to date, the ideal therapeutic antigen target has a homogeneous expression in tumor, minimal expression in normal tissues, no soluble form of antigen to impede tumor binding, and easy accessibility to mAbs. Tumor antigen screening, and an understanding of the internalization characteristics and function of targeted antigen, will allow the optimal selection of mAbs for targeting. The range of tumor antigens recognized by mAbs and the expanding therapeutic strategies that can be employed will form the basis of continuing clinical research.

TUMOR IMAGING

Hirohiko Onoyama and **Yoichi Saitoh**, The First Department of Surgery, Kobe University School of Medicine, Chuo-ku, Kobe, Japan

Masaaki Miyazawa, Department of Immunology, Kinki University School of Medicine, Osaka-Sayama, Osaka, Japan

Tumor imaging is a clinical and experimental medical technology designed to localize neoplastic lesions in a body using a labeled antibody or its fragment. The idea of localizing antitumor antibodies into human cancer originated in the 1890s with attempts to treat malignant diseases using antisera raised against human tumors in animals. These heterologous polyclonal antisera contained, by their nature, overwhelming amounts of antibodies reacting with species-specific tissue antigens, rather than those, if any, reacting with tumor-specific antigens. Thus, researchers in the earlier days tried to increase the specificity of their antitumor antisera by absorbing 'nonspecific reactivities' by incubation with normal human tissues. The problem of mixed specificity was overcome by the development of hybridoma technology that allowed continuous production of a homogeneous antibody reacting only with a single epitope. Production on a large scale, purification, enzymatic and genetic manipulation, and labeling of antibody molecules became easier after the introduction of hybridoma-derived monoclonal antibodies, and even further advances are currently taking place by the development of the phage display technique.

Tumor antigens

Tumor imaging depends on the presence of an antigen that is either exclusively expressed on the tumor or at least has an appreciable difference in its amount

and/or distribution between the tumor and normal tissues. Tumor antigens are usually separated into two categories: tumor-specific antigens and tumor-associated antigens. The former are expressed only in tumors and are never detectable in normal tissues. They are often unique to a single tumor and, thus, not shared by tumors of different individuals. Theoretically, an ideal tumor-specific antigen would be that associated with mutational change(s) of an oncogene or a tumor suppressor gene that caused the malignant transformation. Since peptides produced by enzymatic processing of intracellular proteins are displayed on major histocompatibility complex (MHC) class I molecules, T lymphocytes may recognize a mutated peptide associated with the oncogenesis. How professional antigen-presenting cells that are capable of activating naive T cells capture tumor-specific antigen peptides, which are produced only by the tumor cells but not by the antigen-presenting cells, is still unclear. In any case, most of these tumor-specific antigens are recognized by T cells, and it is generally difficult to imagine that antibodies reacting with an intracellular oncogene product accumulate in a small lesion filled with fully viable tumor cells.

On the other hand, tumor-associated antigens are expressed at an inappropriately high level in tumor cells, whereas the expression of the same antigen in normal tissues is very low or strongly restricted to a certain stage or site in tissue development. Many of

these tumor-associated antigens are detectable with heterologous and sometimes autologous antibodies. Notable examples are carbohydrate antigens including gangliosides and blood group antigens, carcino-embryonic antigen (CEA), α -fetoprotein, mucins, cell surface receptor-like molecules, and some hormones and enzymes. Among them, antibodies reacting with CEA, carbohydrate antigens and mucins have been most extensively studied for use in tumor imaging.

CEA is a cell surface glycoprotein of 180 kDa, and its expression is most frequently associated with adenocarcinomas of colon, breast and lung. CA19-9 or sialyl Le^a is a typical tumor-associated carbohydrate antigen. This modified blood group antigen is highly expressed on most gastrointestinal carcinomas including adenocarcinomas of pancreas, colon and stomach. Mucins are extremely high molecular weight glycoproteins that are abundantly expressed on the surface of breast, colon, pancreas, ovary and lung adenocarcinomas. Since the presence of mucins in normal tissues is confined to the apical surface of the ductal epithelial cells and in the ductal lumen, they are usually sequestered from the immune system. The unipolar and excessive nature of mucin production in tumor cells leads to the production of antibodies. Many monoclonal antibodies reacting with human tumor-associated mucins are generated by immunizing mice with tumor tissues. Human chorionic gonadotropin (hCG) secreted by choriocarcinoma was the first tumor antigen used for targeting.

The antibody and its fragments

The immunoglobulin (Ig) G molecule has a relatively large molecular weight of 150 kDa. Although IgG distributes throughout the body, its penetration into a tumor mass is slow, as demonstrated by autoradiography of tumor xenografts after intravenous injection of ¹²⁵I-labeled antitumor IgG. The number of grains in areas on autoradiography sections that are more than 30 μ m distant from vessel margins

were shown to be increasing even after 72 h postinjection in one study. The whole IgG can also bind to tissue macrophages and circulating leukocytes through Fc receptors. Since immunoglobulins are highly immunogenic in different species, injection of mouse antibodies raised against human tumors into humans results in the production of human anti-mouse Ig antibodies (HAMA). These antibodies accelerate the clearance of injected antitumor antibodies from the blood, and may cause a potentially fatal anaphylactic reaction and/or serum sickness. Replacement of mouse Ig constant domains with human counterparts by ligation of rearranged mouse Ig variable region with human Ig constant region genes results in the production of chimeric antibodies, which have much reduced immunogenicity.

Since Ig effector functions associated with the heavy chain constant region are not necessary for binding and accumulation of antitumor antibodies to neoplastic lesions, the use of smaller fragments of Ig that retain only the antigen-binding activity seems to be a reasonable way to reduce the immunogenicity and molecular mass of antitumor antibodies.

Enzymatic digestion of IgG with pepsin yields a $F(ab')_2$ fragment, which is still divalent because the two antigen-binding portions are linked by disulfide bonds at the remaining hinge regions (Figure 1). Reduction of the disulfide bonds and the blocking of them with iodoacetamide generates the monovalent fragment called Fab', composed of a single light chain and an N-terminal half of a heavy chain. Another proteolytic enzyme, papain, cuts IgG between the antigen-binding portion and the hinge, resulting in the generation of a slightly different monovalent fragment called Fab. Divalent $F(ab')_2$ usually retains the antigen-binding properties of the intact IgG, while binding affinities of monovalent Fab and Fab' are often much lower than those of the divalent counterparts. In a quantitative analysis, the affinity constant of Fab' was calculated to be one-seventh of those of $F(ab')_2$ and whole IgG. Plasma

Figure 1 The structure of IgG and its fragments.

clearance of Fab and Fab' is also much faster than that of F(ab')₂ and whole IgG, leaving limited time for accumulation into the tumor. However, rapid clearance from the blood may conversely improve the contrast between the tumor and normal tissues. Because of the reduced binding affinity and rapid clearance, *in vivo* distribution of monomeric Fab is different from that of dimeric F(ab')₂ and whole IgG. In general, a higher percentage of injected dose per gram of tissue is achieved with IgG but at a much later point after injection than with Fab'. On the other hand, because of the smaller molecular mass of 50 kDa, Fab' penetrates into tumor mass much more rapidly and evenly than F(ab')₂ and whole IgG. Thus, tumor to normal tissue ratios of radioactivities are usually higher when a Fab or Fab' fragment is used as a radiolabeled antitumor targeting agent.

Single-chain Fv and phage display libraries

If monomeric Fab and Fab' fragments penetrate better into the tumor mass than their divalent counterparts, an even smaller fragment of Ig composed only of a single antigen-binding portion and devoid of constant domains may penetrate into the tissue even more rapidly. In addition, complete elimination of the constant regions may further reduce the immunogenicity. Thus, single-chain Fv (scFv) fragments composed of a combination of heavy and light chain variable regions linked with a flexible, synthetic spacer have been constructed by genetic engineering. The resultant scFv fragments have a molecular weight of 27 kDa, and penetrate into the tumor tissue much more rapidly, even in comparison with Fab'. One advantage of scFv technology is that this antigen-binding molecule can be expressed on the surface of filamentous bacteriophages that carry the specificity-encoding V_L and V_H genes. Thus, phages carrying and expressing a combination of high-affinity V_L and V_H genes are directly selected through binding assays. Since a large combinatorial library of V_L and V_H genes can be constructed from B lymphocytes derived from immunized mice, the step of making and selecting hybridoma cells can be skipped, thus

minimizing the time from immunization to isolation of a high-affinity antibody.

As mentioned above, the binding affinity of monovalent Fab' is usually weaker than that of whole IgG. If an scFv molecule is constructed by using a combination of V_L and V_H genes isolated from a hybridoma clone, its binding affinity cannot surpass that of the Fab' counterpart. However, because of the extremely large capacity of a phage display library, it is possible to access all the antibody specificities generated in an immunized animal. In contrast, it is practically impossible to screen more than 10³ clones of different specificities at one time by hybridoma technique. Thus, screening of a large phage display library can potentially result in clones of scFv with unusually high affinity, which is generally not registered by hybridoma technology. Such extreme high-affinity scFv may overcome the disadvantage of the monovalent nature of this fragment. Seemingly promising clinical applications of scFv have been reported.

The radionuclide and imaging technology

A variety of gamma-emitting radionuclides can be used to label antibodies and their fragments. Frequently used radionuclides are shown in Table 1 with their physical half-lives and γ energy. Because penetration and distribution equilibrium take 2–4 days when the whole IgG molecule is used as a labeled antibody, ¹³¹I with a long physical half-life was used in earlier studies. When separated from the antibody, a fraction of this radionuclide is taken up and retained in the thyroid. ¹²³I and ¹¹¹In are more efficient for γ -camera imaging than ¹³¹I, and have been used more frequently with recent advancements of Ig fragment preparation. ^{99m}Tc is most efficiently imaged by γ -camera, but its physical half life is very short. However, with rapid penetration of Fab' and scFv into tumors and improved methods of conjugation between ^{99m}Tc and proteins, this radionuclide has become more attractive for clinical use, especially because it is economical.

The technique of imaging neoplastic lesions *in vivo*

Table 1 Radionuclides used for immunoscintigraphy

Radionuclide	T _{1/2} (h)	Decay	γ energy (keV)	Sources
^{99m} Tc	6.0	Isomeric transitions	141 (89%)	X-ray generator
¹²³ I	13.2	Electron capture	159 (83%)	Cyclotron
¹³¹ I	193.0	β decay	364 (81%)	Nuclear reactor
¹¹¹ In	67.9	Isomeric transition	171 (90%), 245 (94%)	Cyclotron

after administration of a radiolabeled antitumor antibody is known as immunoscintigraphy. The distribution of radiolabeled antibody molecules in the patient's body is mapped using a γ -camera. Experimentally, this technique is often simulated by using human tumor xenografts in athymic mice. The statistical validity of γ -camera imaging depends on the level of radioactivity accumulated in the tumour, the time that a patient can remain still on the γ -camera couch during count acquisition, the physical decay properties of the radionuclide used, and the efficiency of detection. Thus, there are a lot of limitations especially in the clinical application of radioscinigraphy. To produce three-dimensional data, single photon emission computerized tomography (SPECT) has been developed, and is being more frequently reported in the literature. This method is, however, technically demanding. Hand-held γ -detecting probes are used for the detection of subcutaneous lesions including breast carcinomas and their lymph node metastases. They can also be utilized to define the extent of tumor infiltration and metastases during surgical operation (radioimmunoguided surgery).

Micromagnetic beads might be another possibility for labeling antibodies for tumor imaging. Immunomagnetic beads have been successfully utilized for depletion and enrichment of particular lymphocyte subpopulations and hematopoietic stem cells. In experimental models accumulation in carcinoma xenografts of antitumor antibodies labeled with micromagnetic beads was detected by magnetic resonance imaging. Although currently available detectors for magnetically labeled antibodies are unwieldy, if a small enough detector is developed, this method of labeling might be applicable to 'ferroimmunoguided surgery' in the near future.

Uses of antibody imaging

In experimental animals carrying human cancer xenografts tumor imaging has been successful with many tumor types. Clinical application has also been reported, but immunoscintigraphy is still not widely accepted as a prime method of cancer diagnosis. There are several reasons for this limited use of antibody-mediated tumor imaging. First, in many cases less than a few per cent of the injected dose localizes in the tumor, giving unsatisfactory and sometimes invalid data for γ -camera imaging. Second, repeated injection of labeled antibodies can induce the production of human anti-mouse Ig antibodies. This problem can be overcome by the use of humanized monoclonal antibodies or scFv. Third, other techniques used for morphological localization of tumorous lesions, conventional and enhanced CT scanning,

magnetic resonance imaging and ultrasonography, have become widely available, and they often give much better image quality and resolution than immunoscintigraphy. SPECT performed using rapidly penetrating scFv may give images with acceptable resolution, but spatial relationships between labeled lesions and normal organ structures are only seen in combination with conventional CT. Antibody imaging can sometimes surpass other imaging technology for localization of tumors in certain anatomical sites, such as the peritoneum, where other methods perform less effectively.

Thus, the use of immunoscintigraphy for initial diagnosis of tumors is limited to specific regions, such as ocular melanoma, in which biopsies are not possible. Immunoscintigraphy can also be useful for staging of cancer. In particular, immunoscintigraphy may be superior to ^{67}Ga scanning for the staging of malignant lymphoma. Useful application of immunoscintigraphy has been found in the detection and localization of recurrence in colon cancer, choriocarcinoma, germ-cell tumors, and thyroid carcinoma. Antibodies to CEA and CA19-9 are frequently reported to be used for radioimaging of metastatic and recurrent lesions. Hand-held γ -probes in combination with radiolabeled antibodies have also

been used for the staging of breast carcinoma.

Radioimmunoguided surgery performed using a hand-held γ -detector can be effective to determine the extent of tumor infiltration and to detect lymph node metastases during surgery. In some cases lymph node metastases were reported to be detectable with radiolabeled anti-CEA antibody in patients whose serum CEA was below the detectable level. However, there are always false negatives and positives when lymph nodes are histologically examined after radioimmunoguided surgery. Further improvements in labeling and imaging techniques are required for the clinical use of radiolabeled antibody methods.

Antibody targeted therapy

Antibody-radionuclide conjugates themselves may be used for the therapy of human cancers, as are antibody-toxin complexes. Immunoscintigraphy may also be useful to identify patients for therapy with an immunotoxin because efficient imaging with a radiolabeled antibody must correlate with efficient accumulation of the immunotoxin that shares the same specificity.

TUMOR NECROSIS FACTOR α

Lothar Rink, Institute of Immunology and Transfusion Medicine, University of Lübeck
School of Medicine, Lübeck, Germany

The remission of tumors after bacterial infections was first described in 1866. In 1893 Coley described tumor necrosis after treatment of patients with bacterial toxins from *Streptococcus* and *Serratia*, which were later named 'Coley's toxin'. Over 100 years after the first clinical observation, tumor necrosis factor α (TNF α) was described in 1975 by Carswell and colleagues. They reported on a soluble factor in the serum of endotoxin-treated bacillus Calmette-Guérin (BCG)-infected mice, which causes hemorrhagic necrosis of tumors.

TNF α has had a number of synonyms (Table 1). It is induced by all types of microorganisms and a number of their products (Table 2). The expression of TNF α has naturally counteracting cytokines (Table 2). Nearly all cell types are able to produce TNF α (Table 3) and respond to TNF α treatment

(Table 4). Over all the biological effects, the cytotoxic effects of TNF α and its induction of apoptosis seem to be the most important.

Table 2 Inducers and suppressors of TNF α production

Inducer	Suppressor
Allogenic cells	Cyclosporine
Bacteria	Glucocorticoids (i.e. dexamethasone)
Bacterial cell walls	
Complement	Interleukin 4
Cytokines (i.e. IL-1, GM-CSF)	Interleukin 10
Immune complexes	Interleukin 13
Lipid A	Lipo-oxygenase inhibitors
Lipopolysaccharide (LPS)	Metalloproteinase inhibitors
Lipoteichoic acid	(only for soluble TNF)
Mycoplasma membrane	Phosphodiesterase inhibitors
Mycoplasma components	Transforming growth factor β
Parasites	
Peptidoglycan	
Phorbol esters	
Reactive oxygen species	
Superantigens	
Tumor cells	
Viruses	
Yeast	
Zinc ions	
Zymosan	

Table 1 Synonyms for TNF α

Cachectin
Cytotoxin (CTX)
Differentiation-inducing factor (DIF)
Endogenous pyrogen (EP) (also synonym for interleukin 1)
Hemorrhagic factor
Macrophage cytotoxic factor (MCF)
Macrophage cytotoxin (MCT)
Necrosin
Tumor necrosis factor (TNF)

Table 4 Biological effects of TNF α

Antiviral activity
Chemotactic
Decreased lipoprotein lipase synthesis
Differentiation of monocytes
Enhanced antibody-dependent cellular cytotoxicity
Increased expression of adhesion molecules
Increased MHC class I and class II expression
Increased phagocytotic activity
Increased proliferation of fibroblasts
Induced adhesion to endothelium
Induced degranulation
Induced fever
Induced hypotension
Induction of apoptosis
Induction of granulocyte/macrophage-colony stimulating factor
Induction of interleukin 1 and 6
Induction of procoagulant activity
Induction of reactive oxygen species
Influence on hematopoiesis of myeloid cells
Inhibition of intracellular parasites and bacteria
Regulation of acute phase proteins
Regulation of extracellular matrix formation
Regulation of proliferation of T and B cells
Regulation of T and B cell functions

The TNF α gene

The TNF α gene (Figure 1, about 3.6 kbp) is separated from that of lymphotoxin α (LT α , alternatively known as TNF β) by 1.2 kbp within the major histocompatibility complex (MHC) locus on chromosome 6 between 6p21.1 and 6p21.3. The TNF α locus contains six microsatellites. Within the LT α (TNF β)

gene there are three TNF-related polymorphisms: a NcoI RFLP polymorphism, named TNFB*1 (rare allele with less TNF- α production) in the presence of the restriction site and TNFB*2 in its absence in the first intron, an EcoRI restriction site as the rare allele in the 5'-untranslated region (5'-UTR) and an AspHI restriction site as the rare allele in the intron of the 3'-UTR. In the TNF α promoter there are four G/A exchanges in positions -376, -308 (called TNF1 and TNF2), -238 and -163. TNF2 is the less frequent allele and seems to be associated with higher TNF α production. In the 5'-UTR of TNF α there is a cytosine-insertion polymorphism at position +70, resulting in an eight cytosine stretch in contrast to the normal seven cytosine stretch.

The promoter region contains the following binding sites: κ B enhancer 2/CK-1, κ B enhancer 3, TNF repressor site (TRS) showing a 10 bp sequence homologous to the AP-2 binding site, Y-box, an Ets binding element in direct juxtaposition to an AP-1/ATF-like palindromic position, NFAT/ κ 3 binding site of NF κ B, SP-1 and a TATA-box. TNF- α induction is mostly regulated by the κ 3 binding site of NF κ B. This κ 3 binding site also binds NFAT, resulting in a cyclosporine-sensitive TNF α induction. The basal 95 bp upstream of the transcription start are necessary for upregulation of TNF α expression by granulocyte-macrophage colony-stimulating factor (GM-CSF) and downregulation by interleukin 4 (IL-4). The TRS is regulated by TRS-binding proteins of 30–60 kDa.

TNF α transcription results in a primary transcript of 1.7 kbp. Regulation on the translational level predominantly occurs by controlling mRNA turnover by an UA-rich sequence in the 3'-UTR. The mRNA may be stabilized by a 38 kDa protein binding to the 3'-UTR and inhibiting translation. Furthermore, lipopolysaccharide (LPS)-stimulation downregulates this 38 kDa protein and independently enhances the initiation step of translation and formation of TNF α mRNA ribosome complexes. This or similar factors may be the reason for discrepancies observed in TNF α mRNA expression and protein release. It is not known how the elements for translational control are regulated, but endogenously increased nitric oxide (NO), cAMP or prostaglandins levels decrease TNF α production.

Biochemistry of TNF α

The mature human TNF α is a 157 amino acid protein of 17356 Da containing one disulfide-bond (Cys69–Cys101). It has an isoelectric point of pH 5.8. The highly proteolysis-sensitive protein is processed from a 26 kDa (233 amino acid) precursor

Figure 1 (A) One part of the MHC locus on chromosome 6, including the TNF gene complex. All TNF polymorphisms are included in the gene map: the (CT) n sequence microsatellites TNFb (7 alleles), TNFc (2 alleles), TNFd (7 alleles) and TNFe (3 alleles), the (CA) n sequence microsatellite TNFa (12 alleles), the microsatellite Tau-a (11 or 14 GTs), the restriction sites for EcoRI, AspHI and NcoI (TNFB*1/2), the single G/A exchanges at positions -163, -238, -308 (TNF1/2) and -376, and the C stretch (7 or 8 Cs) at +70.

(membrane-bound TNF α , a type II transmembrane protein) and shows no glycosylation. The leader sequence entails a linking domain (amino acids -1 to -20, unnecessary for TNF α function), a hydrophobic transmembrane domain (-21 to -46) and a cytoplasmic domain (-47 to -76). There is an alternative cleavage site at position 11.

Murine TNF α has only 156 amino acids derived from a 235 amino acid precursor and is glycosylated. Despite these differences, protein sequences from porcine, bovine, goat, feline, rabbit, rat, murine and human TNF α show homologies between 70 and 90%. TNF α shows no species specificity but some species preferences in cross-reactivity.

Natural TNF α is a trimeric molecule with an antiparallel β -sheet sandwich and an edge-to-edge packing structural motif. Transmembrane TNF α is cleaved by metalloproteases, neutral serine protease 3 (PR-3) and matrix metalloproteases. Metalloproteinase inhibitors are effective in the treatment of rat endotoxemia and autoimmune inflammatory diseases by blocking both processing of membrane-bound TNF- α and shedding of the 75 kDa TNF receptor. Membrane-bound TNF α seems to be the natural and effective ligand for the 75 kDa receptor.

TNF α develops an intermediate dimer after cleavage from the membrane before forming the natural trimer. The dimer accumulates first and trimerization is finished within 6 minutes. The existence of a TNF α

dimer may also be the natural correlate to TNF receptor dimerization.

The role of TNF α in development

TNF α is expressed during embryonic development. Some of the TNF α functions are important in normal embryogenesis, such as apoptosis. Furthermore, TNF α is important as a growth and differentiation factor, comparable to its function in hematopoiesis. In addition, TNF α plays a critical role in remodeling extracellular matrix and in the induction of cell adhesion molecules and integrins. TNF α promotes liver regeneration by promoting hepatocyte-specific gene expression. Despite this, TNF α is known to enhance ubiquitin.

The involvement of TNF α in development starts before embryogenesis. TNF α induces ovulation and enhances luteinizing hormone (LH)-induced ovulation. Soluble TNFR is increased in the blood of pregnant women and also in amniotic fluid and umbilical serum. However, not only does TNF α have an effect on reproduction but also sexual hormones have an effect on TNF α production. Estradiol and progesterone enhance TNF α release by macrophages, whereas testosterone has no effect. This may be one possible reason for the higher incidence of autoimmune diseases in women.

Figure 1 (B) The region from -618 to +192 of the TNF gene is shown in full sequence including the polymorphisms (G/A exchanges and C-stretch). The binding sites for transcription factors (bold letters) are underlined for each factor, overlapping binding sites for two factors are underlined twice. The promoter region contains the following binding sites: κ B enhancer 2/CK-1, κ B enhancer 3, TNF repressor site (TRS) showing a 10bp sequence homologous to the AP-2 binding site, Y-Box, an Ets binding element in direct juxtaposition to an AP-1/ATF-like palindromic position, NFAT/ κ 3 binding site of NF κ B, SP-1 and a TATA-box. TNF- α induction is mostly regulated by the κ 3 binding site of NF κ B. This κ 3 binding site also binds NFAT, resulting in a cyclosporin A sensitive TNF- α induction.

Autoimmune diseases

Rheumatoid arthritis (RA)

Elevated levels of TNF α are present in about 50% of samples of rheumatoid synovial fluid, particularly in those patients with more severe disease or with high white blood cell counts in synovial fluid. However, high levels of TNF α do not correspond to biological activity, because sTNFR is also enhanced in the fluids. *In vitro* it has been observed that antibodies to TNF α inhibit the spontaneous release of

IL-1 and GM-CSF in synovial cells. However, there is a strong synergism between TNF α and IL-1 in the induction of human articular cartilage degradation during prolonged culture.

In collagen-induced arthritis in mice and rats, the involvement of TNF α has been shown, in that application of rTNF α leads to an accelerated onset and a more severe course of the disease. Infusion of sTNFR or anti-TNF α reduces the frequency and severity of collagen-induced arthritis. TNF α serum levels in RA correlate positively with the number of activated T cells (CD3⁺/HLA-DR⁺ and CD3⁺/CD25⁻) and in acute rheumatic fever, the number of CD4⁺/CD25⁻ cells is enhanced. *Mycoplasma arthritidis*-derived superantigen (MAS), as a pathogenic factor of this arthritogenic organism, induced TNF α in human T cells and not in monocytes, corresponding to the detected activated T cells in RA.

Furthermore, IL-10 counteracts TNF α in RA, whereas TNF α counteracts TGF β to induce α 2(I) collagen gene transcription. This may contribute to the hypothesis that cartilage damage is a combination of destruction and ineffective rebuilding. It was shown that TNF α concentrations correlated with the extent of α ₁-antitrypsin in synovial fluid of RA patients.

In preclinical studies, anti-TNF α treatment of RA patients has a beneficial effect. This important role of TNF α in RA in combination with the defined HLA associations triggered the hypothesis of an association with some TNF α alleles. However, there are no associations between TNF β polymorphism and RA.

Insulin-dependent diabetes mellitus (IDDM)

TNF α is directly involved in the destruction of pancreatic β cells. Furthermore, in the IDDM animal models it is established that islet-infiltrating mononuclear cells produce TNF α . IDDM is associated with the haplotypes TNFB*2, TNFa2 and TNFa1b5. However, the associated TNF haplotypes are in linkage disequilibrium with HLA haplotypes which are established as being associated with IDDM.

Infectious diseases

Sepsis

TNF α plays a critical role in sepsis. In animal models anti-TNF α reduces mortality during sepsis and TNF α serum levels in septic patients correlate with mortality. However, TNF α is necessary in the host defense during experimental peritonitis, and pretreatment of mice with anti-TNF α prior to infection increases the mortality. All clinical trials to prevent negative TNF α effects with anti-TNF α , sTNFR or

TNF α reducing drugs showed no definitive benefit for septic patients. A comparative animal model study showed clearly that blockade of TNF α reduced endotoxemia lethality, but not the lethality of cecal ligation puncture. In abdominal sepsis, TNF α levels correlate positively with nitric oxide end products in the serum. Treatment of septic patients with pentoxifylline (PTX) reduces TNF α synthesis and ICAM-1 expression and produces an improvement of the APACHE II score. IL-13 reduces CD14 expression and blocks TNF α secretion by monocytes. High-density lipoproteins (HDLs) reduce LPS-stimulated TNF α production, whereas low-density lipoproteins (LDLs) enhance the capacity of LPS to induce TNF α . Therefore the balance of HDLs and LDLs in the serum may be critical for TNF α production during sepsis.

HIV

In symptomatic and asymptomatic human immunodeficiency virus (HIV)-positive patients there are elevated TNF α levels in the circulation, which increase during progression of the acquired immune deficiency syndrome (AIDS). The levels of sTNFR also increase and there is a strong correlation between their values and death. TNF α increases HIV replication, but treatment with PTX showed a reduction of TNF α production without reduction of HIV titers. However, PTX inhibits TNF α production but not that of IL-6, and IL-6 correlates, as TNF α did, with progression of AIDS and inversely with the CD4 cell counts. Interestingly, not only sTNFR increases during HIV infection but also the expression of TNF receptor (CD120), with a predominance of CD120b. Thus, it is unclear whether TNF α has more negative effects in AIDS or if the biological role of TNF α against infectious organisms is more important.

Tropical diseases

Strain variants of *Plasmodium falciparum* differ in their capacity to induce TNF α . TNF α overexpression during *Plasmodium* infection results in cerebral malaria, which can be treated with drugs that inhibit TNF α production. Interestingly, IL-10 inhibits *Plasmodium*-induced TNF α production.

Mucocutaneous leishmaniasis (*Leishmania braziliensis*) is accompanied by high levels of circulating TNF α and is associated with the TNF haplotypes TNF2 and TNFB*2 as high-risk factors. TNF α serum levels in African trypanomiasis (*Trypanosoma brucei gambiense*) correlate with the disease severity. However, *in vivo* studies using mice showed that TNF α mediates *Trypanosoma cruzi* killing by

activation of nitric oxide. Therefore, in tropical diseases TNF α has the same dual role as in sepsis.

Transplantation

TNF α and interferon γ (IFN γ) are more sensitive parameters in mixed lymphocyte culture than proliferation and may be possible prospective parameters in bone marrow and organ transplantation. Graft-versus-host disease significantly correlates with enhanced TNF α , but not IL-1 and IL-6 serum levels in bone marrow recipients, even in transplantation of bone marrow from siblings. During acute graft rejection of organs, there is an increase in plasma levels of TNF α . In heart transplantation TNFd3 (associated with high production of TNF α) seems to be a risk factor, whereas the -308 polymorphism is of no relevance, because this promoter region is negatively regulated by cyclosporine. During kidney rejection there are increased TNF α levels resulting from an imbalance between TNF α and sTNFR, which is not observed during cyclosporine nephrotoxicity. In a rat model, anti-TNF α treatment extends allograft survival. This effect is enhanced by a combination of anti-TNF α and anti-IFN γ .

Cancer

It is unclear if the presence of TNF α in tumor tissue indicates immune response against the tumor or promotes tumor progression. TNF α has been ineffective in the treatment of most tumors. However, isolated perfusions with high-dose rTNF α in combination with conventional chemotherapy showed high levels of complete response of melanoma. This therapy showed only moderate TNF α -specific side-effects because the amounts of TNF α entering the circulation were minimal. In a murine model of liver cancer, TNF α treatment increases the number of metastases and therefore the mortality. This showed once more that TNF α may have both tumor-necrotic and tumor-promoting activity.

Endothelial cells and the airway

TNF α induces hyperresponsiveness in the airway. In the lung, TNF α is performed and directly released upon stimulation from mast cells and produced by alveolar macrophages. Interestingly, TNF α inhibits surfactant protein C gene transcription, which may be a critical factor in a number of infections and diseases with production of high levels of TNF α . In asthma, TNF α is upregulated and can be detected in the sputum of patients with acute attacks. Influenza A viral pneumonia is mediated by TNF α , and anti-

TNF α treatment of mice prolongs survival without reducing the virus titer.

TNF α induces cell–cell dissociation of endothelial cells and reduces intracellular cAMP and glutathione levels, resulting in increased permeability of the endothelial cell barrier. TNF α also alters the responsiveness of airway smooth muscle cells.

TUMORS, IMMUNE RESPONSE TO

Karl Erik Hellström and **Ingegerd Hellström**, Pacific Northwest Research Foundation, Seattle, Washington, USA

Around the turn of this century, Ehrlich postulated that cancer cells can be destroyed by immunological mechanisms, for example, by using antibodies as ‘magic bullets’. Cooley then started to treat cancer patients with bacterial toxins and obtained some clinical responses. Today this treatment would be attributed to the effects of ‘biological response modifiers’.

It was only when inbred strains of mice became available, however, that workers in this field could critically investigate whether tumors express antigens that serve as therapeutic targets. Using such mice, Gross, Foley, Prehn and others demonstrated in the 1940s and 1950s that tumors induced with chemical

carcinogens express antigens that can induce an immune response leading to the rejection of transplanted cells from the immunizing neoplasms. These antigens were referred to as tumor-specific transplantation antigens (TSTAs). Klein *et al* went one step further by showing that a chemically induced mouse tumor could be rejected also by the very animal in which it had originated, and that the antitumor immune response could be adoptively transferred with lymphocytes. There was little or no cross-reactivity between different neoplasms, even when they had the same morphology and had been induced with the same chemical agent. It is not surprising, therefore, that attempts to use

tumor cells to immunize against chemical carcinogenesis failed.

Another key discovery in tumor immunology was made in 1961 when Sjögren and Habel, working independently, reported that murine neoplasms induced with polyoma virus express TSTAs. Subsequently, TSTAs were detected among murine tumors induced by several other viruses and were found to be shared by tumors induced by the same virus and different among tumors induced by different viruses. Spontaneous tumors, in contrast, did not reveal any TSTA when tested by preimmunization with tumor cells that had been rendered incapable of dividing followed by challenge with live tumor cells. For example, Hewitt investigated 26 different spontaneous mouse tumors and failed to detect any tumor immunity at all; the spontaneous tumors were thus nonimmunogenic (under the conditions tested). Furthermore, the TSTAs in chemically induced rodent tumors were primarily seen in those neoplasms which had been induced by large doses of the carcinogens, while neoplasms induced by small doses either lacked detectable TSTAs or grew even better in immunized hosts than in untreated animals. This was discouraging, since most human tumors are 'spontaneous', and those which are caused by chemical agents probably result from exposure to low doses of such agents. It is also uncertain to what extent there are human neoplasms induced by viruses similar to those causing the expression of strong TSTAs in rodents.

Fortunately, there is now evidence that an immune response can be detected and/or induced against a large variety of tumors, including human tumors, and that the early failures to detect such a response was not due to a lack of tumor antigen, but rather related to the ways tumor immunity was induced. This raises the hope that immunological mechanisms can be utilized towards developing clinically beneficial immunotherapy in humans.

Antigens which can act as targets for tumor destruction can be detected in many different tumors

Immunologically based tumor rejection can, indeed, be detected against many mouse neoplasms previously believed to be nonimmunogenic. In order to achieve this it is necessary to employ techniques to either change the immunizing tumor antigens themselves or the mode by which they are presented. For example, after *in vitro* mutagenization of cells from some originally nonimmunogenic tumors, they could be used as immunogens to induce the rejection of cells from the respective nonimmunogenic 'wild-

type' tumors. Infection of tumor cells with certain viruses, such as vaccinia, sometimes accomplishes the same result. Another approach involves the transfection of tumor cells with genes encoding certain lymphokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), or of genes which encode molecules that can increase the level of immunological costimulation via 'second signals'. For example, transfection of a gene encoding a costimulatory molecule of the B7 family (B7-1 or B7-2) together with a gene encoding mouse CD48 (the ligand for CD2, which in humans is CD58) made both of two classically nonimmunogenic tumors rejectable by their host and usable as 'vaccines' against wild-type cells from the respective tumors.

Nature of the immune response to tumor antigens

Immunity to the TSTAs of murine tumors has been shown to be primarily mediated by T lymphocytes. Tumor immune T cells adoptively transferred from immune donors can localize in a tumor antigen-specific manner and they retain 'immunological memory' for a very long time (possibly for life).

Both CD8⁺ cytolytic T cells (CTLs) and CD4⁺ T helper (T_H) cells are important in this context. Their relative roles appear to vary between different systems, although CD8⁺ cells are involved almost always and their activity amplified as the result of lymphokines produced by T helper 1 (T_H1) cells. The CTLs can kill tumor cells with high efficacy and antigen specificity. However, as a result of the specificity, any existing antigen-negative tumor cell may escape from killing. Since the target epitope for CTLs needs to be presented at the cell surface together with class I molecules of the major histocompatibility complex (MHC), lack of such molecules will make a cell resistant to killing by CTLs, as will lack of molecules needed for antigen processing and transport within the cell.

T helper cells make lymphokines (such as interferon γ and interleukin 2 (IL-2) made by T_H1 cells). Some of these can activate macrophages and natural killer (NK) cells, in addition to T cells, so as to cause cytotoxic and/or inhibitory effects, others (such as tumor necrosis factor, TNF) can have a direct effect on tumor cells. Neoplastic cells appear to be more sensitive than normal cells towards exposure to activated macrophages and NK cells, and this can lead to their destruction as 'bystanders' also when they are antigen-negative. While T_H1 lymphocytes contribute to tumor destruction, T_H2 cells may act as 'suppressors' of an effective tumor immunity.

While the role of antibodies in tumor rejection may be less than that of immune cells, this role should not be ignored. In particular, antibodies which are directed against certain growth factors or growth factor receptors, such as receptors for epidermal growth factor or heregulin, can have inhibitory activity against certain tumors and they may potentiate the effects of anticancer drugs. Antibodies can also have antitumor effects by mediating antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). In addition, antibodies can be used for the selective delivery to tumor cells ('targeting') of various anticancer agents. Monoclonal antibodies (mAbs) of mouse or human origin have been used for this purpose in many animal models, and promising clinical data are starting to emerge, particularly in B cell lymphomas.

Nature of the tumor antigens

The TSTAs of tumors induced by either the polyoma or the SV40 viruses were the ones first characterized at the molecular level. Both are encoded by genes of the respective viruses, localized to the nucleus and intimately associated with the initiation and maintenance of the neoplastic transformation. An analogous antigen in human neoplasms would provide an optimal target for immunotherapy since its loss is not compatible with a maintained neoplastic phenotype. It is of great interest, therefore, that most cervical carcinomas are associated with human papillomavirus (HPV) 16, and that the E6 and/or E7 genes of HPV-16 encode tumor antigens which can induce a CTL response detected *in vitro* as well as a CD8⁺ immune response leading to tumor rejection in animal models. Peptide targets of the CTLs have been identified both in animal models and, more recently, in human cervical carcinomas. Clinical trials with tumor vaccines have been started based on the latter findings.

Most neoplasms also express a variety of tumor-associated differentiation antigens (TADAs) together with their individually unique or shared TSTAs. Several of the TADAs have been studied in detail, primarily by using mAbs as tools for their isolation. Antibodies, T helper cells and CTL responses to TADAs have been demonstrated. In most cases, the cancer specificity is relative with some TADA expression also in normal cells from the adult host and often a high expression in some fetal tissues.

Immune responses to human neoplasms

The first evidence for immune responses to human cancers was published in the late 1960s. However,

this area remained controversial until technical advances made it possible to characterize the antigenic targets of the immune responses observed. Antigens recognized by patients' antibodies were identified first. While antibodies have been detected to a few antigens which were individually unique for each patient's tumor, most antibodies have defined antigens that are shared by many tumors, generally irrespective of their histological type.

Cell-mediated immune reactions are demonstrated in assays of either CTL activity or T helper cell responses, with most work nowadays concentrating on antigens recognized by CTLs. Since tumor cell killing by CTL is restricted by the ability of a given patient's MHC class I molecules to present target peptides, an antigen targeted by CTLs will appear as unique to each neoplasm, even if it is shared by many tumors, unless the tumor cells and the CTLs are matched for MHC class I. As a result of recent work taking this into account, as well as earlier studies studying the outcome of T helper cell activity, it has been established that the immune response to human neoplasms is primarily directed towards TADAs that are shared by many tumors. The MAGE group of tumor antigens discovered by Boon's group represents an interesting example. While MAGE antigens were first found in melanoma, they are shared by several other tumors as well. Their degree of tumor selectivity varies between different MAGE antigens but can be very high. Major efforts are presently given to identifying additional families of tumor peptides which can be recognized by human CTLs for use as therapeutic targets.

Much work is presently carried out attempting to devise strategies towards inducing a strong and clinically useful immune response, by developing various therapeutic tumor immunogens ('vaccines'). The logical first step in this direction is to define which tumor antigens are normally recognized by the human immune system or can be made to be so recognized. Progress has been made by working with antibodies in patient sera as well as with mAbs made by human hybridomas. For example, several gangliosides that are expressed on human melanomas are immunogenic in humans, and promising, albeit preliminary, clinical results have been obtained using either mAbs to such antigens or 'vaccines' consisting of antigen plus adjuvant.

Tumor vaccines in the form of recombinant viruses, tumor peptides combined with a suitable adjuvant, and anti-idiotypic antibodies are all of interest as other potential immunogens, as are tumor cells that have been modified so as to become more immunogenic, e.g. by transfection of genes encoding GM-CSF, B7-1 or some other lymphokine or

costimulatory molecule. However, 'vaccines' based on whole cells are less likely to become therapeutic products for various logistical reasons. Targeting of various immunomodulators such as lymphokines and anti-T cell antibodies is also of interest, using bispecific mAbs or tumor-reactive fusion proteins, with the goal to expand an ongoing antitumor immune response. Adoptive transfer of *in vitro* expanded, specifically immune lymphocytes provides a different approach. It may be applicable even in the face of a relatively large tumor load, while vaccines and targeted agents may be best confined for prolonging survival in patients with micrometastases.

Conclusions

Many experimentally induced rodent tumors express TSTAs which can induce an immune response that is capable of destroying neoplastic cells *in vivo*. Today there are also ways to induce a tumoricidal immune response against some tumors that are non-immunogenic when studied by the classical assays for TSTAs. T Lymphocytes play a key role in mediating the immunological destruction of most antigenic tumors. Antibody-mediated and cell-mediated immune reactions to human tumors have been identified and their targets characterized towards development of clinically beneficial immunotherapy.

TUMORS, IMMUNOLOGICAL ESCAPE OF

Karl Erik Hellström and Ingegerd Hellström, Pacific Northwest Research Foundation, 720 Broadway, Seattle, WA, USA

Many experimentally induced rodent tumors express tumor-specific transplantation antigens (TSTAs). These are detectable by the rejection of tumor cells transplanted to immunized syngeneic hosts. Many spontaneous mouse tumors express antigens that

can, under certain circumstances, be recognized by the immune system. Human tumors can also induce an immune response which can be detected by assays for serum antibodies, T helper cell activity and/or the generation of cytotoxic T lymphocytes (CTLs), with

most of the targets being tumor-associated differentiation antigens.

Even those tumors that have strong TSTAs appear in immunocompetent hosts in which they grow progressively. A question that needs to be answered is, therefore, why are they not immediately eliminated by immunological mechanisms? Furthermore, immunological mechanisms which can kill tumor cells *in vitro* and reject transplants of small numbers of tumor cells *in vivo* commonly fail to destroy neoplasms which are more than a few millimeters in diameter. Even the transplantation immunity that can be induced against TSTA-positive tumors can be overcome by challenge with a 100- to 10 000-fold larger number of tumor cells than that needed for outgrowth in nonimmune animals. The next question is, therefore, what mechanisms make this possible? We shall discuss several such 'escape' mechanisms here.

Loss of TSTAs and/or their presentation

A simple explanation for the ability of an originally antigenic neoplasm to grow in an immune animal is that it has lost its TSTAs as a result of selection by the immune system. Since tumor rejection is most commonly mediated by CD8⁺ T cells with CTL activity, loss of major histocompatibility complex (MHC) class I molecules, and/or molecules involved in antigen processing and transport will produce the same result, i.e. lack of epitopes for CTLs to recognize.

There is, indeed, evidence that neoplastic cells can lose TSTAs and/or MHC class I antigens. However, the frequency of total loss of such antigens may be lower than that suggested by immunohistology. Furthermore, both TSTAs and MHC class I molecules are commonly expressed by tumor cells growing in immune animals, implying that a failed presentation of TSTA does not provide a general explanation as to why tumor immunity is not more effective. However, it is clearly one of the mechanisms that can lead to the selection of tumors that are not sensitive to immune destruction by CD8⁺ T cells.

Some tumor antigens, such as the TSTAs of polyomavirus-induced neoplasms, cannot be lost without loss of the neoplastic phenotype, since the molecule detected as a tumor antigen is involved in the neoplastic transformation. On the other hand, some tumor-associated differentiation antigens can be eliminated without loss of malignancy. It is noteworthy that polyomavirus-induced mouse tumors did retain their sensitivity to an immune response directed to the polyoma TSTA even after attempts to select for TSTA-negative cells by prolonged tumor

passage in immune animals, since this indicates that their ability to present the polyoma TSTAs via MHC class I molecules remained intact.

Substantially higher cell surface expression of MHC class I molecules is needed for a tumor cell to induce an immune response than to serve as its target, and there is evidence that tumor cells may still be killed by CD8⁺ lymphocytes even when their MHC class I expression is too low to be detectable by immunohistology. Furthermore, the expression of MHC class I molecules can be upregulated, e.g. following exposure to interferon γ . This suggests that immune T cells may be effective in a larger number of cases than might be indicated by the frequent downregulation of MHC during tumor progression. One should also bear in mind that tumor cells which have lost MHC class I molecules are likely to become more sensitive to destruction by natural killer (NK) cells.

Antigenic modulation

Some neoplastic cells can undergo antigenic modulation, i.e. they cease to express the particular tumor antigen as the result of exposure to specific antibodies. This event has been well demonstrated for certain antigens on leukemia cells, e.g. the TL antigen of mouse lymphomas. However, it appears to be less frequent for most TSTAs expressed on carcinomas or sarcomas.

Lack of costimulation

For an immune response to be induced, it is not sufficient that an antigen is presented to the T cell receptor via MHC class I or class II molecules. A second, costimulatory, signal is also required. Interaction between molecules of the B7 family (B7-1 or B7-2) on the antigen-presenting cells (APCs) and the CD28 counter-receptor on T lymphocytes provides probably the most important costimulatory signal. Antigen presentation in the absence of this signal does not induce an effective immune response but results in 'immunological ignorance', and can even lead to anergy. It is noteworthy, therefore, that most tumors fail to express B7-1 or B7-2 (the exception being some B cell lymphomas), i.e. they present their tumor epitopes in a way unable to cause a tumor destructive response. For an effective immune response to occur, tumor antigen needs to reach lymphoid tissues and be presented in the context of MHC class I or II molecules expressed on B7-positive APCs.

Transfection of B7-1 or B7-2 into tumor cells increases their immunogenicity and prevents outgrowth in immunocompetent syngeneic recipients.

Furthermore, tumors so transfected can be used as 'vaccines' to induce the rejection of wild-type cells from the respective neoplasms as well as the generation of tumor-specific CD8⁺ CTLs with high *in vitro* and *in vivo* potency. While transfection of genes encoding B7-1 and/or B7-2 vastly increases immunogenicity, it has failed to cause rejection of nonimmunogenic tumors, i.e. tumors which lack TSTAs according to conventional immunization challenge tests. However, when the B7-1 (or B7-2) gene was combined with a gene encoding a second costimulatory ligand, CD48, both of two classically nonimmunogenic mouse tumors became rejectable by the immune system, and the doubly transfected cells could be used as 'vaccines' to induce the destruction of wild-type cells from the respective tumors.

'Sneaking through'

This term implies that the immune response to a tumor appears too late to be effective, so that the tumor outgrows the ability of the immune system to keep up with it. Lack of costimulation may provide a simple explanation for this, since an immune response against wild-type, i.e. B7-negative, tumors will not be initiated until tumor cells, or released tumor antigen, have reached lymph nodes for antigen presentation in the presence of APCs providing the proper second signal.

'Blocking factors' and 'suppressor' cells

Circulating 'blocking factors' in the form of antigen-antibody complexes and free antigens were discovered in the late 1960s by their ability to inhibit ('block') the destruction of tumor cells by immune lymphocytes. This was demonstrated by using an assay which lasted 3-7 days and, therefore, included both lymphocyte activation and tumor cell killing. The presence of 'blocking factors' correlated with tumor growth in animal models.

The immune response to a growing tumor is less effective at the tumor site than systemically, and animals bearing immunogenic tumors are often able to reject a small number of cells transplanted from the same neoplasm; they display 'concomitant tumor immunity'. This suggests that the local concentration of 'blocking factors' is particularly high, and experimental data support this.

While part of the 'blocking' effect may be via competition for antibody molecules or effector cells, tumor antigen primarily inhibits the induction and/or manifestation of a tumoricidal host response in a more indirect way. It was originally suggested that

tumor antigen (and/or immune complex) can activate 'suppressor' T cells which downregulate the formation of a tumoricidal immune response. Using today's terminology, the phenomenon is explained on the basis of immune deviation, favoring a T helper 2 cell (T_H2) response over one mediated by T_H1 cells; a T_H2 response would disfavor CTL activity as a result of lack of interferon γ and IL-2. One may speculate that the immune deviation results from antigen presentation by B7-negative APCs which take up circulating tumor antigen-antibody complexes and present tumor epitopes in a way which induces anergy.

Suppression can be specific towards the antigens of a given tumor, but it can also occur against unrelated antigens once it has been induced. Treatment of tumor-bearing animals with certain immunosuppressive agents (e.g. cyclophosphamide) or by exposure to low doses of ionizing radiation, can inhibit tumor growth unless the treated animals are injected with lymphocytes with 'suppressor' activity.

Suppression by TGF β , p15E and other 'factors' made by the tumor

Destruction of immunogenic tumors by their hosts can also be thwarted by other molecules produced by the tumor and/or the host. The effect of such molecules is likely to contribute to the downregulated antitumor response at the tumor site, and it may explain why certain molecules involved in T cell signaling are underexpressed in T lymphocytes from tumor bearers. For example, many tumors produce transforming growth factor β (TGF β), which can effectively inhibit T cell-mediated responses, including those mediated by CTLs. Another factor is p15E, which is a peptide related to murine leukemia virus but expressed also on certain human tumors. Exposure of macrophages to p15E can abolish their ability to cause tumor destruction, and antibodies to p15E can facilitate tumor rejection under certain conditions. Sialomucin produced by neoplastic cells can provide yet another type of protection acting as a barrier against immunological destruction, and removal of the sialomucin by treatment with neuraminidase has increased both the immunogenicity and the immunosensitivity of some tumors in experimental animals.

Conclusions

Even those tumors that are immunogenic appear, and continue to grow, in immunocompetent syngeneic hosts, and the *in vivo* effectiveness of an anti-tumor immune response is rather modest. Escape

mechanisms must, therefore, exist which result in tumors evading the destruction of a tumoricidal response and/or make them incapable of inducing such a response. Failure of tumor antigen presentation by MHC class I molecules, lack of costimulation and downregulation of tumor-destructive immune responses by tumor antigens, immune complexes, as well as by molecules such as TGF β and p15E may all contribute to the inefficiency of tumor immunity.

U

ULTRACENTRIFUGATION

Eyvind Rødahl, Department of Ophthalmology, Haukeland Hospital, University of Bergen, Bergen, Norway

Construction of ultracentrifuges and development of the theoretical basis for ultracentrifugation was pioneered by The Svedberg and his collaborators in Uppsala, Sweden during the 1920s. At this time, ultracentrifugation was used only for analytical work. The principal methods were sedimentation

velocity and sedimentation equilibrium analysis. In sedimentation velocity experiments, the rate at which a particle sediments in solution is measured. This is expressed as the sedimentation coefficient of the particle. In sedimentation equilibrium studies, a particle suspension is centrifuged until equilibrium is reached

(i.e. when the process of sedimentation is balanced by that of diffusion). The distribution of the particles in the solvent can then be used to calculate their molecular weight. When measurements of the sedimentation coefficient and the molecular weight of a particle are combined with hydrodynamic theories for frictional resistance of particles as they migrate through aqueous solutions, the shape of a particle can be estimated. Major achievements within the field of protein chemistry were derived from analytical ultracentrifugation experiments, including the recognition of the discrete macromolecular nature of proteins, the association of proteins to form oligomers, and the conformational changes that accompany many enzyme-substrate interactions.

The earliest preparative rotors appeared around 1940, nearly two decades after Svedberg had built his first analytical ultracentrifuge. Two major advances contributed to the development of preparative ultracentrifugation: 1) the observation of the complex internal structure of cells made possible by electron microscopy generated a demand for techniques to isolate subcellular particles for biochemical investigations; and 2) the development of alloys with a high strength in relation to their density permitted construction of rotors withstanding the high *g*-forces generated during centrifugation. The earliest preparative studies were performed using fixed-angle rotors and the technique of differential pelleting. Density gradient centrifugation was introduced in 1951 when Brakke described the use of sucrose gradients.

Density gradient centrifugation can be performed either as rate zonal or as isopyknic centrifugation. In rate zonal centrifugation, the particles sediment as a narrow zone through a preformed gradient. This technique is used analytically for sedimentation rate measurements, and preparatively for separation of particles with different sedimentation coefficients. In isopyknic centrifugation, particles are separated purely on the basis of their density. Isopyknic centrifugation can be carried out both in preformed and in self-forming gradients. In self-forming gradients, the sample is mixed with the gradient medium, centrifuged, and as the solute molecules sediment to form the gradient, the sample molecules band at their isopyknic points. When preformed gradients are used, the size of the particles will affect the rate at which they reach their isopyknic positions.

A variety of gradient media have been used for centrifugal separations. For rate zonal centrifugation, the main function of the gradient medium is to stabilize the liquid column in the tube against convection currents. For most applications, sucrose is a satisfactory gradient medium. Glycerol has been used

among others for protein separations when preservation of enzymatic activity is important. For isopyknic separations, the maximum density of the gradient must be greater than that of the particle to be isolated. No single medium has proved satisfactory for all types of biological particles. High-density solutions of alkali metal salts (e.g. CsCl, CsSO₄, CsTFA, NaI, RbCl) are used for separation of proteins, nucleic acids and some viruses. For isopyknic separation of organelles and viruses, sucrose is the most widely used gradient medium, but colloidal silica suspensions (e.g. Percoll), polysaccharides (e.g. Ficoll) and iodinated compounds (e.g. Nycodenz) are in many cases superior, mainly because the osmotic pressure is lower in such gradients. The iodinated gradient media are, in addition, particularly well suited for fractionation of nuclei and native nucleoprotein structures.

Commercial production of ultracentrifuges started in 1948. The first instruments available were analytical centrifuges. Preparative centrifuges were released around 1960, and soon led to a widespread use of ultracentrifugation techniques. Different rotors were developed, including swing-out rotors, large capacity zonal rotors, and special rotor systems for continuous flow centrifugation. Ultracentrifugation has remained an essential method for purification of macromolecules, macromolecular complexes and subcellular particles such as organelles and viruses.

Analytical ultracentrifugation has partly been replaced by procedures such as gel electrophoresis or gel filtration for molecular weight determinations, but it is still an important tool, especially for studies of the interactions between macromolecules.

Application in immunology

Within the field of immunology, ultracentrifugation has been used extensively for studies of immune complexes and immune complex formation. Sedimentation velocity studies in analytical centrifuges, and rate zonal centrifugation in preparative swing-out or zonal rotors have revealed size distributions of immune complexes formed *in vivo* and *in vitro*, and have allowed measurements of association constants of complexes formed at various antigen:antibody ratios. Density gradient centrifugation has been used both for detection and for preparative isolation of immune complexes from biological fluids.

Centrifugation studies of immune complex formation *in vitro* have revealed that the outcome of antigen-antibody interactions is a mixture of compositionally different complexes, and not a single reactant as is otherwise typical of macromolecular reactions. The smallest complexes are formed in the

greatest amounts, and at a given antigen:antibody ratio, immune complex formation seems to be self-limiting with respect to the maximal size of the complexes. Association constants for immune complexes have been shown to depend on 1) antigen valence, 2) antibody affinity and 3) the concentration of antibody combined with 4) the degree of antibody excess. The association constants observed in antibody excess are higher than those recorded in antigen excess for the same set of antigen and antibody. These observations demonstrate that the interactions between antigens and antibodies are a unique set of biological reactions that are different from ordinary ligand binding reactions.

Rate zonal centrifugation in sucrose gradients has for many years been the 'gold standard' among procedures devised for the detection of immune complexes in biological fluids. After centrifugation, immune complexes are quantitated as immunoglobulins with increased sedimentation rates. The procedure is inconvenient for screening large numbers of samples, but has been used to confirm the presence of immune complexes in patients with a wide range of neoplastic and chronic inflammatory disorders.

Animal studies have shown that several physicochemical properties of immune complexes are important for the development of disease. When complexes are formed with positively charged antigen or antibody, or with antibodies of low affinity or avidity, there is increased risk for the development of glomerulonephritis. In addition, the size of the complex is important, but the critical size, as measured by rate zonal centrifugation, may vary between individual antigen-antibody complexes.

For analysis of the components present in immune complexes, preparative studies have been accomplished using rate zonal centrifugation in sucrose or in combined sucrose-polyethylene glycol gradients. DNA-antibody complexes were isolated by the former procedure from the serum of patients with systemic lupus erythematosus. The sedimentation coefficients of immune complexes varies, however, and rate zonal centrifugation is therefore not an ideal method for preparative work because the complexes will be distributed over several gradient fractions. In contrast, after isopyknic centrifugation, immune complexes can be recovered as sharp bands in the gradients. Analysis of immune complexes isolated by isopyknic centrifugation in sucrose gradients has indicated that antigens related to those present in a retrovirus-like particle may participate in immune

complex formation in patients with psoriasis and seronegative arthritis.

Recent developments within the field of ultracentrifugation include air-cooled, benchtop centrifuges and a novel analytical centrifuge. The benchtop centrifuges are ideal for rapid, preparative work in small volumes and have also been used for analytical studies. Compared to the previous generation of analytical ultracentrifuges, the new centrifuge permits analytical centrifugation to be carried out with considerably increased sensitivity. Although ultracentrifugation has to some extent been replaced by other techniques, it still has great potential, both in analytical and preparative work, and remains an invaluable tool for the immunologist.

UNGULATE IMMUNE SYSTEMS

Alan J Husband, Department of Veterinary Anatomy and Pathology,
University of Sydney, Sydney, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The immune system of ungulates, a group of species including sheep, goats, deer and cattle, has been widely studied. This is not only because of their importance as food animals but also because they are available in large numbers and are a convenient alternative to laboratory animal species for the study of immune function, especially where large sample size and access to anatomical compartments are required.

Structural and cellular components of immunity

Structural elements of the immune system in ungulates is similar to that in most other mammalian species, with the thymus and bone marrow functioning as primary lymphoid tissue for generation of T and B cells, respectively. However, a feature which appears to be unique to ruminant ungulates is the high contribution to primary B cell development made by the ileal Peyer's patch, which in this species occurs as a single patch of up to 1 m in length located in the terminal ileum. Whereas B cells originate from both bone marrow and ileal Peyer's patch, T cells, as in other species, emanate from the thymus, especially in late gestation and early postnatal life. As in other species, B cells committed to immunoglobulin G (IgG) production reside predominantly in systemic compartments such as spleen and lymph nodes, but those committed to IgA preferentially localize at submucosal compartments but have the ability to traffic between mucosal sites. This ensures that the antigenic experience at one mucosal site can be reflected in IgA antibody production at a remote site, the principle often referred to as common mucosal immunity.

The T cell profile of ruminants is unusual in that a higher proportion of γ/δ TCR⁺ cells occurs than in other species. Whereas about 2–3% of peripheral blood lymphocytes in rodents and humans are γ/δ TCR⁺, in ruminants around 60% carry the γ/δ T cell receptor. Also in contrast to other species where γ/δ TCR⁺ cells have a restricted V region repertoire, in ruminants they have a diverse array of antigen specificities and are of much greater functional significance than in other species, although they display the same anatomical localization preference for skin and mucosal tissues.

Ungulate immunoglobulins

Ungulate immunoglobulins have been identified and classified according to their analogy with immunoglobulins in other species on the basis of similarities in amino acid sequence, immunological cross-reaction, physicochemical properties and biological function. In sheep and cattle, the most widely studied of the ruminant species, analogs of IgG, IgM, IgA and IgE have been identified, with structure and function characteristics as defined in Table 1. In contrast to other species there are only two subclasses of IgG, designated IgG1 and IgG2, and, also in contrast to other species, IgA in serum exists predominantly as a dimer, originating from IgA plasma cells at mucosal surfaces rather than from bone marrow.

For many years controversy persisted over the nature of the reaginic or homocytotropic antibody (i.e. the analog of IgE) in ruminants, with some evidence supporting the existence of a minor IgG subclass accounting for these effects. However, more recent work has clearly revealed the existence of a true IgE isotype which can be identified by mono-

Table 1 Structure and function of ungulate immunoglobulins

Immunoglobulin isotype	Molecular weight kDa	Structure	Complement fixation	Serum half-life (days)	Sedimentation coefficient
IgG1	150	 Monomeric	+	9.5	6.5–7.0
IgG2	150	 Monomeric	+/-	10–15	6.5–7.0
IgM	900	 Pentameric with J chain	+	6	19
IgA (serum)	350	 Dimeric	–	3	10
IgA (secretory)	400	 Dimeric with J chain	–		11
IgE	150	 Monomeric	–	?	7.0

clonal antibodies specific for the IgE heavy chain determinant.

Secretory or mucosal surfaces in ruminants, as in other species, are characterized by the predominance of IgA antibodies. These antibodies are synthesized by plasma cells underlying the mucosal epithelia and are secreted in dimeric form with subunit elements held together by a joining chain (J chain). These are transported into external secretions by association with the polymeric immunoglobulin receptor (pIgR or secretory component) expressed on the basal membrane of the epithelial cells. The molecule is secreted as a dimer complexed to a component of the extracellular domain of the pIgR. Dimeric IgA which escapes secretion is returned via draining lymphatics to the blood circulation, from which it may be re-secreted at remote mucosal surfaces, representing an additional dimension of the common mucosal immune system. The extent to which plasma-derived IgA contributes to the total IgA content of external secretions is inversely proportional to the amount of local production, a result of competition between locally-produced and serum-derived IgA molecules for the pIgR molecules on the epithelial cell basal membrane.

The mammary gland in ruminants produces milk with a vastly different immunoglobulin profile to that in most other species. As a consequence of the lack of immunoglobulin transport across the placenta in ruminants (see section on acquisition of passively transferred antibodies), colostrum contains extremely high levels of IgG1 and very little IgA. At this time most of the IgA in milk is plasma derived. As lactation progresses, and particularly during involution, the selective transport of IgG1 into milk declines and there is an increased number of IgA plasma cells contributing to local IgA production, with relatively less serum-derived IgA.

The existence of a biliary pump to remove IgA from serum for delivery via bile to the gut lumen, a feature which is well developed in rodents, has been identified in ruminants, but only small amounts of serum IgA are processed by this route.

Ontogeny of immune function in ungulates

The first lymphoid organ to appear in the developing fetus is the thymus, which is the main component of mammalian primary lymphoid apparatus. In the fetal lamb, it initially consists of epithelial cells arising from pharyngeal pouches and is first observed macroscopically after about 35 days of gestation, at which time small lymphocytes begin to appear in the thymic tissue in the lamb, but this does not occur

until around 60 days of gestation in the calf. Distinct differentiation into cortex and medulla appear by about 50 days in the fetal lamb and the organ reaches its maximum size relative to body weight just before term. In fetal lambs, lymph nodes begin to appear at about 50–60 days of gestation and the spleen is first visible after 55–60 days but organizational structure does not occur until around 75 days. Mucosal lymphoid structures such as Peyer's patches do not appear until around 80–90 days of gestation and lymphocytes are not present in the lamina propria of the gut until around 120 days.

All the immunologic tissues are well developed before birth but differentiation of the peripheral organs does not proceed to any extent until the animal experiences the antigenic stimulation normally associated with extrauterine life. This results in the appearance of follicles and germinal centers, especially in the gut-associated lymphoid tissue, and mitotic figures and plasma cells are seen in the medullary tissues of lymphoid organs at this time.

Acquisition of passively transferred immunity

In all higher vertebrates mechanisms have evolved to ensure that passive immune protection is provided to the neonate to assist in control of microbial challenge after birth until the endogenous immune mechanisms of the newborn animal have achieved sufficient functional maturity. The extent to which this occurs before or after birth differs vastly between species, an adaptation which is related to the type of placentation (Table 2). Ungulates obtain no immunoglobulin prenatally from the maternal circulation and are born agammaglobulinemic, but large quantities of maternal IgG are selectively transported into the mammary gland just prior to parturition and are ingested and absorbed intact into the circulation by the suckling neonate. The intestine in newborn ruminants is consequently adapted for large-scale uptake of intact immunoglobulin across the gut into the neonatal circulation in the first 24–28 hours of life, during which time the large, pale staining vacuolated cells of the intestinal epithelium of the newborn ruminant are replaced by cells characteristic of the adult intestine to achieve gut closure.

In humans, where IgG is transported placentally, there are very low levels of IgG in colostrum but relatively higher levels of IgA, whereas in ruminants the reverse applies, with high levels of IgG1 in colostrum and relatively low levels of IgA, but a higher ratio of IgA:IgG occurs in later lactation and in involution secretion.

Soluble factors other than immunoglobulins in

Table 2 Placentation type and mode of passive antibody transfer from mother to young in various species

Species	Placentation	Transmission of passive immunity				
		Prenatal		Postnatal

Adapted from Brambell (1958).

milk are also important effectors of passive immune protection, and part of the protective capacity of milk is attributable to the nonimmunoglobulin fraction. Antibacterial substances such as lactic acid, interferon, lysozyme, lactoferrin and the complement components C3 and C4 have been demonstrated in both human and ruminant milk and have been shown to affect the establishment of pathogenic bacteria, either through inherent bactericidal activity or in conjunction with specific immune responses.

While antibodies in colostrum are the predominant immune effectors transferred to the ruminant neonate, cells and other soluble factors in milk play an important role in terms of passive protection. There are normally large numbers of viable cells in bovine milk, varying from 5×10^4 to 2×10^6 cells ml^{-1} , although substantially higher numbers may occur if the gland becomes infected or inflamed. After milk ingestion by the suckling ruminant neonate some of these cells are taken up intact across the duodenal mucosa and are transported via lacteal lymph and mesenteric lymph nodes, indicating the potential for cells of maternal origin to have functional relevance in passive protection of the neonate.

The efficacy of passive transfer of antibody via colostrum in ruminants in protecting the neonate from specific diseases has been well documented. Calves which do not receive colostrum usually succumb to disease at an early age, or if they do survive have restricted growth. Deliberate passive immunization against selected diseases has been highly effective and calves fed colostrum antibodies from immunized cows have been demonstrated to be resistant to specific challenge with a range of selected pathogens.

Despite the beneficial effect of maternal antibody transfer, it is well documented that maternal anti-

body acquired postnatally via colostrum has a suppressive effect on the development of endogenous mucosal immune responses in the young animal and the endogenous production of serum IgA occurs earlier in calves deprived of colostrum.

URINARY TRACT INFECTIONS

Catharina Svanborg, Department of Medical Microbiology, Lund University, Lund, Sweden

The term urinary tract infection (UTI) describes clinical conditions caused by the presence of microorganisms (usually bacteria but occasionally fungi or, more rarely, viruses or schistosomes) in the urinary tract. The severity of infection depends on the virulence of the infecting strain and responsiveness of the infected host. Urinary tract infections may therefore be seen as a spectrum of host responses to microorganisms of different virulence. The diagnostic categories used in clinical practice correspond to different parts of this spectrum: acute pyelonephritis is a febrile infection involving the kidney with signs of local and systemic inflammation as well as renal involvement. Acute cystitis is characterized by lower urinary tract symptoms with pain, frequency of micturition, and local inflammation but typically these patients lack signs of systemic infection. Screening of covert bacteriuria is used to describe patients in whom bacteriuria gives rise to few symptoms and is therefore only detected at screening.

UTIs are among the most common bacterial infections. The most reliable frequency estimates, based on extensive screening of different age groups, show that about 1% of schoolgirls, 2–11% of pregnant women and $\geq 10\%$ of elderly women carry $\geq 10^5$ bacteria ml^{-1} of urine. Men mostly acquire bacteriuria during the first year and the last decades of life. The cumulative frequency before 11 years of age of symptomatic infections is about 3.5% in girls and 1% in boys. While acute cystitis is common in women of all ages, the frequency estimates of acute pyelonephritis in adults vary extensively depending on underlying disease conditions.

Bacteria

Escherichia coli, *Proteus*, *Klebsiella*, *Enterobacter* and *Staphylococcus saprophyticus* are the most common etiologic agents in UTI. *E. coli* dominate in both outpatient and hospitalized populations and are the most extensively characterized regarding mechanisms of virulence.

The population structure of *E. coli* is clonal, i.e. genetic elements occur in nonrandom, relatively stable combinations. Uropathogenic *E. coli* are a selected subset of the *E. coli* flora at large. The pyelonephritogenic clones are identified by a limited number of surface antigen serotypes (O:K:H:F = lipopolysaccharide (LPS), capsular polysaccharide, flagellar and fimbrial antigens) and intracellular iso-

enzyme patterns (electrophoretic types), and by the expression of molecules which damage the host tissues. Adherence is mediated by bacterial surface lectins, which may be associated with fimbriae. The lectins bind the bacteria to host receptor molecules consisting of oligosaccharide sequences in glycoproteins or glycolipids. The P fimbrial lectins recognize the Gal α 1–4Gal β and GalNAc epitopes within the globoseries of glycolipid receptors. S Fimbrial lectins recognize sialic acid residues, and type 1 fimbriae bind mannose residues found, for example, on the Tamm Horsfall protein and secretory immunoglobulin A (IgA), and connective tissue proteins such as collagen and laminin.

LPS is the endotoxin of *E. coli*, which contains the lipid A moiety responsible for eliciting a wide array of inflammatory host responses. Hemolysin participates in the destruction of host cells through its lytic activity. The capsular polysaccharides protect bacteria against attack by complement and neutrophils, and aerobactin facilitates the trapping of free iron required for the bacterial oxidative metabolism, especially in environments with limited oxygen supply. These characteristics are all designated as virulence factors, since they occur more frequently in acute pyelonephritis than in screening bacteriuria strains.

Pathogenesis

Uropathogenic *E. coli* first become established at a site outside the urinary tract (the large intestine, the introital or preputial areas). Colonization at these sites is influenced by adherence through P and type 1 fimbriae and by the receptor repertoire of the host. The uropathogenic clones enter the urinary tract and establish bacteriuria via the ascending route. The bacterial properties that determine this initial establishment are still poorly understood. The bacteria resist elimination with the urine flow at voiding and the killing by bacteriocins in the mucosa.

Acute pyelonephritis is caused by bacteria that reach the kidney and trigger local and systemic inflammation. The bacteria activate cells at the site of infection to secrete cytokines and other proinflammatory mediators. The molecular mechanisms through which uropathogenic bacteria elicit cytokine responses have been studied *in vitro*. Attachment to uroepithelial cell receptors activates transmembrane signaling events that upregulate cytokine mRNA

Figure 1 Early events in the pathogenesis of urinary tract infection. 1: Bacteria enter the urinary tract. Persistence is determined by (a) resistance to bacteriocins and (b) adherence factors suitable for host receptors. 2: Bacteria induce the production of inflammatory mediators by the mucosa (cytokines) which trigger local and systemic inflammation. 3: Bacteria induce cell detachment and cross the epithelial barrier. 4: Phagocytic cells eliminate bacteria. 5: Bacteria reach the bloodstream and cause urosepsis. (Drawn by W Agace.)

levels and protein synthesis, and results in cytokine secretion. The transmembrane signaling pathway is influenced by the fimbrial receptor specificity.

The release of cytokines and other inflammatory mediators elicits the chain of events that leads to the classical inflammatory changes associated with acute pyelonephritis (fever, elevated acute phase responses, local inflammation and loss of tubular function). The rapid influx of neutrophils (PMNs) into the urine is partly explained by the local production of interleukin 8 (IL-8), a neutrophil chemoattractant. In response to mucosal IL-8, PMNs from the circulation migrate to the epithelium, and cross the epithelial barrier into the urine. This process is also influenced by epithelial cell adhesion molecules such as ICAM-1 that are upregulated by the presence of bacteria, and bind the CD11b/CD18 neutrophil ligands. The febrile response to UTI and elevation of circulating acute phase reactants like C reactive protein may be explained by the release of IL-6 from the site of infection. Further studies are required to define the *in vivo* relevance of the cytokines as mediators of disease.

In about 30% of patients with acute pyelonephritis bacteria reach the bloodstream and cause urosepsis. This involves the disruption of the epithelial barrier and survival of bacteria in the bloodstream. P Fimbriated *E. coli* are more common in urosepsis than in acute pyelonephritis. The role of mucosal and systemic immunity or inflammation for this phase of infection is not well understood.

Host resistance to UTI

The urine flow is a major host defense mechanism as shown by the drastically increased frequency of UTI in patients with catheters or other mechanical defects.

Individuals prone to UTI have an increased tendency to carry uropathogenic *E. coli* in the intestinal flora and introital area. Epithelial cells from these sites have a higher density of receptors than cells from healthy controls. The establishment of bacteria in the urinary tract is also thought to be influenced by the host expression of receptors for bacterial adhesins. The P blood group determines expression of the globoseries of glycolipids; P_1 individuals run an 11-fold increased risk of suffering from recurrent pyelonephritis compared to P_2 individuals. The mucosal expression of A, B, H determinants is influenced by the ABH blood group and secretor state. Bacteria which recognize the globo A receptor infect individuals of the A_1P_1 blood group, who express this receptor in the urinary tract. Blood group ABH nonsecretors have increased inflammatory reactions to UTI and are enriched in renal scarring.

The establishment of bacteriuria is counteracted by secreted receptor analogs or free oligosaccharides that inhibit bacterial attachment; the Tamm Horsfall glycoprotein which binds type 1 and S fimbriae, and secretory IgA which trap type 1 fimbriated *E. coli*. Secreted Gal α 1-4Gal β -containing oligosaccharides or glycoconjugates that inhibit the attachment of P fimbriated bacteria have not been demonstrated. The tissue affinity of the Gal α 1-4Gal β -specific adhesins combined with the lack of inhibitors may explain their association with disease.

The acute inflammatory response to infection is a key to the symptoms, and to the clearance of bacteria from the urinary tract. Resistance mechanisms have mainly been studied in experimental UTI models. The inflammatory response initiated by bacterial contact with the mucosa mediates clearance of infection. In the absence of this response, e.g. in animals with genetic defects or treated with anti-inflammatory drugs, bacteria are not cleared from the kidneys. In contrast, defects in specific immune response did not influence the natural resistance to UTI in mice.

Animals with B lymphocyte defects or severe combined immunodeficiency, cleared experimental *E. coli* infections as efficiently as their normal counterparts.

The results from the experimental studies cannot immediately be translated to patients suffering from various forms of UTI but some parallels may be pointed out. There is no evidence that specific immune mechanisms determine the resistance to sporadic UTI. Patients with immunodeficiency states do not appear to have an increased susceptibility to UTI. Evidence for immune-mediated protection against recurrent UTI in humans is also lacking.

Patients prone to UTI may have defects in the acute inflammatory response leading to defective clearance of infection but this has not been demonstrated. Defective clearance of bacteria from the tissues combined with an abnormal inflammatory response has been suggested to occur in patients with renal scarring.

V

VACCINATION, METHODS OF ADMINISTRATION

Gordon Ada, Division of Immunology and Cell Biology, John Curtin School of Medical Research, Australian National University, Canberra, Australia

Routes of antigen administration

There are two general routes of antigen administration – parenteral and mucosal. The former refers to routes which involve penetration of the skin; the latter refers to absorption of antigen through a mucosal layer.

Parenteral administration

A number of routes are used in experimental work, including intradermal (i.d.), subcutaneous (s.c.), intramuscular (i.m.), intraperitoneal (i.p.) and intravenous (i.v.) administration. Three routes are mainly used in human administration. The smallpox (vaccinia) vaccine was routinely given by skin scarification.

Most vaccines given parenterally are by s.c. or i.m. administration, the choice largely depending upon the need for an alum adjuvant, when i.m. is the route of choice.

The last decade has seen a range of new preparations which, though not yet licensed as vaccines, hold considerable promise. DNA in the form of a plasmid is injected i.m. and this results in a long-lived immune response (antibody and cytotoxic T lymphocyte (CTL) formation). Rather large amounts are given (100 µg) by this route, but much smaller amounts (<1 µg) if adsorbed to tiny gold beads and delivered by a 'gene gun' into the mouse skin, can also give a good response. In the latter situation, examination has shown that some of the particles are

taken up by Langerhans cells and carried off to the draining lymph nodes.

Mucosal administration

The area of mucosal surface available for infection by infectious agents and for antigen presentation is far greater than the skin area. Correspondingly, the mucosal surface is very well endowed with lymphoid tissue, in the gut by intraepithelial lymphocytes and Peyer's patches. The gut-associated lymphoid tissue (GALT) has been characterized in more detail than other sites. The major routes available for administration are oral, intranasal, ocular, intrarectal and vaginal (Table 1). These are anatomically discrete lymphoid compartments but there is a link between them which is referred to as 'the common mucosal system', whereby immunocytes sensitized at one site, particularly GALT, may transfer immunity after traveling to other mucosal and glandular sites.

Because of this relationship and the ease of administration, it is surprising that the oral route of administration of vaccines has not been more widely used other than for those vaccines which protect against diseases caused by agents, such as certain viruses and bacteria, which normally infect by this route. One reason is the need to avoid positive immune responses in the gut to food antigens, so that suppressor mechanisms are often activated. Second, for many antigens, much higher doses are required to achieve a desired response after oral compared to parenteral administration. Third, feeding an antigen orally does not necessarily result in a good immune response at all other mucosal sites. For example, there are only a few examples where oral administration of an antigen formulation has resulted in protection against a vaginal challenge.

Oral administration of live agent vaccines is effective for the prevention of enteric infections, such as poliomyelitis and typhoid fever and would be used for rotavirus and cholera vaccines. The adenovirus

vaccine, a tissue culture produced live preparation with no markers of attenuation, has been administered to defense personnel in the USA for many years and protects against a respiratory infection by the wild-type agent. The virus is thought to replicate in the GALT underlying the M (microfold) cells which line the walls of the intestine. The rectal route is used extensively in the poultry industry, partly because of the close location of the bursa of Fabricius, where B lymphocytes differentiate. In mammals, there is a high concentration of lymphoid tissue located near the rectum. The ocular route is not used at present, but it would probably be used if a vaccine became available to prevent trachoma caused by *Chlamydia* infections.

The vaginal route becomes increasingly important when one considers the number of sexually transmitted diseases, not the least of which is human immunodeficiency virus (HIV) infection. However, immunization by this route with a noninfectious antigen usually results in a poor and short-lived response. There is little organized lymphoid tissue adjacent to the vagina and the reason for this may be to minimize the risk of an antibody response to sperm. A small proportion of women become infertile for this reason. In experimental work with monkeys, injection of antigens adjacent to lymph nodes which drain the vaginal area has given good vaginal responses. Again experimentally, intravaginal administration of chimeric herpesvirus has resulted in a good response to the encoded antigen.

Immunopotentiality – the need for adjuvants

The term adjuvant is widely used to describe potentiating effects that may be specific or nonspecific. The term vehicle is sometimes used to describe the way in which the antigen is presented. The final mode of presentation has been called the antigen formulation. The only adjuvant licensed for general medical use is alum, which was first used over 50 years ago.

A great variety of materials have been shown to have adjuvant activity, but with increasing knowledge of immune mechanisms and especially the role of lymphokines, it became clear that an adjuvant should preferentially have three functions:

- the formation of a depot at primarily the site of application;
- the presentation or delivery of antigen to cells involved in the immune response, principally antigen-presenting cells; and
- the synthesis and secretion of cytokines which

Table 1 Mucosal routes of administration for current and some future vaccines

Route	Organisms
Oral ^a	Poliovirus (OPV), rotavirus, <i>Salmonella</i> , cholera, adenovirus
Rectal	Many vaccines administered to poultry
Ocular	<i>Chlamydia</i> (trachoma), herpesvirus
Vaginal	Sexually transmitted disease (STD) organisms, including HIV, HTLV, herpesvirus
Intranasal ^a	Live attenuated influenza, measles?, DNA?, some STD organisms?

^aSome antigens administered by this route have given a vaginal response.

would act principally on other cells in the immune system, mainly T cells.

Next to alum, Freund's complete adjuvant (FCA), containing mineral oil and inactivated tubercle bacillus was initially used widely and was regarded as the 'gold standard' but fell into disuse because it formed a granuloma. The active principle of the bacillus is muramyl dipeptide (MDP) and many derivatives of this were made and some have been used in clinical trials.

Table 2 lists some of the different preparations now under trial and the extent to which they fulfill the above roles. A second very important aspect is that these different formulations frequently will pre-

ferentially stimulate a CD4⁺ T cell type 1 or type 2 response which results in the secretion of different patterns of cytokines. Furthermore, it is now possible in some situations to selectively induce a CD8⁺ T cell response. In other words, it is becoming increasingly feasible to manipulate the immune system much more than was originally thought possible.

VACCINES

Gordon Ada, Division of Immunology and Cell Biology, John Curtin School of Medical Research, Australian National University, Canberra, Australia

It was noted in ancient times that those who survived an infection seldom suffered a second, similar sickness. Some people clearly suffered less than others and it might have been observed that this could be related to the site of the infection. Smallpox was particularly feared and the mildness of some infections led to the deliberate induction of disease by the process of variolation, by the cutaneous route as practised in India or by the nasal route in China. It was a hazardous procedure,

with a case fatality of 0.5-2%, but this compared favorably with the rate of 20-30% from the natural infection.

The observation that milkmaids rarely suffered smallpox led to the deliberate inoculation of people with cowpox, but it was Jenner who, in 1796, carried out the critical experiment of inoculating a boy, James Phipps, first with cowpox material and then with smallpox. The prior 'vaccination' protected Phipps from disease. Vaccination with cowpox

rapidly replaced variolation as a prophylactic measure and it became legal in some countries in the early nineteenth century.

Pasteur was the second great contributor to this area, now called vaccinology. He developed (initially by accident) the means of changing the properties of microbes so that their potential for causing disease (the property of virulence) was greatly reduced. This process is called attenuation and is still used in the development of some viral vaccines. Attenuation occurred if the infectious agent was maintained under adverse conditions or, more regularly, by serial passage in an unrelated host or in tissue culture.

The isolation of toxins from tetanus and diphtheria organisms soon followed, and shortly thereafter, the use of the adjuvant, alum, was introduced by the English scientist, Glenny, as a means of delaying the disappearance of antigen from the injection site. Glenny also noted differences in the rate of the antibody response to a toxin in nonimmune compared with immune animals, i.e. the differences between a primary and a secondary antibody response to an antigen. This difference lies at the very heart of vaccination.

Current vaccines and vaccines under trial

Viral vaccines

Many of the current most successful vaccines are composed of attenuated live viruses (Table 1). The

Table 1 Viral vaccines

		Agents
	Current	Under trial
Live attenuated	Vaccinia	Cytomegalo
	Measles	Hepatitis A
	Mumps	Influenza
	Rubella	Dengue

	Rabies	
	Japanese encephalitis	
Subunit	Hepatitis B	
	Influenza	
Combination	Measles, mumps, rubella (MMR)	

introduction of tissue culture technology after World War II greatly facilitated this development. Most of these live virus vaccines are highly effective, inducing long-lasting immunity – sometimes life-long – after one or two administrations.

Disease eradication by vaccination A worldwide program of vaccination with the smallpox vaccine (vaccinia virus) organized by the World Health Organization (WHO) led to the eradication of smallpox (achieved in 1977 and certified in 1980). WHO aims to eradicate poliomyelitis by the year 2000: this disease was declared eliminated from the Americas in 1994 due to the tremendous effort of the Pan American Health Organization (PAHO). PAHO now aims to eliminate measles from the Americas by the year 2000. Eradication is possible for these three diseases because humans are the only host for the viruses. A combination vaccine, measles, mumps and rubella (MMR, Table 1) is widely used and using a two-dose administration of MMR, Finland declared these infections eliminated from that country in 1995.

Inactivated whole virus also forms the basis of some vaccines, most of which are effective although larger doses given more frequently are required. The influenzavirus vaccine is less effective, partly because of the considerable antigenic variation of the envelope proteins, the hemagglutinin and neuraminidase, of this virus.

Vaccines may also be composed of part of an infectious agent, usually the antigen(s) recognized by antibody which can neutralize the viral infectivity. The most successful viral vaccine in this category is the surface antigen, HBsAg, of the hepatitis B virus (HBV). As this virus is infectious only in higher primates, the first vaccine was prepared from the blood of infected people, and is now at last being used in developing countries. A second-generation vaccine, produced by yeast transfected with DNA coding for HBsAg, is in general use in developed countries.

The process of attenuation of viruses has been so successful that most viral vaccines in late-stage clinical trials are of this type. However, many of the new viral candidate vaccines under early development, such as HIV, have followed the earlier lead of the hepatitis B vaccine. Other approaches use some current viral vaccines as vectors of DNA coding for protective antigens of other infectious agents such as HIV, as is discussed later.

Bacterial vaccines

Table 2 lists current bacterial vaccines and those in late-stage clinical trials. In contrast to the viral vaccines, BCG (bacille Calmette–Guérin) was for many

Table 2 Bacterial vaccines

Type	Agent

^aCT, cholera toxin.

years the only attenuated bacterial vaccine. It has given very variable results in several large trials on adults, but is still used in the WHO Expanded Program for Immunization (EPI) of the world's infants. BCG is not administered in the USA, but recently antibiotic-resistant strains have arisen, and this has emphasized the urgent need for a more effective vaccine against tuberculosis. BCG has strong adjuvant activity and can nonspecifically stimulate other immune responses. More recently, an attenuated form of *Salmonella typhi* (Ty21a) has been licensed and has replaced earlier inactivated preparations.

There are several inactivated whole bacterial vaccines. The *Bordetella pertussis* vaccine against whooping cough is effective and is administered as part of a trivalent vaccine, diphtheria-tetanus-pertussis (DTP), with the two toxoids, the detoxified secreted toxins of the tetanus and diphtheria bacteria. The pertussis component is considered responsible for some side-reactions given by this combination vaccine, and recently this component has been replaced by a less reactogenic acellular preparation in a combination called DTaP.

In addition to the two toxoids, there is another form of subunit bacterial vaccines. 'Encapsulated' bacteria have a coating of usually complex polysaccharides which act as protective antigens. They often occur in a variety of serotypes. For example, the pneumococcal vaccine (*Streptococcus pneumoniae*)

contains the carbohydrate epitopes of 23 different serotypes and is administered to the young and the elderly. Generally, children younger than 2 years respond poorly to such preparations, but this can be remedied by conjugating to a carrier protein such as a toxoid or another bacterial protein. The conjugate of the *Haemophilus influenzae* carbohydrate and protein (Hib) is highly effective against meningitis in very young children.

Other vaccines

Other infectious diseases

There is no antiparasite vaccine made by traditional methods currently in use. Q Fever is a debilitating disease particularly prevalent in abattoir workers, and is caused by *Coxiella burnetii*. Inactivated whole organisms caused reactions in those previously sensitized by a natural infection. The vaccine is now administered to nonsensitized personnel and appears to give complete protection.

Anti-insect vector vaccines

During feeding on mammals, most antigens of insect vectors do not come into contact with the host's immune system. If the host was preimmunized with these antigens, however, feeding with uptake of host blood might damage sensitive tissues of the vector. This approach has been tried successfully with the cattle tick, *Boophilus microplus*. Immunization with a tick gut protein results in the destruction of the feeding tick. It would be a great boon if this approach could be successfully adapted to other vectors such as mosquitoes and tsetse flies.

Fertility-control vaccines

Many consider that the greatest threat to the planet is the rapid increase in population, so new approaches to help control this growth are sought. In view of the general acceptance of vaccination as a public health measure, the possibility of using such an approach for fertility control is being evaluated. The finding that some women become infertile because they make antibody to their partner's sperm gives hope to this approach. There are two major targets for such vaccines – gamete antigens and the very early products of conception, and the hormones which control the reproductive cycle. Success has been achieved with some animal models, e.g. the guinea pig, but there is still some way to go with the development of vaccines for human use. The most advanced is based on human chorionic gonadotropin (hCG), a transiently expressed hormone required for implantation of the fertilized egg. In the long run, a

mixture of several gamete antigens may be the more effective approach.

There are also recent advances in the experimental control of noncommunicable diseases such as cancer and autoimmune diseases. Vaccination in these situations is usually referred to as immunotherapy.

The immune response to infections

The development of vaccines has been based on two requirements: safety – the product should not induce undue morbidity; and efficacy – immunization should prevent clinical disease on subsequent exposure to the wild-type agent. Other than measurement in relatively recent times of specific antibody levels and particularly a functional test such as neutralization of infectivity, generally no other parameters of the immunogenicity of the product were considered. Most current vaccines are to 'acute' infections, i.e. those in which the agent replicates for a few days, replication is halted and then cleared without persistence of the infectious agent. Diseases caused by agents which cause chronic infections, i.e. the immune response is subverted in some way, pose a greater challenge to vaccine development. Many of the diseases for which vaccines are now needed are in this category.

Our knowledge of the different responses generated and their role during infection has come from the study of model systems, using laboratory animals. The immune response can be divided into four stages: 1) prevention of infection; 2) limitation of infection; 3) recovery from infection; and 4) the generation of immunological memory.

Stage 1

The only mechanism for specifically preventing infection is antibody directed towards certain epitopes present on 'protective' antigens of the infectious agent. In the case of viruses, usually one or two surface proteins/glycoproteins are important; with bacteria, proteins or oligo/polysaccharides are important. An *in vitro* test which measures the neutralization of infectivity is used to predict the protective effect of an antibody preparation. The epitope(s) recognized may be a linear sequence, e.g. the outer membrane protein of *Chlamydia*, or discontinuous but adjacent sequences, as with many viruses, such as influenza or polio, so that conformation is critical.

Stage 2

If present, pre-existing specific antibody will also greatly limit infection. In its absence, a variety of 'nonspecific' effects are helpful and, for bacteria, may

be critical. These include different cell types (natural killer (NK) cells, neutrophils, macrophages/monocytes, etc.) and factors such as interferons and complement.

Stage 3

Antibody, via mechanisms such as antibody-dependent cellular cytotoxicity (ADCC), complement-dependent lysis and nonspecific factors, can contribute to recovery from infection. For extracellular infections (some bacteria and parasites), antibody is critical. There are several special cases where antibody has been shown to clear a viral infection, but for intracellular infections in general, cell-mediated immune (CMI) responses, consisting of CD4⁺ T_H1 cells and/or CD8⁺ T cells are critical. For most viruses, some bacteria and parasites, CD8⁺ cytotoxic T lymphocytes (CTLs) are the more important because they may lyse infected cells and liberate important cytokines such as interferon γ . CD4⁺ T_H1 cells are usually noncytolytic but secrete cytokines which mediate delayed-type hypersensitivity. The cytokines (interleukins) mediate inflammation, the extent depending upon the amounts produced and the extent of the infection.

Both infectious and noninfectious preparations induce CD4⁺ class II major histocompatibility complex (MHC)-restricted T cell responses. Generally, class I MHC-restricted CTL responses are best induced by infectious agents as the newly synthesized antigens provide peptides in the cytoplasmic pathway which bind to class I MHC antigen. Techniques which permit entry of an antigen preparation into this pathway result in CTL formation, but many infectious agents generate strong CTL responses.

Stage 4

Surprisingly little is known about the pathways leading to the generation of memory B and T cells. It is generally found that the requirements for activation of memory T cells are less demanding than for naive cells and they express quantitatively more of certain markers (though no marker seems to be unique for these cells). Memory B cells, which require T cell help for their generation, express immunoglobulin (Ig) isotypes other than IgM and IgD as receptors. After immunization or infection, the number of specific T or B cells is larger compared to the naive situation.

Immunological requirements/expectations of a vaccine

Vaccines may be administered to populations where

the disease is endemic and a recipient already infected. Both specific and nonspecific immune responses may then have a therapeutic effect and contribute to the control of an existing infection. In most situations, however, vaccination is planned to protect from an infectious agent to which the recipient may be exposed at some variable time in the future. In this case, the requirements differ and depend entirely on the specific components. Because the life of naive lymphocytes is quite short (from days to a couple of weeks), a vaccine should: 1) generate a large pool of memory T and B cells; 2) cause antigen to persist as antigen:antibody complexes on follicular dendritic cells so that memory B cells are formed and constantly recruited to become antibody-secreting cells and thus provide a continuing supply of antibody of increasing affinity; and 3) provide appropriate T cell epitopes to overcome the genetic restriction to this response in an outbred population.

Newer approaches to vaccine development

There are a great variety of diseases – viral, bacterial and parasitic – for which no vaccines are available. The need is great: five parasitic diseases alone affect about one-quarter of the world's population. Reasons such as the inability to grow sufficient of the organism either *in vitro* or in an animal, the complex nature of the infectious process (often including substantial suppressor effects), a lack of understanding of the basis of many chronic and persisting infections, all contribute to the lack of progress in vaccine development. Fortunately, techniques have become available which may overcome some of these restrictions.

Peptide-based preparations

In association with class I or II MHC antigens, specific linear amino acid sequences from foreign proteins may be recognized by the T cell receptor (TCR). By using a sufficient range of such sequences most people in an outbred population should respond. Peptide-based vaccines provide the opportunity to eliminate sequences which may cause immunosuppression or cross-react with self protein. There is great interest in this approach, but to date, no candidate vaccine based on peptides has been licensed. A putative vaccine to prevent malaria and containing several peptides from plasmodial proteins has shown moderate potential in some field trials, but was inactive in a recent trial in The Gambia.

There are fairly severe restrictions on this approach as any B cell epitopes would need to be

continuous sequences and several T helper and CTL epitopes would need to be included so that most people would respond. Special methods of presentation would be needed if a strong CTL response was required. Generally, oligo- or polypeptides are poorly immunogenic, so usually a powerful potentiator, called an adjuvant, must be used to ensure an immune response.

Anti-idiotypic preparations

A number of such preparations have been made and tested in different animal models to control either viral, bacterial or parasitic infections, and many have been relatively successful. But despite the obvious attractions of the approach, e.g. to mimic discontinuous epitopes or those composed of carbohydrate, no candidate vaccine has reached the licensing stage, and in view of the continuing developments with recombinant DNA technology, it seems unlikely that this approach will fulfill its earlier promise.

Approaches using recombinant DNA technology

The ability to manipulate DNA has transformed this area of biology. There are three main approaches with an extra one waiting in the wings. These are as follows.

1. Transfection of cells with DNA coding for the antigen(s) in question. Three classes of cells have been used – bacteria, lower eukaryotes such as yeast, and mammalian cells.
2. The construction of chimeric viruses or bacteria which, upon infection of cells, will express the inserted foreign DNA.
3. Direct immunization with a plasmid containing the foreign DNA.
4. The possibility of producing the antigens in DNA-transfected plants, such as banana, potato or tobacco.

Transfection of bacteria is appropriate for generating relatively simple proteins, such as occur in bacteria and some parasites, but limitations on post-translational processing restrict this approach. Transfected yeast, the source of the first genetically engineered vaccine, the hepatitis B viral vaccine composed of the surface antigen (HBsAg), has also considerable promise for some other products. For some preparations, e.g. viral glycoproteins, transfected mammalian cells – either primary cells (e.g. monkey kidney), cell strains (a finite capacity to replicate) or cell lines (immortalized cells) – offer great promise. All have been used successfully for veterinary vaccines, and will find increasing use in the future for medical products.

Chimeric live vectors In this approach, DNA coding for the antigen is inserted into the genome of an appropriate live virus or bacteria (frequently an existing vaccine). Upon infection, the DNA is expressed with the production of the foreign antigen either in the chimeric virus-infected cell or in the bacterium. Table 3 lists some of the vectors used successfully for this purpose. Each has its advantages and disadvantages. Vaccinia virus has mainly been used and the list of antigens expressed by different vaccinia constructs is now quite long. Though none is yet licensed for medical use, two veterinary vaccines are in use: a vaccinia-rabies glycoprotein construct used in the field to immunize foxes and similar pests, and a vaccinia-rinderpest antigen construct used in Africa to vaccinate cattle. Several vaccinia constructs have successfully undergone clinical trials.

DNA (genetic) immunization When mice are injected intramuscularly with plasmids containing DNA coding for foreign antigens, long-lived immune responses, including both antibody and CTL, occur after a single inoculation. A modification which uses much less antigen has been to coat gold microbeads with the plasmid and inject into skin epithelia with a 'gene gun'. This technique holds great promise in many ways, e.g. the plasmids should be inexpensive to make and effective in the presence of antibody to the donor agent. The next few years should see just how good this approach may be in humans.

Plants as sources of future vaccines? There are encouraging early experiments showing that some antigens can be produced by transfected plants, and even molecules as complex as antibodies have been prepared in this way.

Prospects for the future

One might think from the above that from now on it should be possible to make a vaccine to any infectious agent. But there are many other factors which

Table 3 Main candidates for use as live vectors

<i>Virus</i>	<i>Bacteria</i>
Vaccinia virus	BCG
Fowlpox virus	<i>Salmonella</i>
Canarypox virus	<i>Escherichia coli</i>
Herpesvirus	
Adenovirus	
Poliomyelitis virus	
Mengo virus	
Baculovirus	

Table 4 Factors favoring infectious agent control or eradication by vaccination

1. Only one or a small number of causative strains
2. Agent is only moderately infectious
3. Absence of subclinical cases and a carrier state
4. Infectious process is acute: agent does not persist
5. Generates both antibody and full CMI response
6. Viral DNA is not integrated into host cell genome

Eradication

1. Infectious agent is limited to human host - no animal or environmental reservoir
2. Infection causes a characteristic clinical disease
3. There is a simple marker of successful vaccination

can influence at least the rate at which a vaccine is developed. Table 4 lists some factors which favor vaccine development. It will be noticed that many of the agents for which vaccines are already available fulfill many of these criteria. In contrast, a variety of factors can militate against rapid vaccine development (Table 5). For example, many of these later ones apply to HIV.

Table 6 gives an estimate of the vaccines which may become available within the next 10–15 years. One development which will need to accompany the release of many new vaccines is the need to make combinations. A major cost in this area is the delivery of vaccines to the populace. The current combinations, MMR and DTP, have been highly successful. Determining those vaccines which might be added to existing combinations, such as hepatitis B and *H. influenzae* type B, has become a major activity for vaccine manufacturers.

VACCINES, ADVERSE REACTIONS TO

Gordon Ada, Division of Cell Biology, John Curtin School of Medical Research, The Australian National University, Canberra, Australia

Vaccines developed from the need to prevent the continuing morbidity and mortality from infectious diseases. The earlier attempts included variolation, the practice of deliberately inducing disease by transmission of material from smallpox pus or scabs which was practised in China and India and spread to the Middle East and thence to Europe and America. Despite the high risk of variolation (0.2–2% mortality), it was much less than the risk of death from being infected during a smallpox epidemic. Benjamin Franklin stated in his autobiography, 'In 1736, I lost one of my sons (Francis Folger), a fine boy of four years old by the smallpox. I long regretted bitterly and still regret that I had not given it to him by inoculation. This I mention for the sake of parents, who omit the operation on the supposition that they should never forgive themselves if a child died under it; my example shows the regret may be the same either way, and that therefore the safer should be chosen.'

The history of vaccination has many dark episodes and it has been vigorously opposed by different groups during the 200 years since Edward Jenner showed the value of 'vaccinating' with material from cowpox in protecting from a subsequent attack of smallpox. The value of vaccination has always been a balance between benefit and risk.

For livestock, the benefit outweighs the risk; for medical use, safety has increasingly become the major consideration. Rigorous criteria for the assessment of a candidate vaccine's safety and efficacy now exist, particularly in a number of industrialized countries. Prior to human use, regulatory authorities, such as the Food and Drug Administration (FDA) in the USA, require extensive animal tests for toxicity and sometimes for teratogenicity, and trials for efficacy in lower primates. The primate may or may not be an entirely relevant model for the human disease. For example, neither the chimpanzee for human immunodeficiency virus (HIV) nor different monkeys

for *Plasmodia* reproduce the human disease symptoms, but at least the animals sustain an infection.

Clinical trials in humans occur in three or four stages which may vary according to the preparation. In a phase 1 trial, the candidate vaccine is administered to human volunteers to test mainly for safety but also where practical for an indication of immunogenicity. If a vaccine is produced in an industrialized country, it is usual for the trial to be carried out in that country, even though the vaccine may be destined for use in a developing country. Phase 2 trials are conducted to test further safety and immunogenicity, but in addition, an indication of the efficacy of the product in those who may be exposed to the infectious agent. Phase 3 trials are carried out in the field on a much larger number of participants, perhaps up to 100 000 depending on the prevalence of the disease in the population. Phase 3 trials in particular may be very expensive, sometimes running into millions of dollars. Finally the vaccine is licensed or registered for use but where possible, a large number or a cohort of vaccinees should be followed in a postregistration program.

A candidate vaccine may run into difficulties at any of these stages or after registration, depending on the frequency of occurrence of the side-effects. Several examples are now quoted which illustrate past or present experiences.

Respiratory syncytial virus

A member of the pneumovirus genus, respiratory syncytial virus (RSV) is a highly important cause of lower respiratory tract disease in infants. It replicates at that site in several species, but the mouse and cotton rat are the main models, though neither accurately demonstrate the symptoms of the human disease. Shortly after its discovery, virus grown in African green monkey kidney tissue culture was inactivated to form a vaccine. The rationale for this approach was the prior experience with both the influenza and poliovirus vaccines which had been prepared using similar approaches, though an early batch of the latter had been found to be incompletely inactivated. However, the candidate RSV vaccine not only failed to confer protection against a subsequent RSV infection, but the disease which RSV vaccinees experienced on subsequent infection with the wild-type virus was unexpectedly severe, many vaccinees developing pneumonia or bronchiolitis with some deaths. Both humoral and cell-mediated reactions may have contributed to this result. Many attempts to make an effective subunit vaccine have since been made, but currently, a live, attenuated vaccine may turn out to be the best preparation.

Influenzavirus vaccines

To avoid a possible outbreak in 1976 of swine influenza (the viral subtype which caused the 1918 influenza pandemic in which an estimated 20 million people died), a rush program was instituted in the USA to vaccinate many millions of US citizens with a vaccine containing this serotype. The vaccine went through the usual tests during which it was administered to many volunteers. But in a total of 41.5 million people who finally received the vaccine, about 500 cases of Guillain-Barré syndrome occurred in vaccinees within a few weeks of vaccination, an incidence of about 1/80 000 recipients. The chances of detecting such a relationship in clinical trials is negligible. This relationship had not been seen previously or since, and it has been speculated that such an effect might only be seen in an extremely large, rushed program.

***Bordetella pertussis* vaccination**

The whole-cell (inactivated) pertussis vaccine is the most reactive component of the triple antigen diphtheria-tetanus-pertussis (DTP) vaccine. Several categories of reaction are recognized. Some of these, like protracted bouts of crying with unusual shock-like states or minor local and systemic effects, do not have long-term consequences. Another category includes more major neurological reactions which may lead to permanent disability. It has been extraordinarily difficult to establish a causal relationship between such injuries and vaccination. For example, the frequency of encephalopathy with residual brain damage one year after DTP administration was estimated to be 1/300 000 cases, but the correct figure could be between 1/54 000 and 1/5 300 000 cases.

A study by the Institute of Medicine (IOM) in the USA concluded that the pertussis component of DTP is responsible for rare instances of encephalopathy, but not for other disabling effects. Some countries stopped vaccination with this vaccine and in the UK this had disastrous effects following adverse publicity in the media in the mid-1970s (Figure 1). Two severe outbreaks of disease occurred with 29 deaths, and hundreds of cases of serious complications. Following a government publicity campaign, public acceptance of the vaccine increased. But there was obviously a need for a less reactogenic vaccine, and recently, an acellular preparation was licensed for use in the USA, as part of a trivalent combination, DTaP.

Figure 1 Whooping cough notifications: cases and deaths, England and Wales 1940–1993 (Source: OPCS. Prepared by CDSC).

Other childhood vaccines

More recently, the IOM has published findings on adverse events associated with a number of other childhood vaccines, to see whether any evidence bearing on causality could be established. Reactions to the diphtheria and tetanus toxoids, measles, mumps, polio, hepatitis B, and *Haemophilus influenzae* type B (Hib) vaccines, were examined. Evidence for neurological disorders (both demyelinating and nondemyelinating diseases) and a series of immunologic reactions (anaphylaxis, Arthus reaction, delayed-type hypersensitivity and autoimmunity in particular) was sought. After an exhaustive review of the available data, the findings suggested that these vaccines are remarkably safe.

Chimeric virus vectors

One of the first fruits of the biological revolution brought about by recombinant DNA technology was the concept of using some current viral vaccines as vectors of DNA coding for antigens from other infectious agents. Much work has been carried out using vaccinia virus (the smallpox vaccine) as the vector. But the use of this vaccine on very large numbers of people during the smallpox eradication campaign revealed that there was an unacceptably high incidence of undesirable reactions (Table 1), so that it is unlikely that these days a medical vaccine based on the use of this virus would be approved. Two approaches have been used to overcome this. One was to selectively delete particular DNA sequences from the viral DNA. The resulting virus, called NYVAC, was shown to be much less reactogenic but to retain the immunogenicity of the parent virus. A second approach was to use a poxvirus – fowlpox or canarypox viruses – which undergo only abortive infections in mammalian cells. These have given encouraging early results and should be safer than vaccinia virus.

Table 1 Reported cases (deaths) per million in the United States following smallpox vaccination

Reported complications	Primary vaccination (5 959 000)
Encephalopathy	6.5
Encephalitis	2.4
Progressive vaccinia	0.9
Eczema vaccinatum	10.4
Generalized vaccinia	23.4
Accidental infection	25.4
Other complications	11.8
Total	80.8

There was a much lower frequency of complications after revaccination and occasionally, complications occurred in contacts of vaccinated people.

Groups at risk from vaccination

Certain groups have a higher morbidity and mortality rate to natural infections compared to the normal population. This includes diabetics (influenza and pneumococcal pneumonia), immunocompromised or immunodeficient people. Pregnant women represent a special case because of the potential harm to the embryo. Live agent vaccines should be withheld from such groups. On the other hand, maternal immunization to protect the fetus and mother from certain diseases, e.g. tetanus, is the aim of the World Health Organization.

As vaccine development becomes more highly specialized with the great potential for peptide and subunit preparations, for recombinant live vectors and for direct immunization with nucleic acids, the risk of side-effects following vaccination should decrease. It may never be possible however to completely eliminate all hazards but these are likely to occur at such a low frequency that they are detectable only after mass immunizations. Though society in the long run must make the decisions, the eradication of smallpox, the elimination of poliomyelitis from the

Americas and of measles from Finland and from some Caribbean communities argues strongly in favor of vaccination.

VALENCY OF ANTIGENS AND ANTIBODIES

David Catty, Departments of Immunology and Infection, University of Birmingham Medical School, Birmingham, UK

Valency is an intrinsic property of both antigens and antibodies, the term being adopted early in the description of these molecules to carry the concept of binding properties and to define its numerical complexity. Confirmation of the structural basis of valency came with the subsequently acquired knowledge of the nature of binding sites of antibodies (paratopes) and of antigenic determinants (epitopes) of antigens.

Valency is usually considered in operational (or effective) terms, the valency of an antigen being a statement of the number of paratopes with which each antigen molecule can (or does) combine under particular conditions and, likewise, the valency of an antibody is the number of epitopes with which an antibody can (or does) combine. Native antibody molecules carry a theoretical (structural) valency of two (divalent, with two binding sites per molecule) or a multiple of two, according to the degree of polymerization of the antibody involved (see below: Valency of antibodies). Subunits of antibodies carrying a single binding site have a valency of one. Operationally, native antibodies may express a valency less than that defined by structure for several reasons outlined below.

Antigen molecules carry, by definition, at least one epitope. Monovalent antigens are rare in nature but can be produced as peptides and chemical haptens and these have been used extensively to study antibody valency, specificity, and affinity. Most native

antigens are multivalent and often carry a mosaic of structurally different epitopes. Multivalency in both antigen and antibody has important consequences in terms of how these molecules interact; it is the basis for the formation of immune precipitates (or agglutinates) which consist of a complex lattice of bound antigen and antibody molecules. Through this the physiological host defense purpose of the antibody response is achieved as it leads, through various pathways, to the neutralization and removal of bacterial and other toxins, the inhibition of virus entry to host cells and of adhesion of bacteria to tissues, the fixation and activation of complement, efficient phagocytosis of microorganisms and the removal of foreign molecules from the circulation. Precipitation and agglutination have been exploited as *in vitro* reactions for diagnostic purposes and to measure antibodies and antigens.

Valency has been applied in some circles to describe the specificity of antisera. In some branches of serology antisera are referred to as monovalent or polyvalent to define the extent of their reactions with a range of antigens. A good example of this other usage of antibody valency came from the production of anti-snake venom antisera for therapeutic use in some parts of the world. Antisera reacting with (neutralizing) only a single (immunizing) species venom are described as monovalent, whereas others, either cross-neutralizing other species, or raised deliberately to a mixture of species' venoms are

described as polyvalent. This practice persists although it is tending to be replaced by descriptions of specificity.

Valency of antigens

Monovalent antigens are molecules which, with respect to antibody, carry a single epitope. Antigens of this structural simplicity are not normally immunogenic – i.e. they cannot individually induce an antibody response. However, antibodies to small chemical groups (haptens) were the basis of much important classical early work that revealed the remarkable diversity potential of antibodies and the structural features and limitations of antigenic determinants. The limitations to immunogenicity of simple chemical groups was overcome by coupling (as haptens) to larger carrier molecules; some of the antibodies then induced are specific to the hapten and bind to soluble monovalent hapten in solution, the latter behaving as a homogeneous monovalent antigen.

The reacting system of antibody and hapten is sufficiently homogeneous to allow a good estimate of antibody binding affinity. Antibodies binding to monovalent antigens in solution carry no potential for immune complex lattice formation and the measurement of binding requires certain strategies. Haptens in free solution will cross a dialysis membrane into an antibody solution and binding affinity of the antibody can be measured by means of equilibrium dialysis in which, in effect, the capacity of the antibody to hold diffusible hapten in its compartment is a measure of its affinity. High-affinity antibodies have been used since the early 1960s in radioimmunoassays to measure the concentration of small peptide and steroid hormones in the blood which behave as monovalent antigens. The antibodies are usually raised by using hormone-carrier conjugates as immunogens, and the binding of free hormone in the assay is measured after precipitation of soluble complex, usually by addition of divalent antiglobulin.

Monoclonal antibodies have homogeneous specificity towards a single epitope of complex antigens and are thus very different from conventional antisera raised to the same antigen. Except where epitopes are repeated on the molecule, monoclonal antibodies treat a target molecule as a monovalent antigen. Mixing monoclonal antibodies to different epitopes of a complex antigen has shown that an antigen needs to express a valency of four to achieve precipitation. The reaction of a monoclonal antibody with a hapten in solution represents the most homogeneous system for measuring antibody affinity.

Polyvalent antigens are structurally complex molecules with intrinsic immunogenicity that elicit complex antibody responses. The reaction with antibody *in vitro* of polyvalent antigens is a correspondingly complex phenomenon with a mixture of antibody specificities binding to different epitopes with different affinities. No true affinity measurement can be achieved in such a heterogeneous system but the overall binding capacity of the antibody mixture (antiserum) for the antigen can be measured and more generally described as the avidity.

Under appropriate conditions antibodies will operate as bivalent molecules and this leads to complex precipitation. The precipitation phenomenon with polyvalent antigens has been studied throughout the twentieth century, although an adequate theoretical and mathematical model of precipitation has yet to be formulated. The first precipitin equation was put forward by Arrhenius on observations of precipitation of serum proteins by antiserum (1907). He assumed that the soluble reactants and the insoluble product were in equilibrium according to the law of mass action.

By the 1930s it had been shown by Heidelberger that precipitation could be used to measure absolute amounts of antibody nitrogen in antisera to polyvalent pneumococcal polysaccharide and a further set of classical experiments was performed with egg and serumal bumin. Antibody measurement depended upon the critical observation that precipitation occurred at optimal proportions of antibody and antigen, with greater amounts of reactants remaining in solution in conditions of increasing antibody and antigen excess on each side of the equivalence zone. At equivalence, antibody is brought completely out of solution and the zone ends as conditions move into mild antigen excess. Heidelberger's data on the content of antibody and antigen in complexes formed at different molar ratios have been extensively analyzed. At equivalence the effective valency of antibodies to albumin approaches a figure of two and the valency of egg albumin is five in regard to one studied antiserum. The composition of the precipitate is thus of 2–3 antibody molecules per antigen molecule, with most antibodies utilizing both binding sites in the complex.

In contrast the precipitate formed in conditions of antibody excess contains a predominance of antibodies with an effective valence of one, the degree of precipitation depending upon the extent to which some antibodies can still operate as divalent molecules to bridge between antigens. In growing antigen excess, the precipitate again begins to break down with more antigen in solution. The antigen component still involved in precipitation dwindles in

proportion to antibody and the effective valency rises, becoming, for egg albumin, eight when the total amount of the antigen in the system is twice that of equivalence. In conclusion, it has to be recognized that valency expressed by multivalent antigens, and by antibodies, is a property that is variable according to the conditions of interaction and this in turn affects the nature and properties of the product. Physiologically, immune complexes formed in antibody excess are more efficiently removed and are less pathogenic, whereas small soluble complexes formed in antigen excess are less readily removed and may be deposited in tissues to cause inflammatory, tissue-damaging reactions.

Valency of antibodies

Most antibodies in the serum of hyperimmune animals, i.e. of the sort used in the original precipitation studies which measured their valency properties, are known to consist predominantly of immunoglobulin G (IgG) which, as described above, exhibits at equivalence a valency approaching two consistent with its determined structure. While all antibodies have a basic unit structure similar to IgG, some other classes of antibody exist in polymeric form and in consequence may express a greater valency.

IgA can exist in polymers of various sizes, the most common being found in secretions as a dimer with the two units joined end-to-end by a J chain. Such molecules have a structural valency of four. This is of little significance in considering antibodies in serum as most IgA in serum of normal individuals is monomeric. However, the polymeric secretory IgA active at mucosal surfaces may owe its protective properties in part to the distribution of binding sites and polyvalent nature.

Serum IgM antibodies are constructed on a pentameric form with ten combining sites. In some circumstances, especially in primary responses, IgM may be a significant component of specific serum antibody and its multivalency offers certain distinct advantages in efficient bacterial and viral agglutination and complement fixation. In practice steric hindrance

between binding sites and the local availability of antigen epitopes for all binding sites may reduce the effective valency of IgM to less than that predicted by structure. In reactions of pure IgM antibody with soluble antigen a valency of five is given as the normal property of this molecule.

The special properties of IgE antibodies depend upon it first attaching through receptors to the surface of mast cells and basophils. In this position they are known to bind antigen (allergen) to initiate the release of mediators of immediate hypersensitivity. Evidence suggests that the trigger mechanism for mediator release depends upon the cross-linking of IgE molecules on the cell membrane by allergen, and the divalent property of IgE would be an essential feature of this mechanism.

Recent studies suggest that antigen valency may also be a critical factor in mast cell degranulation. In an experimental system with rat leukemic mast cells, a conjugate of dinitrophenyl (DNP) hapten with a carrier molecule, with high DNP valency (DNP32-HSA) gave a much greater degranulation response by anti-DNP IgE-coated mast cells than the same allergen design with lower DNP valency.

VARICELLA-ZOSTER VIRUS, INFECTION AND IMMUNITY

Charles F Grose, Departments of Pediatrics and Microbiology, University of Iowa College of Medicine, Iowa City, Iowa, USA

Chantane P Buranathai, Department of Microbiology, University of Iowa College of Medicine, Iowa City, Iowa, USA

Varicella-zoster virus (VZV) is one of seven human herpesviruses. The other six are herpes simplex virus 1 (oral), herpes simplex virus 2 (genital), cytomegalovirus, Epstein-Barr virus, human herpesvirus 6, and human herpesvirus 7. An eighth herpesvirus-like DNA sequence has been discovered recently in tissues obtained from Kaposi sarcoma; this agent has been designated Kaposi sarcoma herpesvirus. VZV is the etiologic agent of two distinct illnesses. The primary infection is called chickenpox or varicella. Virus reactivation in adulthood causes the dermatomal exanthem shingles or herpes zoster.

Characteristics of the virus and its antigens

The human herpesviruses share a common morphology and genome structure. The VZV virus is about 200 nm in diameter and includes an inner nucleocapsid surrounded by a lipid envelope from which protrude the immunogenic viral glycoproteins. The DNA molecule is housed within the nucleocapsid. The sequence of the genome contains nearly 125 000 base pairs, including 71 open reading frames which may encode viral proteins. Six of the open reading frames specify viral glycoproteins; these have been designated gB, gC, gE, gH, gI and gL (Figure 1).

The glycoproteins are important structural components of the viral particle; in addition, they are inserted into the plasma membrane of the infected cell. As such, they are important antigens by which the host regulates the immune response after infection. The predominant viral glycoprotein is gE, a

98 kDa product which is the main component within the membrane of the infected cell. This glycoprotein is easily identified in cells removed from a chickenpox or zoster vesicle. Therefore, it is an ideal antigen for rapid diagnosis of VZV infection with a monoclonal antibody probe. Monoclonal antibodies to this antigen have neutralization activity only in the presence of an exogenous source of complement.

Varicella-zoster virus gB is a 140 kDa product which is the second most prominent viral glycoprotein constituent of the infected cell membrane. Antibodies to this glycoprotein exhibit complement-independent neutralization as evidenced by their ability to reduce VZV plaque formation. The same antibodies inhibit VZV-induced cell-to-cell fusion in infected monolayers. The third glycoprotein, VZV gH, has a molecular weight of 118 kDa. This glycoprotein is barely detectable in the membrane of infected cells. However, of the three major glycoproteins, it appears to possess the most immunogenic neutralization epitope. Monoclonal antibodies to VZV gH have the ability to inhibit plaque formation at dilutions of 1:40 000. Glycoprotein gL forms a complex with gH and, likewise, gI forms a complex with gE. The gE/gI complex can bind to the Fc portion of immunoglobulin G (IgG) and both components of the complex contain phosphorylation sites in their cytoplasmic tails. In addition to the glycoproteins, other virally encoded proteins are important antigens, but they have been less well characterized.

Immune responses of the host to chickenpox

In order to properly understand the immune response of the host, it is first necessary to visualize the pathogenesis of primary VZV infection. A schema is shown in Figure 2. This model includes two viremic stages, with the characteristic chickenpox exanthem appearing after the second viremia. Chickenpox is acquired from small virus-laden droplets which are carried by air currents from an infected child to a nonimmune (susceptible) individual. The site of infection is probably the conjunctivae or the

Figure 1 Diagram of the VZV genome. The VZV genome contains about 71 open reading frames. The locations of the glycoprotein genes are designated by their gene numbers. Both the old and the new nomenclatures are listed. UL, unique long sequence; US, unique short sequence; IRs, internal repeated sequence; TRs, terminal repeated sequence.

Figure 2 Schema for pathogenesis of chickenpox. This scheme is explained in greater detail in Grose (1981). (Reproduced by permission of the American Academy of Pediatrics.)

nasal mucosa, as illustrated in **Figure 2**. An IgM immune response is detectable by the end of the incubation period, when the vesicular rash first appears. One of the better tests to measure VZV-specific antibodies is by fluorescence antibody to membrane antigen (FAMA); this indirect fluorescence method detects antibodies to VZV antigens present in the outer membrane of live VZV-infected cells. The first antibodies to appear are often directed to VZV gB, followed in rapid succession by antibodies to gH and gE. The infected host also develops antibodies to certain nonglycosylated structural components of the virion.

In addition to the humoral response, individuals with chickenpox mount a cellular immune response. Among the important targets for cellular immunity following VZV infection are the same viral glycoproteins that are recognized by antibodies, as well as the regulatory protein called IE62. When measured by lymphocyte proliferation assays, most healthy individuals with chickenpox develop proliferative responses to VZV gE, gI, gB, gH and IE62 antigens. The responder cell frequency has been estimated at 1:39 000 in adults who had chickenpox as children. In cytotoxicity assays, both CD8⁺ class I-restricted T cells and CD4⁺ class II-restricted T cells mediate VZV-specific cytotoxicity. The mean precursor frequency for T lymphocytes that recognize gE is 1:121 000; the precursor frequencies were similar for CD4⁺ and CD8⁺ populations. The VZV cellular responses appear to limit the severity of the chickenpox exanthem in normal hosts.

Immune response following VZV reactivation

Most children with chickenpox develop a latent VZV

infection, i.e. the virus remains dormant in the dorsal root ganglia for decades. However, in late adulthood, the virus occasionally reactivates and causes herpes zoster (shingles). Waning immunity over a lifetime is considered to be an important factor in reactivation. In the weeks prior to the onset of zoster, very little anti-VZV glycoprotein antibody is present in the serum. Cellular immunity is similarly diminished; in particular, the frequency of cells producing interferon γ (T_H1 cells) declines more than those producing interleukin 4 (T_H2 cells). Within a few weeks after appearance of shingles, there is a dramatic anamnestic humoral response, resulting in high titers of VZV-specific antibody. Likewise, there are heightened lymphoproliferative responses to VZV antigens shortly after onset of herpes zoster.

Immune globulin and vaccines

Chickenpox can be prevented by administration of high-titer human varicella-zoster immune globulin (VZIG) by intramuscular injection. In order to be effective, the globulin must be given within 3–4 days after exposure to chickenpox. Based on the schema of pathogenesis (**Figure 2**), the most likely explanation is that antibody to VZV abrogates the primary viremia and thereby inhibits spread of virus throughout the host.

The medical indications for VZIG include prevention of chickenpox in VZV seronegative children with cancer who are exposed to chickenpox; VZIG is also administered to newborns, especially premature newborns, who are exposed to chickenpox in the postpartum period. Some experts recommend VZIG administration to VZV seronegative pregnant women who are exposed to chickenpox, but there are conflicting data about VZIG efficacy in adults. The data are difficult to interpret because the clinical studies have been performed with two different VZIG preparations (one produced in the USA and another made in Europe). Not only are the VZIG preparations prepared in different facilities, the recommended dosages differ between the European and North American preparations. In the USA, one infant with congenital varicella syndrome has been born to a pregnant woman who received VZIG but still developed gestational chickenpox. These issues have been recently reviewed (see Further reading).

A live attenuated varicella vaccine was developed in the 1970s and is currently licensed in Japan, Europe and the USA. The vaccine virus was designated Oka strain after the name of the 3-year-old boy with chickenpox from whom it was isolated. The first human studies of the VZV vaccine were carried out in Japan with subsequent clinical trials in Europe and

the US. Because of their increased susceptibility to severe complications of chickenpox, the initial recipients of the vaccine were children with leukemia. Initially, one vaccination was given. However, because of low seroconversion rates the number of vaccine doses was raised to two injections. Under the latter regimen, 95% of vaccine recipients developed antibody; 66% remained seropositive 3 years after immunization. A small number of vaccine recipients have developed clinical chickenpox after exposure in the community; this disease is called 'breakthrough chickenpox'. Usually the disease has been mild.

Based on efficacy data derived from the large clinical trials in the USA, the vaccine is estimated to be 80% effective in children with leukemia. In other clinical trials, the vaccine was administered to healthy children in Japan and the USA. Healthy children require only a single immunization. Immunized children have been followed for several years; over 90% of the vaccinees showed persistence of both cellular and humoral immune responses. Like the children with leukemia, however, a few healthy vaccinees with declining immunity have occasionally contracted breakthrough chickenpox following a community exposure.

Healthy young adults who failed to contract chickenpox as children have been immunized in clinical trials. Two doses of vaccine were required to achieve a seroconversion rate of 92%. Even after two doses, the cellular immune responses of immunized adults were significantly lower than those of immunized children. Furthermore, at 1 year after immunization, the lymphocyte proliferation indices continued to be lower in the adult population.

Finally, varicella immunization has been investi-

gated in seropositive adults older than 55 years of age, who had a history of wild-type chickenpox as children. Both cellular and humoral immunity was boosted by immunization with live attenuated varicella vaccine. Future studies will investigate whether shingles can be prevented by booster immunization of the elderly.

VENOMS

Donald R Hoffman, Department of Pathology and Laboratory Medicine, East Carolina University School of Medicine, Greenville, North Carolina, USA

Historical background

The immunological effects of envenomation have been known since ancient times. Ancient Egyptian hieroglyphics indicate that the Pharaoh Menes of Memphis died 5000 years ago from the sting of a great wasp. In modern times, Waterhouse first distinguished between allergic reactions to insect venoms and the natural toxic effects in 1914. Then Braun introduced skin testing with extracts prepared

from honeybee abdomens in 1925. The first treatment with pure venoms was reported by Loveless in 1956, and in the 1970s Lichtenstein, Valentine, Sobotka and coworkers conclusively demonstrated that Hymenoptera venoms were the materials of choice for diagnosis and treatment of allergic reactions to stings. The insect venom model has been extensively studied in attempts to understand the mechanism by which immunotherapy with allergen reduces clinical hypersensitivity.

Insects

Allergic reactions to the venoms of social Hymenoptera are relatively common. Estimates of the prevalence of stinging insect allergy by history range from 1 to 10% of the population. A random screen of industrial employees in the mid-Atlantic USA found that 26% exhibited evidence of sensitization by being either skin test or radioallergosorbent test (RAST or specific immunoglobulin E (IgE) antibody measurement) positive. Highly exposed populations have been found with over half of the subjects positive. The major insects causing reactions are those of the genera *Apis* (honeybees) and *Bombus* (bumblebees) in the family Apidae; *Vespula* (yellowjackets), *Dolichovespula* and *Vespa* (hornets) and *Polistes* (paper wasps) of the family Vespidae; and a wide variety of stinging ants of the superfamily Formicoidea, especially the genera *Solenopsis* (fire ants) and *Pogonomyrmex* (harvester ants). Many of the venoms have been extensively characterized and the allergens identified. Honeybee venom protein allergens include phospholipase A₂, hyaluronidase, acid phosphatase, allergen C and the aggregated peptide melittin. The vespid wasp venoms contain hyaluronidase, a phospholipase A₁B unrelated to the bee phospholipase, an invertebrate neurotoxin called antigen 5 and at least two minor proteins. Bumblebee venoms contain a tryptic amidase. Venoms from ants of the genus *Solenopsis* are over 90% water-insoluble piperidine alkaloids, but contain nanogram amounts of three or four allergenic proteins de-

pending on the species. *Pogonomyrmex* venom contains several enzymes including a phospholipase. Ponerine ant venoms are as yet uncharacterized. Australian bulldog and jack-jumper ants (*Myrmecia* spp.) contain a series of apparently unique allergens. Immunologic cross-reactions are commonly seen among the vespid venoms and between bee and vespid hyaluronidase. Allergen Sol i and r I from *Solenopsis* cross-reacts with vespid wasp venoms. Well-characterized insect venom allergens are summarized in Table 1.

There is good evidence that almost all severe reactions to insect venoms are IgE mediated. These range from extensive subcutaneous swelling contiguous with the sting site (large local reactions) to fatal anaphylaxis. In several studies specific IgE antibodies against venom were demonstrated in blood from all victims of fatal sting anaphylaxis. Uncommon reactions to venoms include a serum sickness-like syndrome, recurrent cold urticaria, and a nonimmunologic mediator release that mimics anaphylaxis in patients with mast cell disorders like urticaria pigmentosa. IgE antibodies in patients can be detected by either intradermal skin testing with 1 µg ml⁻¹ or lower concentrations of venom or by *in vitro* tests for specific IgE antibodies. High concentrations of venom may give nonspecific skin reactions because of the mediator and basic peptide contents of venoms. Sting challenge is used as a research tool for diagnosis and evaluation of immunotherapy. Approximately 50–60% of untreated patients with a

Table 1 Characterized insect venom allergens

Allergen	From	Molecular weight	Related to	Male related
Phospholipase A ₂	Bees	16 000 14 500 (–CHO)	Vertebrate secretory phospholipase A ₂ s	+
Hyaluronidase	Bees, wasps	43 000 39 000 (–CHO)	Vertebrate hyaluronidases	+

recent history of a prior systemic reaction will have a systemic reaction to a live sting challenge. Extensive studies using sting challenges have demonstrated a 90–98% efficacy of venom immunotherapy in protecting from systemic reactions.

The mechanisms of protection in venom immunotherapy have been extensively studied. It was first noted that beekeepers who are frequently stung suffer systemic reactions very rarely, while those that are stung once or twice a year have a high incidence of reactions. Laboratory studies showed comparable prevalence and levels of specific IgE antibodies in both groups, but very high levels of specific IgG antibodies in the frequently stung group. A group of volunteers who were sting challenge positive were administered IgG fractions prepared from beekeepers with a high level of specific IgG antibody. On rechallenge all experienced either no reaction or much milder symptoms. It is proposed that the IgG acts as a blocking antibody, preventing the venom allergens from combining with mast cell-bound IgE. During the first years of immunotherapy there is a good correlation between increased specific IgG levels and a state of protection. Long-term studies of patients on immunotherapy have shown that virtually all patients can stop receiving venom after 5 years and that they remain protected for at least 2 additional years, even though the specific IgG has significantly declined and the specific IgE is still present. The mechanism of this effect is not known. Studies of the natural history of venom allergy have shown that children tend to lose their specific IgE antibodies and reactivity naturally; however many adults remain sensitive for 20 years or more.

Ants of the genus *Pseudomyrmex* have a venom that inactivates C2, C3, C4, B and I components of complement. It also contains a trypsin-like enzyme. *In vivo* this venom has a significant anti-inflammatory effect.

Arachnids

Over 1000 people die annually from scorpion stings. Scorpion venoms contain neurotoxins, cardiovascular toxins and toxins that induce necrotic inflammation, e.g. pancreatitis. The neurotoxins have been extensively studied and are generally basic polypeptides of 60–65 amino acids with four disulfide bonds. The α -toxins slow down the inactivation of the sodium channel and the β -toxins bind synaptosomes at a distinct site and are voltage independent. Many of the neurotoxins have been sequenced and their immunology extensively studied. The toxins show more antigenic cross-reactivity between species than between types and subtypes of toxins. Scorpions can

also project venom, which can cause severe eye damage. A variety of antivenoms are prepared in France, Egypt, Mexico, Brazil, Britain and other countries. Some cross-neutralization has been found between antivenom for the North African *Buthrus* and North American *Centruroides*, but it is best to use the antivenom preparation raised against the appropriate species.

All spiders can inject venom when they bite. Severe reactions usually fall into two patterns: lathrism and loxoscelism. Lathrism consists of excruciating cramp-like pain, chest tightness and various other symptoms. It is primarily mediated by a neurotoxin and follows bites of the genera *Latrodectus*, black widows and *Atrax*. Loxoscelism is a necrotic type of reaction, many times exhibiting repeated waves of partial healing followed by expanding necrosis. Hemolytic anemia is the most common systemic symptom. Occasionally a slow progressive deterioration develops, ending in death. Bites of spiders of the genus *Chiracanthium* may lead to reactions that are both neurotoxic and locally necrotic. Antivenom prepared in horses against *Latrodectus* is commercially available in the USA. Antivenom against *Loxosceles* is only useful when administered within 36 h of the bite.

Reptiles and amphibians

Poisonous snakes belong to four families, Viperidae or vipers with two subfamilies Viperinae and Crotalinae, Elapidae or fixed front-fanged snakes, Hydrophidae or sea snakes including some Australian snakes, and Colubridae or back-fanged snakes. The crotalid venoms are usually toxic to tissues, although there are some species that have venoms with primary neurotoxic activity. The elapid venoms function primarily as neurotoxins; some contain factors that react with complement components (e.g. cobra venom factor). In various venoms cytotoxic, cardiovascular, anticoagulant, hemorrhagic, myotoxic, nephrotoxic, autopharmacologic or neurotoxic effects may dominate. Direct host immunologic reactions to reptile and amphibian venoms are unusual. There are now a number of reports that convincingly demonstrate IgE-mediated allergic reactions to reptilian venoms. As can all foreign proteins, venoms induce antibody formation. Individuals who suffer repeated envenomations develop high levels of protective IgG antibodies against the venoms. This has been best studied in those who milk snake venom for commercial producers.

Symptomatic envenomation is treated by injection of passive antibody, usually of horse or goat origin. Antivenom is given until the progression of symp-

toms is halted or reversed. The antivenom for crotalids is polyvalent and is known to be effective against venoms from *Crotalus*, *Agkistrodon*, *Sistrurus*, *Bothrops* and *Lachesis* species. Antivenoms against elapid, hydrophid and colubrid venoms are much more specific and are generally available in only the countries in which the particular snake is found. In the USA many snake envenomations are the result of keeping exotic species as pets. Immunologic reactions to antivenom are common. IgE-mediated allergic reactions to the foreign serum proteins can be ruled out by performing an intradermal skin test with diluted antivenom before administration. Individuals with positive skin tests need to be desensitized by having antivenom administered starting with a very small amount and doubling the dose every 15 min. Serum sickness, both primary and accelerated, is a common complication of antivenom therapy. Its incidence and severity increase in a dose-dependent manner.

Immunoassays are used in the diagnosis of snake bite, especially in Australia, where a commercial kit is available.

Marine animals

Approximately 100 species of fish inject venoms dangerous to humans. These include some sharks, rays, catfish, weever fish, scorpion fish and star-gazers. The most dangerous are *Scorpaena* (scorpion fish) and *Synanceja* (stonefish). Stings cause excruciating pain and extensive multisystemic symptoms. Antivenoms are commercially available from Australia.

Many marine coelenterates have venomous nematocysts on their tentacles or spines. The venoms generally cause direct toxic symptoms and release mediators including histamine and prostaglandins. Local treatment with 4–6% acetic acid usually reduces symptoms significantly. Allergic reactions,

presumably IgE-mediated, from *Physalia* (the Portuguese man-of-war) have been reported. The sea wasp (*Chironex fleckeri*) can deliver life-threatening stings and an antivenom is available from Australia.

VETO CELLS

Richard G Miller, Ontario Cancer Institute, Princess Margaret Hospital, Toronto, Canada

Veto cells were initially proposed on theoretical grounds as cells which could inactivate mature T lymphocytes that recognize them. One could regard them as antigen-presenting cells that inactivate rather than stimulate T cells that recognize them. Cells with this property could play a useful role in the establishment and maintenance of T cell tolerance to self anti-

gens, and in the downregulation of an immune response. Veto cells are readily distinguishable from T suppressor cells, which are thought to have a specific receptor; they regulate T cells they recognize via this receptor. With veto cells recognition is the other way. They carry specific antigen and regulate T cells on being recognized.

There is a growing body of experimental evidence for the existence of a veto cell that can delete cytotoxic T lymphocyte (CTL) precursors reactive against allogeneic class I major histocompatibility complex (MHC) molecules or against antigens presented in association with self class I MHC. Certain cells in bone marrow and in fetal liver, as well as CTLs themselves, can act as veto cells. Note that when any cell (including a CTL) acts as a veto cell, specificity is determined by the class I MHC molecule and associated peptide on the veto cell surface rather than the specificity of any T cell receptor which might be present on that cell.

Veto activity was first described in *in vitro* mixed lymphocyte cultures (MLC). Letting A, B and C be three MHC different inbred mouse strains, veto cells from strain A block CTL precursor activation when included in a B anti-A MLC but not when included in an A anti-B or B anti-C MLC. Studies in this system have led to the following conclusions:

1. Veto cells must carry the antigenic determinant (including the class I MHC restricting element) against which the response is being suppressed.
2. Veto cells act early in an immune response and produce functional deletion of CTL precursors capable of recognizing them. Deletion is probably physical, with death occurring by apoptosis. Veto cells are ineffective against mature CTLs.
3. Veto activity can occur in the presence of appropriate stimulatory antigen-presenting cells and lymphokines such as interleukin 2 (IL-2).
4. Cells carrying CD8 can act as veto cells. CD8 on the veto cell interacts with the α_3 domain of the class I MHC on the recognizing T cell. This, in

conjunction with the signal through the T cell receptor, leads to the death of the T cell.

What appears to be veto activity has also been demonstrated *in vivo*. CTL precursors reactive against allogeneic class I MHC molecules or against minor H antigens can be inactivated *in vivo* by injecting the host with viable CD8⁺ T cells carrying those antigens. Survival of subsequent grafts carrying the same antigens as the injected T cells is greatly enhanced.

There are conflicting data as to whether there are veto cells capable of inactivating T cells restricted by or reactive against class II MHC. Note that if such veto cells do exist, they must necessarily carry class II MHC products and it is these products that would determine their specificity.

The *in vivo* role of veto cells remains unclear but they may be important in establishing/maintaining peripheral T cell tolerance and in immunoregulation.

VIABILITY, METHODS OF ASSESSING LEUKOCYTE

Francis J Hornicek and **George I Malinin**, Department of Orthopaedics and Rehabilitation (R-12), University of Miami School of Medicine, Miami, USA

The advent of cell culture methodology in the early twentieth century imposed a requirement for rapid and reliable methods to assess the viability of cells maintained *in vitro*. In 1914, by establishing a positive correlation between the capacity of intact cells to exclude exogenous dyes and their viability, Evans and Schuleman laid the foundation of all viability assays based on the dye exclusion principle. Soon thereafter Pappenheimer determined the viability of

isolated thymocytes by microscopic enumeration of trypan blue stained and unstained cells. Although many dyes have been used for viability assays, the anionic dye trypan blue (961 Da) is the one most frequently employed.

The viability of leukocytes as assessed by trypan blue exclusion is usually determined by suspending the cells either in a balanced salt solution or in phosphate-buffered saline. After diluting the cell suspen-

sion with the corresponding salt solution, it is mixed with 0.4% w/v freshly filtered trypan blue dissolved in an identical salt solution. Thereafter, leukocytes are counted on a hemacytometer, and the percentage viability is calculated by dividing the number of viable (unstained) cells by the number of all counted cells (stained and unstained). Until the middle of the twentieth century, microscopic assessment of dye exclusion was the sole practical method of determining viability. Rapid strides in particle counting, computing and ancillary technologies made in the 1960s spawned a number of commercially produced, versatile flow cytometric systems. In contrast to microscopic viability assays, numerically large cell samples can be analyzed by flow cytometry within minutes. In this case the fundamental principle of viability assessment, i.e. viability implies plasma membrane integrity, remains inviolate. In flow cytometric procedures, fluorochromes such as fluorescein diacetate, 4'-6-diamidino-2-phenylindole, acridine orange and propidium iodide are commonly used instead of non-fluorescent dyes employed in microscopic assays.

All cell populations assayed for viability invariably contain dead and dying cells. Regardless of whether necrosis or apoptosis is the underlying cause of cell death, dead and dying cells undergo progressive degradation of their macromolecular components, such as RNA, and consequently lose their affinity for supravital dyes. For this reason any leukocyte population to be assayed for viability must be regarded from the onset as consisting of viable dye excluding cells, morphologically intact nonviable stained cells, and dead chromophobic cells. The failure to include all three categories of cells in viability determinations may yield a significantly higher viability index than its true value.

The identification of nonviable chromophobic cells is practically unattainable with a hemacytometer. They can, however, be identified and counted in fixed leukocyte smears after staining at acidic pH with a cationic dye such as toluidine blue. Dead chromophobic cells in these smears are recognized by the absence of cytoplasmic and/or nuclear basophilia.

Analogous determinations can be performed more expeditiously by flow cytometric methods. In such cases, unfixed cells stained with acridine orange and ethidium bromide are quantified by single-laser multiparametric flow cytometry. Moreover, cells with damaged plasma membranes (nonviable)

undergoing progressive structural degradation (apoptosis) have a lower refractive index than viable cells. As a consequence, optical properties and especially forward light scatter of such cells differ from their viable counterparts. These differences may also be used for flow cytometric assessment of cell death by forward and right-angle light scatter.

Viability assays performed with a hemacytometer and by flow cytometry usually yield higher viability values with the latter method. This quantification disparity is generally attributed to the higher sensitivity of flow cytometric systems as compared with visual observation. A real possibility that laser illumination of cells stained with photosensitizers may inflict lethal photosensitization of analyzed cells is essentially ignored in reporting results. For all practical purposes there is no ideal method of cell viability determination. Therefore, a choice of a specific assay procedure is frequently a matter of personal preference and the accessibility of requisite instrumentation and facilities.

VIBRIO CHOLERAЕ, INFECTION AND IMMUNITY

Paul A Manning, Microbial Pathogenesis Unit, Department of Microbiology and Immunology, The University of Adelaide, Adelaide, Australia

Vibrio cholerae is the causative agent of the acute diarrheal disease cholera. It is a complex pathogen expressing a variety of virulence factors necessary for adherence to and colonization of the gut, as well as a variety of toxins including the potent cholera enterotoxin and other secreted proteins. A number of protective antigens have been defined and considerable progress has been made along the path of vaccine development. However, matters have been complicated by strain variation and the ability to change, apparently under immune pressure, which only in 1992 led to a newly evolved serotype being associated with the disease.

Characteristics of the organism and the disease

Cholera is a term from the ancient Greek and the early writings could have equally well referred to dysentery and diarrhea which are associated with other enterobacterial pathogens such as *Shigella* spp., enteropathogenic *Escherichia coli* and some *Salmonella* spp. However, although Indian writings had various names for the disease, descriptions from as early as the time of Lord Buddha (500–400 BC) basically describe the disease of cholera as we know it. Cholera was probably endemic to the Ganges delta and its spread from this region corresponds well with the development of travel.

Seven great pandemics have been described, beginning in 1817. During this time cholera has produced mortality and morbidity of immense proportions to humanity, reaching every continent with the probable exception of Antarctica. The Russian composer Peter Ilich Tchaikovsky is reported to have died, under suspicious circumstances, of 'the cholera' in the outbreak of 1891–92 which was brought to European Russia by pilgrims returning from Mecca.

In 1854, John Snow brought notoriety to the Broad Street pump by correlating deaths due to cholera with the source of water used in different households, and so providing the first explanation for the etiology of cholera. In the same year Pacini described the comma-shaped organism now known as *Vibrio cholerae*, which subsequently was shown to be the causative agent by Koch in 1883.

V. cholerae is a gram-negative facultative bac-

terium with a single polar sheathed flagellum (Figure 1), with the sheath being essentially an extension of the outer membrane lipid bilayer containing lipopolysaccharide (LPS). There are more than 139 O serogroups (variant forms of LPS) and prior to 1992 only organisms of the O1 serotype were responsible for epidemic cholera in humans. Non-O1 or non-cholera-vibrios (NCVs) or *V. cholerae* which do not agglutinate (NAGs) with O1 antisera were not associated with cholera although they could cause acute diarrheal disease. However, in 1992 a new serotype designated O139 (Bengal) arose on the Indian sub-continent and rapidly replaced the O1 strains as the epidemic agent, but after about 2–3 years the O1 strains re-emerged as the major form.

O1 strains can also be grouped into two biotypes: classical and El Tor. The El Tor biotype was first isolated at an Arabian field station of the same name in the early part of this century. These strains could be differentiated by their ability to produce a soluble hemolysin, for sheep and goat erythrocytes, not detected in classical isolates. More recently, this property has been shown to be variable amongst El Tor

Figure 1 Electron micrograph of cells of *Vibrio cholerae* stained with uranyl acetate. The cells were grown under conditions to optimize the expression of TCP (T) which have been identified by immunogold labeling. The polar sheathed flagellum (F) can also be seen.

strains and other methods such as sensitivity of the classical biotype to the antibiotic polymyxin B and the type IV phages of Mukerjee are used for biotype differentiation. El Tor strains also produce a positive Voges-Proskauer reaction and can agglutinate chicken erythrocytes.

The O groups are associated with the O antigens of the lipopolysaccharides (LPS). O1 strains can be subdivided into Inaba and Ogawa serotypes and a third form, Hikojima, would appear to be a regulatory variant of Ogawa. *V. cholerae* O1 can undergo a form of antigenic variation involving serotype switching from Inaba to Ogawa or the reverse and genetic and chemical analyses have demonstrated that Ogawa O antigen is a methylated form of Inaba, and that Inaba strains are mutants in the 'methylase'. Thus, switching from Ogawa to Inaba involves selection of a mutation in the methylase and the reciprocal switch involves reversion of a mutation. The selection pressure for the switch is thought to be provided by the immune response. The new O139 (Bengal) serotype has been shown to be essentially an O1 El Tor strain in which the region of the chromosome encoding O antigen biosynthesis was replaced by genes encoding both the O139 O antigen and an antigenically related capsule. The genetic means by which this event has occurred are somewhat obscure but there is evidence for the involvement of an insertion sequence (IS1358).

Pathogenesis

V. cholerae typically infects by the oral-fecal route, primarily via contaminated food and water supplies. The bacteria are very sensitive to stomach acid, which provides a natural barrier. However, food particles in particular may provide sufficient protection for an infectious dose to reach the small intestine where the organism must adhere, multiply and colonize the mucosal surface. The vibrios remain attached to the intestinal epithelium throughout the course of the infection. They do not invade or cross the epithelium although some local damage can be detected and this is most marked with El Tor strains. Whilst in association with the small bowel, the vibrios secrete, besides cholera toxin, a number of extracellular products which facilitate the colonization process and are responsible for the net secretion of fluids into the intestinal lumen resulting in the typical rice-water stools. The extent of fluid loss in the diarrhea is variable but can approach one-third of body weight per day.

Thus, the symptoms of cholera are essentially the result of extreme fluid loss and a relatively simple treatment has been developed. This involves fluid

replacement therapy based upon a defined solution of salts and glucose designed to facilitate restoration of the fluid and electrolyte balance. This treatment does not reduce the amount of purging, and antibiotic therapy, usually with tetracyclines, may be additionally used.

Toxins

The *V. cholerae* enterotoxin, cholera toxin (CT), is one of the best studied bacterial toxins both in terms of structure, function and genetics. CT is comprised of one A and five B subunits and the A subunit is nicked and activated by either an endogenous *V. cholerae* protease or one encountered in the gut, to give the A₁ and A₂ chains which are held together via a disulfide bridge. The N-terminal A₁ subunit possesses the ADP-ribosylating activity which catalyzes the transfer of NAD to the G_s regulatory component of the adenylate cyclase, resulting in increased activity of the enzyme. The direct consequence of an elevation of the intracellular cAMP concentration is an increase in specific ion (primarily Cl⁻) efflux and a decrease in specific ion (primarily Na⁺) absorption which provides a potent osmotic driving force for the loss of water. Hence, the watery diarrhea ensues.

Extensive genetic analysis has shown that the cholera toxin genes *ctxA* and *ctxB* exist as an operon under the control of a positive regulatory environmental sensory system which also coregulates the expression of several other virulence determinants including a critical colonization factor, the toxin-coregulated pilus (TCP). The *ctxAB* operon is contained within a virulence cassette associated with transposon-like repeat sequences which are capable of mediating the tandem multiplication of the operon. Under the appropriate selection conditions, such as *in vivo* passage, this can lead to many copies of the CT genes within the cell and consequently increased capacity to produce cholera toxin. The B subunits are essential for the secretion of CT and also provide the binding component to permit it to interact with its receptor, GM₁ ganglioside on the surface of the eukaryotic cell.

The genes for two other toxins, ACE (accessory cholera enterotoxin) and ZOT (zonula occludens toxin), are contained within the same virulence cassette as the CT genes. However, their functions in pathogenesis are less well-defined than CT, except that ACE has enterotoxin activity and ZOT is reported to destroy the tight junctions in the intestinal epithelium.

Other toxins have been reported in *V. cholerae* but the most significant is the El Tor hemolysin which

has both enterotoxic (cytolytic) and cytotoxic activities. It is under different genetic control to CT and classical strains possess a small deletion within the *hlyA* structural gene rendering them nonhemolytic. Elimination of the hemolysin from El Tor strains markedly changes the pathology of the tissue at the site of infection, as well as the appearance of the diarrheal stool.

Adherence and colonization

Numerous components have been implicated in the processes of adherence and colonization. These include surface components such as LPS, outer membrane proteins, the flagellum and pili or fimbriae, as well as extracellular products like DNAases, proteases and neuraminidase. Mutants in the production of TCP or a mannose–fucose-resistant hemagglutinin are dramatically affected in their ability to colonize presumably because of a defect in adherence. Mutations eliminating LPS O antigen biosynthesis are also attenuating but this is probably due to pleiotropic effects including preventing the assembly of TCP. The mannose-sensitive hemagglutinin is also a pilus adhesin and was initially thought to be an El Tor equivalent to TCP, but its role in colonization of the gut is questionable.

The neuraminidase is capable of converting higher gangliosides to GM₁, effectively increasing the availability of receptors for CT. Under appropriate conditions a significant reduction in virulence can be detected in neuraminidase-less mutants. Although other components may contribute to adherence and colonization, the corresponding mutants are not necessarily attenuating. However, as was the case with the neuraminidase, due to insufficient knowledge, the conditions under which these components are critical for virulence may not have been used for comparing the parent and mutant strains. It is also clear that there are factors which may be only expressed *in vivo* and have not been detected by conventional experimental protocols.

Protective antigens and immunity

Protection against cholera requires mucosal immunity optimally mediated via locally produced secretory IgA antibodies. Since *V. cholerae* is a noninvasive pathogen, it is thought that these antibodies function to block adherence and inhibit colonization, and possibly to either neutralize the toxins or prevent them from binding to their specific receptors. The immune response in the intestine is initiated in the lymphoid follicles which can occur in isolation or as clusters known as Peyer's patches. The mononuclear

cells of this tissue are responsible for the phagocytic sampling of antigen from the intestinal lumen. Live *V. cholerae* organisms are a more efficient antigen for stimulating an immune response than killed organisms.

Epidemiological data suggest that an initial cholera infection provides long-lasting immunity and this agrees with studies performed on human volunteers. The most significant protective antigen appears to be the O antigen of the LPS, however, it is clear from animal model studies that antibodies to TCP are protective but biotype restricted due to biotype-specific antigenic variation in the major structural subunit. The B subunit of CT is the best-documented other protective antigen, but there also appears to be biotype-specific epitope differences.

The ability of the newly evolved O139 serotype to replace O1 as the epidemic strain heightens the importance of anti-LPS immunity, since O139 strains possess all of the known virulence attributes of O1 El Tor strains. The incidence of O139 was the same throughout all age groups suggesting that acquired immunity to non-LPS antigens was far less significant than to the specific LPS type. The available data also imply that non-LPS antigens are less immunogenic. O139 strains are also novel in that they produce a capsule, but because of its antigenic similarity to the O139 LPS, the relative protective activity of antibodies to these two structures is not clear.

Vaccine development

No effective cholera vaccine has yet been put into widespread use. Immunity to cholera can occur in the absence of antibodies to CT, but experimental studies suggest that antibacterial and antitoxic immunities can act in synergy. A vaccine based on killed whole cells and purified CT B subunit has shown promise in extensive field trials in Bangladesh and elsewhere, but the presence of B subunit in the preparation only seems to be important for immunity in the first year or two.

The incorporation of the B subunit may have other benefits since CT has been demonstrated to have adjuvant activity, and at least the B subunit is critical. However, recent data indicate that this can be further enhanced by using whole CT in which the A subunit has been mutated to eliminate its ADP-ribosylating activity.

Much attention has been given to constructing attenuated *V. cholerae* strains in which specific genes have been deleted or their expression modified. Various strains have been constructed in which one or both of the *ctx* genes have been deleted, but all still produce a mild diarrheal response in a significant

proportion of volunteers. This is in part correlated with the colonizing potential of the vaccine strain. One construct, CVD103Hg^R, based upon a poorly colonizing strain in which *ctxA* has been deleted, as well as several other modifications, seems to be efficacious and is being evaluated in the field. There is also considerable variation in the success of this approach and this again appears to be strain-dependent, as was observed with O139 strains into which the same mutations were introduced.

A further approach has been to express the genes for the protective antigens in heterologous vaccine strains such as attenuated *Salmonella typhi*. Experiments with strains expressing the *V. cholerae* O antigens show that construction of such chimeric vaccine strains has potential.

Environmental *V. cholerae* O1

The so-called environmental *V. cholerae* O1 El Tor strains commonly isolated from surface waters have a number of features which distinguish them from the epidemic cholera strains. They are referred to as nontoxigenic in that they lack the *ctxA,B* genes; however, they invariably express the El Tor hemolysin. These strains also lack the genes encoding the biosynthesis of the colonization pilus, TCP, but although other pili have been identified, there are no convincing data on their role in colonization. The mechanism by which these organisms cause disease appears to differ from toxigenic epidemic O1 and O139 strains.

VIRUSES, IMMUNITY TO

Andrew Carmichael and **JG Patrick Sissons**, Department of Medicine, University of Cambridge Clinical School, Cambridge, UK

Viruses are obligate intracellular parasites which can cause a spectrum of disease from asymptomatic persistent infection to fatal illness. The need to resist virus infection has been a major driving force in the evolution of the immune system, in particular of those facets of the immune response involved in the recognition of foreign antigens on the surface of cells. From the time of Jenner's observation that exposure to cowpox gave protection, or immunity, against smallpox, the study of viruses has prompted research in immunology, and the disciplines of virology and immunology continue to be closely interrelated. For instance, a considerable amount of

work in immunology is still driven by the need to produce vaccines to protect against current pathogens, such as human immunodeficiency virus (HIV). Detailed studies of individual viruses (such as influenza) have made important contributions to the understanding of molecular recognition of antigen by T cells, and recombinant vaccinia viruses provide a research tool for introducing foreign antigens into cells. As well as producing tissue damage by direct cytopathic effects, viruses may also evoke immune responses which are harmful to the host; these may include responses directed primarily against virus-infected cells (in which uninfected bystander cells

may also be damaged), and autoimmune responses against uninfected cells.

Viruses as antigens

Viruses consist of a central core of nucleic acid which may be RNA or DNA, and single- or double-stranded. This is surrounded by a coat (capsid) of repeating protein subunits (capsomers). In most viruses, the capsomers are arranged symmetrically around the nucleic acid, either as an icosahedron or as a helix. Some viruses also have a lipid envelope derived from the host cell membrane into which viral glycoproteins are inserted. The structure of some smaller viruses (such as polio), and component proteins of more complex viruses (such as influenza hemagglutinin, HA) has been solved at high resolution by X-ray crystallography. Viruses are classified according to the type of nucleic acid making up the genome, whether the genome is segmented or not, and the presence or absence of an outer envelope. Viral genomes vary in size from very small (such as parvovirus with 5 kb of single-stranded DNA) to large (such as poxviruses with up to 280 kb of double-stranded DNA).

Viral infection begins with the attachment of the virus to a component of the cell membrane which acts as its specific receptor, such as the CD4 molecule on T cells to which HIV binds, or sialic acid for the influenza virus hemagglutinin. Enveloped viruses may penetrate the cell by fusion with the cell membrane (mediated by fusogenic viral glycoproteins, e.g. Sendai virus) or by endocytosis after binding to their specific receptor (e.g. influenza). In the latter case, the virus then enters the cytoplasm by fusion with the endosomal membrane following an acidic pH-dependent cleavage of viral glycoproteins. Viruses are then uncoated allowing transcription and translation of viral nucleic acids (single positive-stranded RNA viruses are translated directly). In more complex viruses, some of the viral proteins expressed in the infected cell do not form part of the virion; these nonstructural proteins serve functions such as regulating the transcription of other viral and cellular genes, and shutting down synthesis of host cell proteins. Other viral proteins are structural and are incorporated into new virions. Following viral nucleic acid replication, virus particles are assembled by aggregation of structural proteins around the nucleic acid. Nonenveloped viruses may be released from the cell by lysis, whereas enveloped viruses insert their viral glycoproteins into the host cell membrane and bud from the cell surface.

The immune response to viruses

Studies of patients with isolated immunodeficiencies give an insight into the relative importance of the different components of the immune response. Individuals with isolated defects of cell-mediated immunity develop severe, sometimes fatal viral infections such as measles and chickenpox. A single case of natural killer (NK) cell deficiency has been reported, with increased susceptibility to severe primary herpesvirus infections. Those subjects with isolated immunoglobulin deficiency recover normally from most viral infections, except enteroviruses (which may cause chronic central nervous system infection). Such 'experiments of nature' coupled with an extensive body of experimental work in animal models permit the following generalizations.

Antibodies appear to act principally by neutralizing virions (i.e. rendering virions noninfectious), whereas cell-mediated responses are directed against virus antigens present in the infected cell. Antibody is important in preventing primary infection and reinfection, by neutralizing viruses on mucosal surfaces and limiting their dissemination in body fluids, while cell-mediated immunity seems to be responsible for eliminating intracellular infection and limiting reactivation of persistent viruses.

The immune response may be divided into three phases (see Table 1) and into humoral and cell-mediated components, which include specific and nonspecific mechanisms.

Nonspecific immunity (natural killer cells and interferons)

Natural killer (NK) cells are large granular lymphocytes (CD16⁺, CD56⁺ but without an expressed T cell receptor or CD3), which are able to kill virus-infected cells without prior exposure to that virus. NK cell recognition of virus-infected cells differs

Table 1 Phases of the immune response against virus infection

Phase	Characteristics	Mechanism
Immediate <4 h	Nonspecific, innate No memory No specific T cells	NK cells
Early 4–96 h	Nonspecific, inducible No memory No specific T cells	IFN α , IFN β IFN-activated NK cells
Late >96 h	Specific, inducible Memory Specific T cells	Antibody Cytotoxic T cells Cytokine-secreting T cells

IFN, interferon.

from the classical major histocompatibility complex (MHC) restriction of T cells, but is affected by MHC molecule expression; the lower the level of MHC class I expression on the surface of the target cells, the greater their susceptibility to killing by NK cells. This is because specific MHC class I alleles on the surface of target cells can *inhibit* killing by defined NK cell clones, and thus normal levels of expression of certain autologous MHC class I molecules may protect uninfected host cells from being killed by NK cells.

NK cells are activated by interferon α (IFN α) and IFN β released by virus-infected cells, and by certain viral glycoproteins, e.g. mumps hemagglutinin. Virus-infected cells show increased susceptibility to NK cell lysis compared to uninfected cells. The reasons for this are not fully understood, although several mechanisms have been proposed. These include enhanced binding of NK cells to virus-infected cells; increased susceptibility of infected cells to NK killing due to inhibition of host cell RNA and protein synthesis; altered surface expression of host cell proteins (e.g. reduced surface expression of MHC class I); and the protective effects of IFNs on noninfected cells. Natural killer lysis is not prevented by blocking the synthesis or surface expression of structural viral proteins.

It is thought the NK cells are an important defense mechanism early in the course of viral infection, before specific cytotoxic T lymphocytes (CTLs) and antibody responses have fully developed. In experimental models, NK cells seem to be more important in resistance to certain viral infections, such as herpesviruses, than to others. In mice, for example, NK cells protect against murine cytomegalovirus (MCMV), but not against lymphocytic choriomeningitis virus (LCMV).

Type I interferons (IFN α and IFN β) are proteins produced by a wide variety of cell types in response to virus infection and other stimuli such as double-stranded RNA. IFN α and IFN β bind to a common receptor on the surface of uninfected cells and produce an 'antiviral state' by stimulating synthesis of cellular proteins which interfere with viral RNA transcription and translation. Type I IFNs are completely nonspecific, and are produced in response to, and against, a wide range of viruses. The importance of IFN α and IFN β in host resistance to viruses is clearly illustrated by transgenic mice which lack a functional type I IFN receptor; these animals show greatly increased susceptibility to acute virus infection, leading to death within 3 days of infection associated with very high titers of virus in many organs. The type II interferon IFN γ is produced by NK cells and by T cells on exposure to specific anti-

gen, and activates monocytes and macrophages, enhancing their ability to process and present antigen. IFNs also activate NK cells and the effector cells responsible for antibody-dependent cellular cytotoxicity (ADCC) and give rise to many of the systemic symptoms associated with viral infections, such as fever, malaise and myalgia. Tumor necrosis factor α (TNF α) also has an antiviral effect which may be synergistic with that of IFNs.

Humoral response

The major class of virus-specific antibody is immunoglobulin G (IgG). IgM is also produced during the early phase of primary infection, and secretory IgA is important in prevention of viral entry via mucosal surfaces. Virus-specific antibodies may bind to viral epitopes on the surface of the virion, or to viral glycoproteins expressed on the surface of the infected cell. In order to neutralize the virion, a specific antibody must bind with high avidity to particular epitopes on viral proteins that interact with cell surface receptors. While antibodies can be raised against individual small linear peptides derived from a viral glycoprotein such as influenza hemagglutinin, these antibodies are frequently non-neutralizing; many or most neutralization epitopes are probably conformational ones. Antibody may also limit the spread of infection by agglutination of virions (reducing the number of infectious units), and by enhancing the phagocytosis of virions by mononuclear phagocytes (opsonization).

Antibody may also recruit other effector systems. *In vitro*, antibody attached to viral glycoproteins may lead to complement-mediated lysis of the infected cell and of enveloped virions. Certain cells with Fc receptors (CD16⁺ cells such as NK cells and monocytes) may bind to the Fc portion of virus-specific antibodies bound to viral glycoproteins on the cell surface and subsequently lyse the infected cell by ADCC. The precise importance of ADCC and complement-mediated lysis of virus-infected cells *in vivo* is unclear.

Complement enhances the effect of neutralizing antibody by coating the surface of sensitized virions preventing their interaction with cellular receptors. Complement also acts as an opsonin for phagocytic cells. Some viruses may activate complement directly by the alternative pathway.

Specific cell-mediated responses

Virus-specific CTLs are predominantly CD8⁺ in phenotype, although approximately 10% of human peripheral blood CD4⁺ T cells are potentially cyto-

toxic and capable of giving rise to virus-specific CTLs. CTLs recognize viral antigens which have been processed and presented as peptides on the surface of infected cells by the appropriate MHC molecules; class I in the case of CD8⁺ T cells, class II for CD4⁺ T cells. Processing and presentation of viral antigen allows viral proteins not otherwise expressed on the cell surface to be exposed to T cells, e.g. influenza nucleoprotein. Hence, an infected cell can be recognized and killed by T cells before the virus can replicate, thereby limiting the spread of the infection. Whilst recognition of viral antigen by T cells requires interaction between the T cell receptor and the MHC-antigen complex, interactions between accessory molecules including LFA-1 and ICAM-1, and LFA-3 and CD2 facilitate effector T cell binding to a virus-infected cell. With a few exceptions such as reovirus, CTLs are not serotype specific, i.e. they do not recognize the same epitopes as virus-specific antibodies. The ability of CTLs to confer protection against viral disease can be demonstrated by adoptive transfer in many experimental virus models; for example, naive mice can be protected against lethal influenza A by prior transfer of an influenza A-specific CTL clone. The T cell response to virus infection includes cytotoxic effector T cells and an expanded population of virus-specific memory T cells. After clearance of an acute virus infection (e.g. influenza, in which viral antigen is completely eradicated), effector T cells rapidly disappear, and the size of the memory T cell population may gradually diminish over time. In contrast, in many persistent virus infections (e.g. Epstein-Barr virus (EBV), human cytomegalovirus (HCMV)), virus-specific memory CTL precursors remain at high frequency for many years, and probably play a role in controlling the reactivation of persistent virus and maintaining the normal equilibrium between virus and host.

CD4⁺ T cells may recognize multiple epitopes within a given viral protein, such as influenza HA, and these epitopes may differ from those recognized by antibody. CD4⁺ T cells augment T cell, B cell and NK cell responses to viral proteins through secretion of cytokines including IL-2, IL-12 and IFN γ . Cytokines secreted by subpopulations of virus-specific CD4⁺ T cells and CD8⁺ CTLs contribute to the generation of the delayed-type hypersensitivity (DTH) response, an inflammatory reaction characterized by a mononuclear cell infiltrate of activated lymphocytes and macrophages. In some experimental virus infections, DTH responses can confer resistance to infection; in response to local infection with herpes simplex virus (HSV) inoculated into the ear pinna in mice, CD4⁺ T lymphocytes from the draining lymph nodes proliferate in response to HSV antigens,

mediate DTH and upon adoptive transfer can mediate protection against HSV in naive mice. However, DTH can sometimes be harmful. Mice which have previously been exposed to noninfectious influenzavirus suffer increased mortality when they are subsequently challenged with live influenzavirus: adoptive transfer experiments have shown that induction of strong DTH (by prior exposure to non-infectious virus) may be responsible for this observed increase in mortality.

In vivo, the different T cell populations obviously interact together rather than producing effects in isolation, and can show considerable plasticity. Transgenic mice that lack β_2 -microglobulin (which results in grossly impaired CD8⁺ T cell development), are able to resist infections by induction of increased numbers of virus-specific CD4⁺ CTLs.

Persistent viral infections

Many viruses are able to maintain long-term infections which are often symptomless. This may involve chronic production of infectious virus, or latent infection with intermittent reactivation leading to virion production. Certain viruses may exhibit both patterns dependent on host cell type – for example, hepatitis B virus appears to latently infect lymphocytes but produces infectious virus in hepatocytes. In order to establish a successful persistent infection, a virus should minimize damage of host cells. Certain noncytopathic viruses such as the murine arenavirus LCMV replicate with little apparent disruption of cell function. Other viruses have evolved different strategies that can reduce their lytic potential. These include restricted virus gene expression (in the herpesviruses during their latent nonlytic infection of neuronal or lymphoid cells); the generation of mutant viral strains which do not cause cell lysis (in reovirus after *in vitro* passage in fibroblast lines); and infections where only a small percentage of cells are infected at any one time (in lactic dehydrogenase virus in mice).

The persistent virus also has to evade detection and elimination by the host immune system. Various mechanisms have been described for this, although their relative importance is not known. Some viruses exhibit antigenic variation which presents the immune system with a continually moving target, best demonstrated in chronic infections by the lentivirus equine infectious anemia virus. An excess of non-neutralizing antibody has been found in some chronic viral infections, which may interfere with neutralizing antibody function. A number of viruses are now recognized to encode genes which downreg-

ulate the surface expression of class I MHC molecules through a variety of mechanisms (see Table 2).

Persistent viruses frequently infect immunocompetent cells, thereby compromising their function and preventing elimination of the virus, for example HIV infection of CD4⁺ T cells and dendritic cells. Certain viruses are more likely to establish persistent infection if infection occurs very early in life when the immune system is immature. Infections *in utero* or at birth in mice may be associated with selective impairment of virus-specific immune responses, e.g. neonatal infection with LCMV is accompanied by a defect in the LCMV-specific CD8⁺ CTL response, that can be restored by adoptive transfer of CD8⁺ CTLs from LCMV immune normal adults.

It is likely that several mechanisms for avoiding the host immune response are active in any given persistent virus infection.

Viral immunopathology

The immune response to viruses may also inflict damage on host cells, as a result of immune responses directed against virus-infected cells, or as a result of indirect mechanisms that damage uninfected cells. In addition, a number of viruses can alter immune responses by infecting immunocompetent cells.

In immunocompetent adult mice that are infected

with noncytopathic LCMV, virus-specific cytotoxic T cells induce immunopathology by attacking virus-infected cells in the brain, causing a lethal choriomeningitis; the meningitis can be prevented by immunosuppression with cyclophosphamide. Virus-specific CTLs may contribute to the liver damage seen in chronic hepatitis B virus infection (although in this infection, immunosuppression *worsens* the clinical outcome). Mice experimentally infected with coxsackie B virus develop inflammatory myocarditis which is reduced by T cell depletion, and is abolished in transgenic mice lacking the proinflammatory C-C chemokine MIP-1 α . In addition, DTH cells have been shown to enhance tissue damage in mice infected with influenza-virus.

It is believed that the adverse reactions evoked by certain killed virus vaccines when the vaccine recipients encountered the natural infection (particularly respiratory syncytial virus and measles virus) may have resulted from an immunopathological mechanism such as DTH or Arthus reaction.

The generation of non-neutralizing antibodies to certain viruses may have a pathological effect. Non-neutralizing antibody to flaviviruses such as dengue virus can facilitate their entry into macrophages via Fc receptors, where they replicate. Immune complexes are frequently found in many viral infections, e.g. in acute hepatitis B virus infection, immune complexes may be responsible for the arthralgia and rash seen in 10–20% of cases. Immune complexes also occur in chronic hepatitis B virus infection, although only a small proportion of these patients develop vasculitis or chronic glomerulonephritis. It has been suggested that certain human chronic diseases with immunological abnormalities, e.g. chronic immune complex diseases of unknown etiology and multiple sclerosis, might have an underlying viral etiology.

There has been much speculation that viruses may initiate or promote autoimmune disease. Several mechanisms by which this may occur have been suggested. These include generation of anti-idiotypic antibodies against antiviral antibodies which could react with host cells; molecular mimicry, where virus and host share antigenic determinants; promotion of endogenous antigen presentation in virus-infected cells; and impairment of normal immune response suppressor mechanisms. In general there is little direct evidence in support of any of these theories to date. However mice infected with reovirus develop transient diabetes and weight loss in association with autoantibodies to islet and anterior pituitary cells, and these abnormalities can be prevented by immunosuppression with cyclophosphamide.

Table 2 Examples of viral molecules which modulate host immune responses

Virus	Gene product	Mechanism
<i>Interference with antigen presentation</i>		
HSV	ICP 47	Inhibition of peptide transport by TAP1/TAP2 complex
HCMV	US 3	Retention of class I molecules in endoplasmic reticulum
Adeno	E3	Retention of class I molecules in endoplasmic reticulum
<i>Virus-encoded cytokines</i>		
EBV	BCRF-1	Homology to IL-10
H. saimiri	HVS-13	Homology to IL-16 (CTLA8)
Vaccinia	VGF	Homology to epidermal growth factor
<i>Modulation of host cytokines</i>		
Vaccinia	B18R	Soluble receptor for IFN α , IFN β
Vaccinia	E3L	Inhibition of activation of IFN-inducible cellular kinase DAI
Vaccinia	K3L	Competitive inhibition of cellular kinase DAI
HCMV	US 28	Membrane-bound receptor for C-C chemokines

DAI, double-stranded RNA activated inhibitor of translation.

VIRUSES, INFECTION OF IMMUNE CELLS BY

Raymond M Welsh, Department of Pathology, University of Massachusetts Medical Center, Worcester, Massachusetts, USA

Robert T Woodland, Department of Molecular Genetics and Microbiology, University of Massachusetts Medical Center, Worcester, Massachusetts, USA

Most viruses can infect cells of the immune system, and certain viruses display clearly defined though seldomly exclusive tropism for specific leukocyte subsets. Infection of leukocytes is often relatively innocuous to the host, as usually only a small percentage of the total leukocytes are infected, and most of the cells of the immune system can readily repopulate. In other cases, however, viral infections of immune cells may lead to severe immunodeficiency and/or lymphocytic or myelogenous malignancies.

T and B lymphocytes

The immune suppression associated with human immunodeficiency virus (HIV) infection has focused attention on viral infections that target lymphocytes as host cells. The outcome of the virus–lymphocyte interaction is sensitive to multiple restrictions that are imposed at many levels by the biology of the tar-

get lymphocyte and that effectively limit virus replication. The requirement for an appropriate receptor and accessory molecules on the cell surface for initial virus entry is the first level of restriction. This explains the tropism of HIV, which requires the CD4 molecule found on T cells for attachment and a coexpressed member of the chemokine receptor family for entry into the cytoplasm. Similarly, the B cell tropism of Epstein–Barr virus (EBV) is a result of attachment and entry being mediated by the complement receptor CR2, which is found on B cells. Other viruses using more ubiquitous receptors can target many types of host cells in addition to lymphocytes.

Virus entry *per se* does not necessarily lead to a productive infection, which is usually dependent on the activation state of the lymphocyte. The majority of peripheral lymphocytes, both virgin and memory, are resting cells in the G₀ stage of the cell cycle. Their scant cytoplasm and quiescent metabolism make

resting lymphocytes inefficient hosts for high-level virus production, whereas lymphocytes activated by antigen or mitogen stimulation readily support a productive infection by many viruses. The finding that inactivated virions and/or isolated glycoproteins from measles, Sendai, Newcastle disease and influenza viruses are polyclonal lymphocyte mitogens suggests that viruses may in some cases indirectly or directly cause the generation of inductive signals promoting their replication. One illustration of this is the life-cycle of mouse mammary tumor virus (MMTV). Virus-free newborn pups ingest MMTV present in the milk of the mother. MMTV infects resting B cells in the mouse gut, but this infection is not productive. Infected B cells display the MMTV superantigen, provoking recognition by T cells with antigen receptors of the appropriate V_{β} subgroup. The infected B cells recirculate, and a superantigen-specific cognate T cell:B cell interaction activates the B cell in a CD40-dependent fashion to produce and disseminate infectious virus.

The transition from the nonpermissive to permissive state accompanying the activation of resting lymphocytes has been studied *in vitro* and occurs in discrete activator-dependent stages. Vesicular stomatitis virus (VSV) infection of small B lymphocytes does not lead to a productive VSV infection, but primary viral transcripts are readily detected within 8 h of infection of resting B cells. Primary viral transcription is enhanced when infected B cells are cultured with T cell-derived cytokines, including interleukin 4 (IL-4), but viral proteins are not produced, even though the viral mRNA is associated with polysomes. This translational block can be relieved when infected B cells are activated polyclonally with anti-immunoglobulin or phorbol ester. Although all viral proteins and the positive strand of VSV (the replicative intermediate) are synthesized, no infectious particles are produced. Virus assembly and/or release is effected by simultaneous exposure to multiple B cell activators. Thus primary viral transcription, protein synthesis, and assembly and/or release are all found to be activator-dependent regulated processes that can be separated from B lymphocyte proliferation and differentiation to antibody synthesis.

The release of large amounts of infectious virus is associated with death of the host cell. Acutely infected lymphocytes are no exception, and they die by either apoptotic or necrotic mechanisms. Virus infection can induce apoptosis directly through the activation of the cell death program or indirectly by the induction of the Fas (CD95) molecule through which an apoptotic signal can be delivered. Apoptosis following Fas cross-linking is enhanced in

both $CD4^{+}$ and $CD8^{+}$ T cells taken from HIV-infected donors, and the Fas ligand is upregulated on HIV-infected macrophages. This raises the possibility that the depletion of T cells during HIV infection may be in part due to Fas-mediated apoptosis. The programmed cell death pathway in infected host cells can be suppressed by a number of DNA viruses, including adenovirus, cowpox and EBV. The virus-encoded gene products E1B 19K of adenovirus, and *crmA* of cowpox directly suppress the apoptosis pathway, whereas the LMP product of EBV works indirectly by inducing the synthesis of endogenous antiapoptotic proteins such as Bcl-2. Suppression of apoptosis promotes the completion of the replicative cycle, allowing either cell transformation or a larger burst of infectious viral particles.

Examples of retroviruses and large DNA viruses that have developed strategies to disseminate and perpetuate the viral genome by insertion into the host's DNA are well known. The activation-dependence for full viral replication in infected lymphocytes, however, can make resting lymphocytes hosts for persistent infections by RNA viruses that normally induce acute lytic infections. Both VSV and measles virus can infect and remain dormant in resting lymphocytes. The persistence results from the stability of the virus nucleocapsid. Primary VSV mRNA transcripts are readily detected for up to 5 weeks in VSV-infected resting B lymphocytes taken from Bcl-2 transgenic mice and maintained in culture. As was seen in the case of acute infections, no VSV protein or infectious VSV particles were detected throughout the culture of unactivated cells. Infectious particles were readily induced when the cells were activated appropriately. The relatively long lifespan of resting lymphocytes, the stability of the viral nucleocapsid in the cytoplasm of resting cells, and the ability to recirculate and release fully infectious particles upon appropriate cellular activation, combine to make resting lymphocytes ideal reservoirs for RNA virus infection.

Natural killer (NK) cells

In contrast to nonproliferating T and B lymphocytes, NK cells have large, active cytoplasm capable of supporting virus growth. Little is known about the frequency or significance of virus infections of NK cells *in vivo*, but cytomegalovirus (CMV), measles and influenza viruses infect human NK cells *in vitro*. These infections are not lytic, and influenza virus does not inhibit NK cell-mediated cytotoxicity; in contrast, both CMV and measles virus inhibit the ability of NK cells to mediate natural cytotoxicity but do not impair their ability to mediate antibody-

dependent cellular cytotoxicity (ADCC). The reason for this selective inhibition in lytic function is not known, but it is of interest that some strains of HIV can infect NK cells and that NK cells isolated from patients infected with HIV similarly display a selective defect in natural cytotoxicity but not ADCC. Also during HIV infection there is a selective loss of CD8⁺ NK cells; it has been suggested that HIV infection of CD8⁺ NK cells leads to tumor necrosis factor α (TNF α) production, which activates HIV synthesis, resulting in lysis of the cell, whereas the predominant cytokine made in CD8⁻ NK cells is interferon α (IFN α), which inhibits viral synthesis and protects the cell. The cytotoxic mechanism of NK cells can be triggered directly by treatment with glycoproteins isolated from a variety of viruses, including mumps, measles, influenza, Sendai, and lymphocytic choriomeningitis viruses, and this may provide a means by which NK cells can selectively lyse virus-infected targets.

Monocytes and macrophages

By secreting antiviral cytokines such as IFN and TNF α and by serving as antigen-presenting accessory cells which stimulate specific immune responses, monocytes and macrophages play fundamental roles in resistance to viruses. Intravenous injection of mice with radiolabeled virus results in a rapid clearance of the label from the bloodstream and concentration by the liver Kupffer cell macrophage population. The ability of viruses to replicate in monocytes, macrophages, and the more differentiated macrophage-like histiocytes such as Kupffer cells is thought to be an important virulence factor. This concept is supported by the fact that nearly all persistent virus infections involve extensive infections of macrophages.

Many viruses replicate in macrophages, but few viruses have macrophage-specific tropism or bind to macrophage-specific receptors. Lactic dehydrogenase (LDH) virus, which causes a persistent infection in mice, has a predilection for infecting macrophages expressing major histocompatibility complex (MHC) class II antigens and may use these molecules as receptors. Some macrophages express CD4, which leave them permissive to HIV. Some viruses enter macrophages by an aberration of opsonization known as 'immune enhancement'; macrophages have high-affinity receptors for complement and for the antibody Fc region, which facilitate the adsorption, penetration and productive infection by some antibody- and/or complement-coated viruses, such as dengue virus and HIV. More conventionally, antibody-coated viruses are suitably disposed of. Infection of macrophages by vaccinia virus normally

results in entry of virus into the cytoplasm, followed by productive replication; antibody-coated vaccinia virus suffers a different fate, as it is engulfed in a phagolysosome and degraded.

Viral infections of macrophages may be abortive, productive, latent and/or transforming, and the outcome of infection commonly depends on the macrophage activation state. Many viruses, such as herpes simplex virus (HSV) and influenza, grow poorly in activated macrophages, but others, such as murine CMV or LDH virus may grow better in activated macrophages. The reasons for these responses vary with the virus, but abortive infection in activated macrophages may be due in part to the lack of requisite host cell factors not found in nonreplicating, poorly differentiated cells. The ability of viruses to grow in macrophages is extensively influenced by cytokines. Genetically determined resistance of mouse macrophages to influenza virus has been shown to be due to an IFN-induced Mx gene product, which is a protein essential for resistance to influenza virus but not to VSV. IFN γ , produced by NK cells or T cells, has been shown to induce nitric oxide synthase in macrophages, and the liberated nitric oxide inhibits the replication of several viruses, including HSV-1, vaccinia virus, murine CMV, and VSV.

Dendritic cells and Langerhans cells

Epidermal Langerhans cells and follicular dendritic cells play important roles in antigen presentation and may be an important leukocyte source for virus-induced IFN α . Hence, infection of these cells may be advantageous to the host, by stimulating T cell responses and facilitating the activation of NK cells and other IFN-dependent mechanisms of natural resistance. These cells express some CD4 and complement receptors, and it is of interest that they can be infected with HIV *in vivo*. In animals, viruses such as murine retroviruses, Aleutian disease of mink virus, and bovine lentivirus, have been shown to replicate in dendritic cells.

Granulocytes

Infection of granulocytes with viruses occurs but is seldom of great significance, because mature granulocytes are so short-lived. However, granulocytes harboring viruses such as CMV may be a source for transmission of viruses during blood transfusions.

Virus-induced transformation of lymphoid cells

Tumors of the immune system are commonly caused by retroviruses and herpesviruses. Avian, murine, and feline leukemia virus-induced lymphomas and leukemias correlate with virus-induced mutations in host cell genes that control cell growth and differentiation (proto-oncogenes). The insertions of retrovirus DNA (the provirus) into the host chromosomal DNA represent mutations, most which are benign. However, occasionally an insertion mutates the activity of a proto-oncogene such that the gene becomes an oncogene. The genes that viruses mutate to cancer-causing genes are remarkably specific; for example, mutations in *c-myc* are associated with IgM⁺ B cell lymphomas. The frequency at which tumors are brought about by insertional mutagenesis correlates with the level of retrovirus replication in a tissue, with, for example, murine leukemia virus variants which grow well in the thymus being more likely to cause thymomas, because of the increased likelihood for generating the appropriate mutagenic event.

In contrast to the above, bovine and human T cell leukemia virus (HTLV)-induced cancers do not correlate with viral mutations of specific host sequences. These cancers appear to result from a viral gene product (Tax) altering the expression of host genes (including IL-2 and the IL-2 receptor) in such a way that the cells are under an intermediate level of growth control. These partially destabilized cells are at a greater than normal risk for a mutation stimulating an oncogenic conversion. Such a situation also occurs in cells immortalized by the herpesvirus EBV; here, lymphoma induction correlates with a mutation of the *myc* proto-oncogene in the form of a chromosomal translocation which puts this growth-promoting gene under the influence of immunoglobulin transcriptional control regions.

Many viruses encode proteins which inhibit the ability of the cell to abort the transformation process by undergoing apoptosis. One EBV gene product, BHRF1, has homology with the cellular anti-apoptosis gene Bcl-2; a second EBV-encoded gene product, LMP1, can induce the expression of cellular Bcl-2. A third EBV gene product, EBNA5, binds to and inactivates the tumor suppressor gene products

Rb and p53, which regulate cell growth and apoptosis. By usurping these normal cellular regulatory mechanisms successful transformation events can take place.

VITAMIN A AND THE IMMUNE SYSTEM

Richard D Semba, Department of Ophthalmology, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

J Cecil Smith, Phytonutrients Laboratory, Beltsville Human Nutrition Research Center, United States Department of Agriculture, Beltsville, Maryland, USA

Worldwide, it is estimated that vitamin A deficiency affects over 200 million individuals. It is the leading cause of blindness in children, a major cause of child mortality, and a key determinant of measles severity and mortality. Infants, preschool children, pregnant women and women of childbearing age are at greatest risk for developing vitamin A deficiency.

Vitamin A is a fat-soluble vitamin essential for immunity, cellular differentiation, growth, reproduction and vision. It is found as preformed vitamin A in foods such as liver, cod-liver oil, eggs and butter, or as provitamin A carotenoids in foods such as dark green leafy vegetables, carrots, mangos and papayas. About 90% of the vitamin A in the body is stored in the liver, and most of the rest circulates in the blood bound to retinol-binding protein (RBP) and transthyretin (TTR). After entering cells, vitamin A is converted to retinoic acid, its active metabolite, and within the nucleus, retinoic acid influences gene activation via specific receptors known as retinoic acid receptors (RAR) and retinoid-X receptors (RXR). These nuclear receptors are in the thyroid and steroid hormone receptor superfamily. Vitamin A, through its active metabolite retinoic acid, acts as a powerful gene regulator. Vitamin A deficiency has major consequences for immunity and the clinical course of many infectious diseases.

Vitamin A deficiency and infection

Vitamin A deficiency is associated with a variety of infectious diseases, including diarrheal and respiratory disease, measles, and human immunodeficiency virus type 1 (HIV-1) infection. Epidemiological studies demonstrate that preschool children with moderate vitamin A deficiency, i.e. nightblindness and/or Bitot's spots, have a higher risk of subsequently developing diarrheal disease or respiratory infection. Likewise, children suffering from diarrheal disease or respiratory infection have a higher risk of subsequently developing mild vitamin A deficiency. These data suggest that vitamin A deficiency and infection are related in a vicious cycle, which may result in increased mortality. Longitudinal studies in Indonesia show that mild vitamin A deficiency is linked with a fourfold increased risk of death in preschool children.

The severity of measles, a disease characterized by immunosuppression and infectious complications, is related to the degree of vitamin A deficiency. In a large study of children with acute measles in Zaire, those with the worse vitamin A status had the highest mortality. During HIV infection, another disease characterized by immunosuppression, vitamin A deficiency has been associated with higher mortality. There may be a specific relationship between vitamin A deficiency and mother-to-child transmission of HIV-1. Studies from Malawi, Haiti, Kenya and Rwanda suggest that HIV-infected women with vitamin A deficiency during pregnancy have a higher risk of transmitting HIV infection to their infants. The increased transmission of HIV may possibly be due to vitamin A-related immune compromise in mother and infant, increased chorioamnionitis, and higher HIV viral burden in breastmilk. Infants born to women who are vitamin A-deficient during pregnancy have lower birthweight, child growth retardation and higher mortality.

Infections may predispose to vitamin A deficiency because of low intake of vitamin A-rich foods, anorexia, malabsorption, increased utilization of vitamin A, inability to mobilize vitamin A from the liver, and accelerated depletion of vitamin A. During the acute phase response, retinol-binding protein can cleave away from the circulating RBP-TTR-retinol complex, allowing high, abnormal urinary losses of vitamin A. An episode of infection, such as chickenpox, has been shown to hasten the depletion of liver vitamin A stores in preschool children. Vitamin A deficiency during infection has widespread implications for innate and adaptive immunity.

Vitamin A and innate immunity

Vitamin A is essential for maintenance of mucosal surfaces, the first line of defense against infection. Vitamin A deficiency causes squamous metaplasia, loss of ciliated epithelium, and loss of goblet cells and mucus in the respiratory tract, as well as loss of microvilli, goblet cells and mucus in the gastrointestinal tract. The mucosae of the genitourinary tract and eye also exhibit pathological alterations. Immune effector cells which mediate nonspecific immunity include polymorphonuclear cells, macro-

phages and natural killer (NK) cells. In experimental animals, phagocytosis by neutrophils is compromised during vitamin A deficiency. In the vitamin A-deficient host, viral infections may be more severe because of increased viral replication, reduced cytolytic activity by NK cells, and increased damage to the mucosal epithelia. Vitamin A supplementation has been associated with increased circulating NK cells in both animal models and in children.

Vitamin A and acquired immunity

Vitamin A deficiency compromises acquired (adaptive, antigen-specific) immunity. Vitamin A deficiency has been associated with atrophy of the thymus, spleen, lymph nodes and Peyer's patches, suggesting major alterations in the microenvironment of immune effector cells. *In vitro* studies demonstrate that vitamin A and its metabolites are essential for growth, differentiation and activation of human T cells and B cells. Lymphopenia and T cell subset alterations, including a lower proportion of circulating CD4 T cells, have been reported in vitamin A-deficient children. The production of cytokines may be altered during vitamin A deficiency. In vitamin A-deficient mice, immune effector cells produce less interleukin 4 (IL-4) and IL-5 but more IL-12 and interferon γ , suggesting that vitamin A deficiency may be involved in the regulation between T helper type 1- and type 2-like responses. Vitamin A also seems to influence the expression of IL-2 receptor.

A hallmark of vitamin A deficiency is the impaired ability to generate an antibody response to T cell-dependent antigens (tetanus toxoid, proteins, viral infections, etc.) and T cell-independent type 2 antigens (pneumococcal polysaccharide, meningococcal polysaccharide). Vitamin A-deficient animals are generally less able to mount an antibody response against a wide variety of protein antigen challenge. Children supplemented to normal vitamin A status have higher immunoglobulin G (IgG) antibody responses after challenge with tetanus toxoid compared to children who are clinically or subclinically deficient in vitamin A. The observations of compromised innate and adaptive immunity during vitamin A deficiency may explain the increased severity of infections and higher mortality observed in both experimental animal models of infection and in epidemiological studies in humans.

Vitamin A as an immune enhancer

Vitamin A, in the form of liver oils, has been used to treat various infections since antiquity. Clinical trials conducted in the 1930s showed that cod-liver oil therapy reduced mortality in children with measles and reduced morbidity in women with puerperal sepsis (the infectious complications of delivery and postpartum period). In the last decade, clinical trials have shown that periodic, high-dose vitamin A supplementation can reduce child mortality in developing countries by 20–50%. Vitamin A supplementation reduces morbidity and mortality primarily by reducing the severity of diarrheal disease but seems to have little effect upon acute lower respiratory infections. Vitamin A supplementation is now standard therapy for infants and children with acute measles. Many developing countries have adopted periodic vitamin A supplementation to reduce morbidity and mortality in preschool children. The use of vitamin A for disease-targeted therapy, i.e. HIV infection, diarrheal disease, and as a means to enhance immune responses to vaccination are currently under investigation.

VITAMIN B GROUP AND THE IMMUNE SYSTEM

Lorraine T Miller, Department of Nutrition and Food Management,
Oregon State University, Corvallis, Oregon, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The B-complex vitamins differ markedly in chemical structure and biological function. Pyridoxal phosphate (PLP), the predominant coenzyme form of vitamin B₆, has a paramount role in the metabolism of amino acids and protein, including protein synthesis. Folate coenzymes function in the transport of single carbon moieties and are essential for the synthesis of DNA. Folate deficiency results in impaired cell division and altered protein synthesis, particularly of rapid growing tissues. Vitamin B₁₂ is needed for the utilization of folate and the synthesis of DNA. Thiamin performs its coenzyme function as thiamin pyrophosphate in metabolism of 2-ketosugars and α -keto acids. Riboflavin and niacin are precursors of coenzymes involved in biological oxidations. Pantothenic acid functions in acyl-group activation reactions as a component of coenzyme A. Biotin is involved in biochemical reactions which add carboxyl groups to molecules.

Vitamin B₆ deficiency produces profound changes in immune function in animals. The thymus is the lymphoid tissue most severely affected. Thymic hormone activity is decreased and lymphopenia is observed. Vitamin B₆ deficiency impairs delayed cutaneous hypersensitivity responses, primary and secondary T cell-mediated cytotoxicity and rejection of skin grafts. Impaired humoral responses in vitamin B₆-deficient animals are indicated by poor antibody production after primary or booster immunization. Both B and T lymphocytes from vitamin B₆-deficient animals have depressed proliferative responses to *in vitro* antigen or mitogen stimulation. Vitamin B₆ deficiency, however, does not affect phagocytosis by macrophages or activity of natural killer (NK) cells. Increased amounts of vitamin B₆ do not enhance immune function in mice that are not vitamin B₆-deficient.

Humans depleted of vitamin B₆ have fewer circulating lymphocytes. Vitamin B₆ deficiency, produced by a vitamin B₆ antagonist, mildly impaired humoral antibody responses to tetanus toxoid and typhoid vaccine. In patients with Hodgkin's disease or renal failure, in whom both biochemical vitamin B₆ deficiency and impaired immune responses were observed, supplementary vitamin B₆ normalized vitamin B₆ status and improved results of various immunological tests. In elderly subjects who had no

evidence of any underlying systemic disease, vitamin B₆ supplementation improved *in vitro* lymphocyte blastogenesis in response to various mitogens. Lymphocyte blastogenesis after vitamin B₆ supplementation was higher in subjects whose presupplement vitamin B₆ status was subnormal than in those whose presupplement vitamin B₆ status was normal. Vitamin B₆ supplementation in the elderly also resulted in increased proportions of CD3⁺ and CD4⁺ cells, but not CD8⁺ cells. A vitamin B₆ intake slightly higher than the US recommended dietary allowance (RDA) improved *in vitro* lymphocyte proliferation and interleukin 2 (IL-2) production in young and elderly adults.

The biochemical lesion(s) underlying the detrimental effects of vitamin B₆ deficiency on the immune system are not well understood. Early studies suggested that synthesis of DNA is diminished through a decrease in one-carbon pools resulting from the depressed PLP-dependent conversion of serine to glycine in vitamin B₆ deficiency.

Folate and vitamin B₁₂ deficiencies are associated with reduced host resistance and impaired lymphocyte function. Folate-deficient animals have a smaller thymus, a decrease in T cells, as well as impaired cytotoxicity and *in vitro* lymphocyte response to mitogens. Additionally, folate deficiency results in reduced complement-fixing antibodies and impaired response to murine rotavirus. Patients with megaloblastic anemia due to folate deficiency had impaired neutrophil phagocytosis. Patients with low serum concentrations of vitamin B₁₂ also had impaired neutrophil function, which was corrected by vitamin B₁₂. In animals, vitamin B₁₂ improves antibody function and mitogenic responses.

Pantothenic acid deficiency suppresses humoral antibody responsiveness to antigens in animals. In humans, when a combined deficiency of pantothenic acid and vitamin B₆ was induced by antagonists of these vitamins, antibody responses to tetanus toxoid and typhoid antigen were almost completely inhibited and hypogammaglobulinemia developed. Antibody response, however, to polio vaccine immunization was normal.

Deficiencies in thiamin, biotin and riboflavin interfere moderately with immunologic function. Riboflavin deficiency decreases the ability to produce

humoral antibodies in response to antigens. Rats deficient in thiamin, riboflavin or biotin had a reduced development of plaque-forming cells in response to immunization. Infants with multiple biotin-dependent carboxylase deficiencies showed delayed cutaneous hypersensitivity, impaired *in vitro* lymphocyte response to antigens and depressed antibody formation response to immunization.

Although isolated B-complex vitamin deficiencies have been found to have a detrimental effect on immune functions, the problem in reality is more complex. The metabolism of this group of vitamins along with other micronutrients is interconnected and multiple nutritional deficiencies occur in humans. Current research suggests that an intake of micronutrients, including the B-complex vitamins, two to three times higher than the US RDA, is necessary to obtain optimal immune function in healthy older adults. In placebo-controlled, double-blind studies in older adults a micronutrient supplement which included B-complex vitamins significantly enhanced NK cell cytotoxicity, lymphocyte proliferation and antibody titers to influenza vaccine, and reduced the number of sick days. Research is needed

to determine the amounts of B-complex vitamins, as well as other micronutrients, needed for optimal immune function in humans and the mechanisms by which these micronutrients function in the immune system.

VITAMIN C AND THE IMMUNE SYSTEM

Reto Muggli, Department of Immunochemistry, Faculty of Pharmaceutical Sciences, Okayama University, Okayama, Japan

Ascorbic acid (vitamin C) is required for the optimal functioning of all cells, tissues, and organs. It is the most important water soluble antioxidant and is a cofactor in many hydroxylating reactions. Man, primates, guinea pigs and a few other species lack the capability to synthesize ascorbic acid, for them ascorbic acid is an essential nutrient. There is abundant evidence from animal and human studies that the immune system is sensitive to the level of intake of vitamin C.

Ascorbate concentration in plasma and leukocytes

All leukocytes maintain high levels of ascorbate which are correlated with their functions. In normal healthy individuals the ascorbate levels are 1.0–1.4 mM in neutrophils and even higher in monocytes, B lymphocytes and T lymphocytes, reaching about 6.0–7.0 mM. Thus, compared with physiological plasma ascorbate concentrations of 0.03–0.06 mM, the leukocyte levels are on average 20- to 100-fold

greater than in plasma. The uptake occurs primarily by a stereospecific active transport which is temperature and energy dependent. Many infections and inflammatory diseases lower plasma and neutrophil ascorbate levels.

Nonspecific immune functions

Natural barriers

The skin and the epithelial linings of the bodily openings provide the front-line protection against infectious organisms. Collagen is an essential component of these natural barriers, as it forms the matrix for the dermal and epidermal layers and is a constituent of basement membranes which serve as attachment for epithelial cells. Functionally intact collagen occurs in the form of fibrils composed of collagen molecules cross-linked via hydroxylated prolyl and lysyl residues. Ascorbate is a cofactor in the hydroxylation reactions of proline and lysine and is therefore involved in the maintenance of the natural barrier.

Neutrophil function

Clinically an association exists between recurrent infections and impairment of neutrophil function. As opposed to a vitamin C deficiency state, adequacy of ascorbate nutrition improves several aspects of neutrophil function, specifically chemotaxis, and motility.

Neutrophils from vitamin C-deficient guinea pigs have depressed chemotaxis and bactericidal activities. Vitamin C can enhance the chemotactic response and motility of neutrophils from healthy individuals and has also been reported to normalize the reduced chemotactic and bactericidal activities of neutrophils from individuals with an inherited phagocytosis dysfunction.

Humoral defense

In the guinea pig, tissue saturating intakes of vitamin C produce higher plasma concentrations of the hydroxyproline-rich complement protein C1q than lower intakes. In man the role of ascorbate in maintaining complement levels is controversial. While complement levels have been found unaltered during scurvy and in volunteers taking 1 or 3 g vitamin C, and no relationship between blood vitamin C levels and complement titers was apparent in patients with acute infections, some studies reported increases in serum complement component C3 following vitamin C supplementation.

Ascorbic acid enhances the production of interferon in cultured mouse cells and in mice *in vivo*, and in human fibroblasts infected with some viruses but not with others.

Specific immune functions

Antibody production

Significant increases in serum immunoglobulin G (IgG) and IgM were found in institutionalized women when given 200 mg vitamin C twice daily for 4 months; this was also found in middle-aged people. However, in another study on volunteers, the levels of IgA, IgG and IgM were not affected by 1 or 3 g vitamin C.

Lymphocyte proliferation and transformation

The proliferative response of lymphocytes from vitamin C-deficient monkeys is significantly depressed *in vitro*, but the findings in guinea pigs are not consistent.

A number of investigators have found that vitamin C supplementation (1 g day^{-1}) enhanced *in vitro* lymphocyte proliferative responses in adults. In

elderly individuals, tissue saturating doses (500 mg, intramuscularly, daily for 1 month) enhanced cell-mediated immune function as manifested by enhanced T cell lymphocyte proliferative responses *in vitro* and tuberculin hypersensitivity *in vivo*.

After high doses of vitamin C, increased neutrophil motility associated with an increased T lymphocyte transformation was observed. The effect was explained by the prevention of induction of suppressor activity in human mononuclear leukocytes or protection of essential oxidizable groups in the monocyte membrane of ascorbate.

Delayed-type hypersensitivity

Depressed delayed-type hypersensitivity skin reactions as a result of inadequate vitamin C intake are restored following supplementation in guinea pigs. Normal delayed-type hypersensitivity responses were enhanced following megadose supplementation of vitamin C to young adults and after injections of 500 mg day^{-1} of vitamin C in a study in an elderly population. However, in another study, oral supplementation of 2 g day^{-1} vitamin C in an elderly population did not affect delayed-type hypersensitivity responses.

Antimicrobial and antiviral effects

Deprivation of vitamin C leads to decreased cellular immune functions and increased susceptibility to microbial infections. The effect of vitamin C on leukocytic microbicidal activity is controversial. No effect was found *in vitro* and a connection between the antimicrobial activity of phagocytes *in vitro* and the vitamin C status of healthy individuals could not be established. However, it was shown to exist in patients with Chediak-Higashi syndrome, where the microbicidal activity of the neutrophils against *Staphylococcus aureus* could be restored by giving the patients 50 mg kg^{-1} body weight of ascorbic acid daily. In general, orally administered high-dose vitamin C seems to have little effect on the course of infectious disease.

Leukocyte ascorbate levels rapidly decrease following a virus infection and return to normal after recovery. *In vitro* and in some animal experiments, ascorbic acid has displayed antiviral activity. In humans, in a very careful, placebo-controlled, double-blind study it was shown that vitamin C not only lessened the severity of rhinovirus cold but also reduced the potential for virus transmission.

Mechanism of action

There is now good evidence which indicates that part of the immunostimulatory properties of vitamin C are related to the antioxidant activity of ascorbate. During the activation of neutrophils, reactive oxidants are generated for the killing of phagocytosed microorganisms. Neutrophils are susceptible to damage by these self-produced oxidants. Protection against autooxidative neutrophil dysfunction is provided by ascorbate together with other antioxidants. The protection afforded by ascorbate does not compromise the bactericidal activity of neutrophils. Clearly, it is crucial that leukocytes possess antioxidant mechanisms to protect themselves from auto-oxidation during mobilization of host defenses.

Indirect effects via maintenance of vitamin E

Apart from direct effects, vitamin C may improve immune responses by protecting the antioxidant capacity of vitamin E, a potent immunoenhancing nutrient in its own right. Chronic vitamin C deficiency lowers the vitamin E levels in tissues and plasma. The free radical scavenging action by vitamin E is associated with the production of a vitamin E radical. Vitamin C reacts with the free radical of vitamin E and regenerates the reduced form, while being oxidized. The net result is a decrease in ascorbate and a maintenance of the antioxidant vitamin E level.

Summary

The high concentration of ascorbate in leukocytes and its rapid expenditure during infection and phagocytosis suggests a role for vitamin C in the immune process. Vitamin C enhances neutrophil chemotaxis and migration, stimulates the production of interferon, maintains the integrity of the mucous membranes and is involved in the induction and expression of delayed-type hypersensitivity. Its effects on complement and antibody production are controversial. Increased T and B lymphocyte proliferation following high-dose vitamin C supplementation is likely. Vitamin C reduces nonspecific extracellular free radical damage and autotoxicity following the oxidative burst activity of stimulated neutrophils. Vitamin C may enhance immune function indirectly by maintaining optimal vitamin E levels. Clinically, vitamin C has a role in the compensation of increased metabolic demands during infections and in prophylaxis, especially in individuals prone to infections because of functionally defective neutrophils.

VITAMIN D AND THE IMMUNE SYSTEM

Nobuto Yamamoto, Laboratory of Cancer Immunology and Molecular Biology, Albert Einstein Cancer Center, and Socrates Institute for Therapeutic Immunology, Philadelphia, Pennsylvania, USA

Vitamin D₃ is hydroxylated in the kidney to its physiologically active form, 1 α ,25-dihydroxyvitamin D₃ (1 α ,25(OH)₂D₃), known as calcitriol. Substantial evidence is accumulating that the hormonal form of vitamin D, calcitriol, can regulate the differentiation, growth and function of a broad range of cells or organs that are not directly involved in calcium homeostasis. In particular, calcitriol plays an important regulatory role in cell differentiation and proliferation of the immune system. It mediates its effects via specific intracellular vitamin D₃ receptors (VDRs). Malignant cell lines of the myelomonocytic and lymphocytic cell lineage, as well as normal peri-

pheral blood monocytes and tissue macrophages express VDRs similar to those found in classical target tissues of calcitriol. These receptor proteins bind the ligand with high affinity (K_d 10⁻¹⁰ M).

Some of the key findings with calcitriol *in vitro* and *in vivo* are shown in Table 1.

Effects of calcitriol on a variety of cells mediated by specific receptors

Accumulated evidence has established that the biological actions of calcitriol on calcium metabolism are mediated by binding to specific receptors in the

Table 1 Effects of calcitriol *in vitro* and *in vivo* on the immune system

In vitro studies:

Monocytes/Macrophages

- Induction of monocyte differentiation to macrophages
- Increased expression of MHC class II antigens induced by IFN γ
- Enhancement of chemotaxis, phagocytosis and cytotoxic functions
- Increased production of hydrogen peroxide
- Modulation of cytokine production

T lymphocytes

- Decreased proliferation of activated lymphocytes (antigen-, mitogen- or cytokine-induced)
- Inhibition of IL-2 production by activated T lymphocytes
- Inhibition of IFN γ and GM-CSF production by activated T lymphocytes
- Decreased proliferation of IL-1/PHA-activated thymocytes

B lymphocytes

- Inhibition of IgM and IgG synthesis mediated by an inhibitory action on the helper function of T lymphocytes

In vivo studies:

- Inhibition of cytokine release from monocytes from human volunteers
- Inhibition of autoimmune encephalomyelitis and thyroiditis in mice
- Prolongation of skin allograft survival in mice
- Potential of primary immune responses and inhibition of hyperimmune responses in mice
- Restoration of defective macrophage and lymphocyte functions in vitamin D-deficient rats and in patients with vitamin D-resistant rickets
- Restoration of lymphocyte proliferation and IL-2 production in patients on hemodialysis

intestine, bone and kidney. It has been shown that after binding to its receptor in the intestinal epithelial cells, calcitriol can induce the synthesis of calcium-transporting proteins, named calbindins, that mediate the uptake of calcium from the gut into the organism. In the last decade, calcitriol has been shown to exert biological activities far beyond its effects on calcium uptake, control of serum calcium levels and regulation of bone mineralization. The specific calcitriol receptor has been found in many cells and tissues not traditionally involved in the regulation of calcium metabolism, including various cancer cell lines, skin cells, muscle cells, hematopoietic cells and also in the pancreas, brain and pituitary. These ubiquitously expressed proteins appear to function as transcription factors mediating effects of calcitriol on a range of genes.

Initial observation in mouse myeloid leukemia cells suggested that calcitriol possessed a number of cell-regulating properties in differentiation and proliferation. Since then a large number of undifferentiated or low-differentiated cancer cells have been shown to differentiate towards the normal phenotype under the influence of calcitriol. At the same time, their rate of proliferation was reduced markedly. The cells of the upper layer of the skin, the basal epithelial keratinocytes, also responded to calcitriol *in vitro* by inhibition of growth, coupled with an increased rate of terminal differentiation. Among the cells of the immune system, monocytes and macrophages have been found to express the calcitriol receptor constitutively, whereas lymphocytes require prior activation with antigen or mitogen before expressing the receptor. The proliferation of activated T lymphocytes *in vitro* was found to be inhibited profoundly by calcitriol.

The immunological role of calcitriol

The secretory role of macrophages for calcitriol

In contrast to endocrine synthesis of calcitriol in the kidney, normal macrophages have also been shown to synthesize calcitriol when activated by agents such as interferon γ and lipopolysaccharide. Production of the hormone may thus act as part of the normal immune response and induction of calcitriol synthesis in response to infection may stimulate the synthesis of other inflammatory mediators such as interleukin 1 (IL-1), which will in turn affect the level of lymphocyte activity. Initial evidence for the interaction of calcitriol with the immune system arose from studies of the disease sarcoidosis, a chronic granulomatous disorder often associated with hypercalcemia and elevated circulating levels of calcitriol. The latter have been attributed to ectopic synthesis

of calcitriol by immune cells associated with sarcoidosis, such as alveolar macrophages. The production of the hormone by sarcoid macrophages appears to be insensitive to feedback control by calcitriol itself, as well as other regulators such as calcium and parathyroid hormone.

Effect of calcitriol *in vitro* on monocytes and macrophages

Monocytes and macrophages from both human and animal sources constitutively express the calcitriol receptor. Upon incubation with calcitriol, monocytes acquire characteristics of functionally mature macrophages, and a general enhancement of the antigen-presenting cell function is observed. Calcitriol also enhances the antibody-dependent cytotoxic function of monocytes/macrophages, and calcitriol-treated human monocytes exhibit enhanced phagocytosis and killing of mycobacteria. Other studies have shown that the hormone increases Fc receptor expression on monocytes. Reports have also demonstrated that calcitriol treatment of peripheral blood monocytes increases the production of hydrogen peroxide and of heat shock proteins. Several studies indicate that calcitriol downregulates cytokine production (IL-1, IL-6, tumor necrosis factor α (TNF α)) by antigen or lipopolysaccharide (LPS)-stimulated monocytes, whereas others have found unchanged or increased production, depending on the eliciting stimulus and the culture conditions.

Macrophages are derived from less mature myeloid stem cells which originally have a common pluripotent cell origin and many laboratories have examined the effect of vitamin D on stem cell development, in particular the mononuclear phagocyte system. These studies have been greatly facilitated by the development of leukemic cell lines from myeloid precursor cells. It is not yet clear at which point in the stem cell pathway VDR induction occurs, but more mature cell lines such as HL-60 and U937 express these receptors and are responsive to calcitriol, which stimulates differentiation towards macrophage-like cells. In this respect the antiproliferative effects of calcitriol are similar to those observed with agents such as retinoic acid, dimethylsulfoxide and phorbol esters. These *in vitro* effects of calcitriol are observed at physiological concentrations of 10^{-10} – 10^{-8} mol l $^{-1}$.

Effect of calcitriol *in vitro* on lymphocytes

Calcitriol has also been shown to act on T and B lymphocytes, and antibody-producing function of lymphocytes (Table 1). Studies *in vitro* have suggested that the main effect of calcitriol is to inhibit the proliferation of activated T cells which, unlike

resting T cells, express VDR. Lymphocytes require activation in order to express the calcitriol receptor. Following this initial activation induced by antigen, cytokine or mitogens, incubation with calcitriol inhibits T lymphocyte proliferation. IL-2 production by activated T lymphocytes is strongly inhibited by calcitriol and this seems to be one of the crucial events in the immunoregulatory activities of calcitriol, linking it to the immunosuppressive properties exerted by known immunosuppressants such as cyclosporine.

Calcitriol also inhibits interferon γ synthesis by T cells, and this may act as part of the control of calcitriol synthesis by macrophages which produce the hormone (calcitriol) when stimulated with interferon γ .

T cell development takes place in the thymus with VDR being expressed in medullary cells, but not in the less mature cortical cells. However, the precise role of calcitriol in T lymphocyte development is unclear as VDR expression is lost after the cells leave the thymus. VDR are also present in natural killer cells, indicating that calcitriol may have a role in modulating the immune response to viral infection and neoplastic development. The interaction of vitamin D with B cells is less clear than its effects on T cells, and although calcitriol inhibits immunoglobulin production by B cells this appears to be due to indirect suppression of the antibody-stimulating activity of T helper cells rather than a direct effect on B cells.

Effect of calcitriol on immune functions *in vivo*

Administration of calcitriol can prevent the development of experimental autoimmune encephalomyelitis and thyroiditis in mice and prolong the survival of transplanted skin allografts in mice. In normal mice, administration of 1α -hydroxyvitamin D_3 [$1\alpha(OH)D_3$], a synthetic vitamin D analog that is converted to calcitriol in the organism, leads to an increased primary antibody response, but the same treatment suppresses the hyperimmune response induced by concomitant administration of colchicine. Reports have demonstrated a reduction in antibody formation in ricketic rats challenged with diphtheria toxin or Sendai virus, a more fulminant spread of pneumococcal and *Klebsiella* infection when ricketic rats were inoculated with these organisms, and a decrease in antibody-forming cells in the spleen from ricketic rats. Several studies have shown that treatment with calcitriol or $1\alpha(OH)D_3$ can restore deficient macrophage and lymphocyte functions in vitamin D-deficient rats and patients with vitamin D-resistant rickets. Calcitriol blocks the development of renal disease and improves survival in the MRL

mouse model of autoimmunity. These findings suggest a role for calcitriol under physiological conditions as an important factor in sustaining normal functions of the immune system (which can be compromised by vitamin D deficiency).

Clinical studies

Nutritional vitamin D deficiency has been shown to be associated with impaired immune responses such as decreased leukocyte chemotaxis, and has also been reported to increase susceptibility to infection and predisposition to disseminated tuberculosis. Calcitriol or $1\alpha(OH)D_3$ can restore deficient macrophage and lymphocyte functions in patients on hemodialysis. The contribution of immune effects of calcitriol on mineral homeostasis have yet to be studied in detail, but may have a significant effect on calcium mobilization. Calcitriol stimulates monocyte secretion of IL-1 and prostaglandin E_2 , both of which induce bone resorption but inhibit lymphocyte production of interferon γ , a suppressor of calcium mobilization.

Because a large number of undifferentiated or low differentiated cancer cells have been shown to differentiate toward normal cell phenotypes, efforts to treat cancer with calcitriol have been developed. A potentially important clinical application of the anti-proliferative effects of calcitriol on monocytes has been in the development of antileukemic agents. The use of vitamin D metabolites in myeloproliferative disorders *in vivo* has, so far, been less successful than related agents such as retinoic acid. This idea has stimulated an interest in the possible use of calcitriol in the treatment of other proliferative diseases such as psoriasis and also in the treatment of autoimmune disorders and in the prevention of graft rejection. However, the therapeutic application of calcitriol is limited by its potent effects on calcium metabolism which may result in development of hypercalciuria, hypercalcemia and soft tissue calcifications. A wide range of new vitamin D analogs are currently being investigated with the aim of retaining the sensitive differentiating properties of calcitriol with a decreased risk of induction of the dangerous hypercalcemic side-effects. The interested reader is referred to the comprehensive review by Binderup concerning structural and clinical aspects of various calcitriol analogs. Recent studies have also shown that calcitriol inhibits both CD4 expression and human immunodeficiency virus (HIV) infection of human monocytes, and this offers another potential application in the development of new vitamin D analogs for the treatment of immunodeficiency.

There is now accumulating evidence for the contribution of endocrine systems to the immune response,

and calcitriol may have a particularly versatile role in this interaction. Localized production of the hormone can benefit the immune environment in several ways. First, by stimulating phagocytic and antigen-presenting actions, calcitriol may help to promote initial immune responses. This would include the recruitment of additional monocytes by promotion of stem cell differentiation, but may also involve activation of T cells via antigen presentation and cytokine secretion. These stimulatory effects are counterbalanced by the ability of the hormone to inhibit T cell proliferation and thereby act as part of the feedback control of the immune response. Vitamin D may be seen as an addition to the long list of cytokines which have been reported in recent years. However, its close association with immune disorders and potential therapeutic applications have made a particularly important contribution to these studies.

The role of vitamin D-binding protein in the immune system

Vitamin D-binding protein is a precursor for the macrophage-activating factor

Inflammation results in chemotaxis and activation of macrophages. Inflamed tissues release lysophospholipids. Administration of lysophosphatidylcholine (lyso-Pc) or other lysophospholipids to mice activates macrophages for phagocytic and superoxide gener-

ation capacities. This inflammation-primed macrophage activation process is the major macrophage-activation cascade, which requires serum vitamin D₃-binding protein (DBP; human DBP is known as Gc protein) and participation of B and T lymphocytes. Stepwise incubation of inflammation-primed (or lyso-Pc-treated) B cells and T cells in a medium containing purified human Gc protein generates a potent macrophage-activating factor. However, stepwise cultivation of inflammation-primed T cells and B cells in a medium containing purified human Gc protein generates no macrophage-activating factor.

Analysis of intercellular signal transmission among these lymphocytes revealed that inflammation-primed (or lyso-Pc-treated) B cells modify Gc protein to yield the macrophage-proactivating factor which can be converted by T cells to the macrophage-activating factor. Gc glycoprotein (mol. wt 52 000; 458 amino acid residues) carries a trisaccharide composed of *N*-acetylgalactosamine with dibranched galactose and sialic acid termini. The generation process of the macrophage-activating factor was also demonstrated by stepwise incubation of Gc protein with an inducible membranous β -galactosidase of B cells and the membranous sialidase (Neu-1) of T cells to yield the macrophage-activating factor (MAF), a protein with *N*-acetylgalactosamine as a remaining sugar. Thus, Gc protein (or DBP) is a precursor for MAF as shown in Figure 1A. Conversion of Gc protein to macrophage-activating factor requires a sequential

Figure 1 Schematic illustration of formation of macrophage-activating factor (A) and deglycosylation of Gc protein (B). *. lyso-Pc-treated B cells.

contact of Gc protein with the inducible β -galactosidase of B cells and the Neu-1 sialidase of T cells. These glycosidases are present in limiting amounts on the plasma membranes. Native Gc protein must first interact with B cells and, through the action of β -galactosidase, have a galactose moiety removed. This yields a proactivating factor whose structure allows it to then interact with T cells. The T cell sialidase cleaves off the sialic acid residue, producing a macrophage-activating factor. Thus, the specific oligosaccharide sugars of the native Gc protein and its derivatives would appear to recognize the respective lymphocyte receptors. The affinity studies of the membranous receptors for Gc derivatives revealed that the native Gc protein binds B lymphocytes while the proactivating factor binds T lymphocytes exclusively. Further, the macrophage-activating factor binds macrophage exclusively. However, there is no evidence that these Gc derivatives or macrophage-activating factors, transmit calcitriol or its precursors to lymphocytes and macrophages during these processes.

Enzymatic conversion of vitamin D-binding protein to MAF

In vitro incubation of Gc protein with a mixture of commercial β -galactosidase and sialidase generates a

potent macrophage-activating factor, termed GcMAF. For clinical application of GcMAF, immobilized glycosidases should be used to prevent contamination of enzymes. Stepwise incubation of Gc protein with immobilized β -galactosidase and sialidase revealed that either sequence of hydrolysis of Gc glycoprotein by these glycosidases yields a remarkably potent GcMAF (Figure 2). A 3 h incubation of mouse peritoneal macrophages or human peripheral blood monocytes/macrophages with 4–10 $\mu\text{g ml}^{-1}$ of GcMAF results in greatly enhanced (5- to 7-fold) phagocytic capacity and a 15-fold increase in superoxide generation. Administration of 4–10 $\mu\text{g/mouse}$ (10–100 ng/human) of GcMAF also results in a greatly enhanced (5- to 7-fold) phagocytic and 15-fold increased superoxide-generating capacities of macrophages.

Administration to mice of GcMAF (3–50 $\mu\text{g/mouse}$) and sheep red blood cells simultaneously produces a large number of antibody-secreting splenic B cells (8×10^4 to 24×10^4 cells per spleen) in 2–4 days. Thus, the structurally well-defined macrophage-activating factor has a potent adjuvant activity for immunization of mice with sheep erythrocytes.

Figure 2 Two stepwise enzymatic pathways of Gc protein with immobilized glycosidases to yield the macrophage-activating factor (GcMAF). Stepwise hydrolysis of Gc protein by β -galactosidase and sialidase (A). Stepwise hydrolysis of Gc protein by sialidase and β -galactosidase (B).

Clinical significance of GcMAF

Vitamin D-binding protein, the precursor protein for the macrophage-activating factor, is abundant in the serum because Gc protein circulates in remarkably high concentration (250–350 $\mu\text{g ml}^{-1}$) in the blood-stream. Only 5% of Gc protein carries 25-hydroxy-vitamin D_3 which is a reservoir form of vitamin D. Gc protein has a strong affinity for 25-hydroxyvitamin D_3 but a weak affinity for calcitriol. This differential affinity of vitamin D metabolites allows Gc protein to transport and transmit the vitamin D metabolites to target cells. However, purified Gc protein, free of 25-hydroxyvitamin D_3 , is enzymatically converted to GcMAF. Addition of vitamin D metabolites during the above GcMAF generation process has no effect on generation rate or potency of GcMAF.

The membranous glycosidases of inflammation-primed lymphocytes rapidly convert serum Gc protein to the potent macrophage-activating factor. This inflammation-primed macrophage-activation process appears to be the major macrophage-activation cascade which is shared by other phagocytes such as osteoclasts. A defect in the inducible β -galactosidase of B lymphocytes in the macrophage-activation cascade produces dysfunctional macrophages and osteoclasts which manifest osteopetrosis in newborn. GcMAF can bypass the defective lymphocyte function and act directly on phagocytes. *In vitro* incubation of human osteoclasts with GcMAF efficiently activates osteoclasts as determined by superoxide generation. GcMAF has a capacity to rectify the osteopetrotic disorder as demonstrated by increased bone resorption and marrow formation when administered to osteopetrotic mice.

Another defect in the macrophage-activating cascade can be caused by deglycosylation of serum Gc protein by α -N-acetylgalactosaminidase secreted into the bloodstream from cancer cells or HIV-infected cells, as shown in Figure 1B. Deglycosylated Gc protein can not be converted to macrophage-activating factor, leading to immunosuppression. An impairment of immune function of the host will enhance opportunities for survival and proliferation of neoplastic cells.

VITAMIN E AND THE IMMUNE SYSTEM

Ronald R Watson, Department of Family and Community Medicine, University of Arizona, College of Medicine, Tucson, Arizona, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Vitamin E refers to a group of eight naturally occurring compounds: α -, β -, γ - and δ -tocopherols and tocotrienols, with the naturally occurring D- α -tocopherol having the highest biological activity. Rich sources of vitamin E include vegetable oils and products made from these oils, with smaller yet appreciable levels found in nuts, green leafy vegetables and wheat germ. Meats, fruits and vegetables seem to have little vitamin E.

Vitamin E is the major chain-breaking antioxidant in body tissues, protecting cell membranes at an early stage of free radical attack through its free radical-quenching activity. Singlet oxygen (an energized form of oxygen) is produced as a result of an oxidation process, damaging cell membranes and chromosomal material as well as producing free radicals. In addition, environmental pollutants such as smog, radiation, cigarette smoke, pesticides, herbicides and many drugs can react with tissues to produce free radicals, which react very quickly causing damage to membranes, enzymes, nucleic acids and inactive proteins. Specific damage to cells' RNA or DNA may result in uncontrolled cellular transformation and cancerous cell growth. Unless quenched by an antioxidant like vitamin E, highly unstable free radicals attack the polyunsaturated fatty acids of membrane phospholipids.

Vitamin E is also effective in preventing biological damage by immunoenhancement. High doses of vitamin E decrease CD8⁺ T cells and increase CD4⁺:CD8⁺ T cell ratio, increase total lymphocyte count, and stimulate activity of cytotoxic cells, natural killer (NK) cell activity, phagocytosis by macrophages and mitogen responsiveness. The immunostimulatory nature of vitamin E provides a basis for its use in the therapeutic modulation of immune functions in humans. Vitamin E supplementation is nontoxic, and may provide an effective therapy for prevention of several different diseases.

Substantial evidence from tissue culture and animal studies show that vitamin E is required by the immune system. In experimental models resistance to infections, antibody production in response to antigens, delayed cutaneous hypersensitivity skin tests, *in vitro* mitogenic responses of lymphocytes, phagocytic index and reticuloendothelial system clearance can be suppressed by vitamin E deficiency. Conversely, vitamin E has been found to stimulate helper

T cells, NK cell cytotoxicity, cytotoxic T lymphocyte activity, antibody response, macrophage phagocytosis, T and B cell mitogen responsiveness, and resistance to infection in animals.

The effect of vitamin E on the immune system depends on interaction with other antioxidant and pro-oxidant nutrients, polyunsaturated fatty acids, and other factors modulating the immune response, such as age and stress. The extent to which these vitamin E-induced immunological changes are associated with meaningful clinical outcomes has not been well studied. However, high plasma vitamin E levels are associated with a low incidence of infectious disease and colon cancer.

As immune responsiveness declines with age, with an increased incidence of infectious disease and tumors, vitamin E stimulation of immunity may be particularly applicable to the elderly. There was a significant increase in helper T cells and lymphocyte proliferation responses in institutionalized elderly patients given vitamins A, C and E for 28 days. In a community-based survey of 100 healthy subjects over 60 years of age, plasma vitamin E levels were positively correlated with delayed hypersensitivity responses to diphtheria toxoid, *Candida* and *Trichophyton*. Positive correlations were also observed between vitamin E levels and the number of delayed hypersensitivity responses in men; subjects with tocopherol levels greater than 135 mg l⁻¹ were found to have higher CD4:CD8 cell ratios.

Vitamin E may be beneficial to host defense mechanisms by preventing the infection-induced increases in tissue prostaglandin production from arachidonic acid.

Regulation of cytokine production by vitamin E could have major consequences on the prevention of disease development via modulation of immune responses. Vitamin E supplementation to levels 15-fold over standard mouse diets significantly increased interleukin 2 (IL-2) and interferon γ production by mitogen-stimulated splenocytes *in vitro*. Vitamin E at physiological concentrations (1–5 μ g ml⁻¹) *in vitro* significantly stimulated the production of IL-2 and interferon γ by mitogen-stimulated lymphocytes. Although vitamin E supplementation (800 IU D, α -tocopheryl acetate for 48 days before exercise) of elderly human subjects did not affect the basal production of IL-1 or tumor necrosis factor, it prevented

the exercise-induced rise in IL-1, and inhibited the production of IL-6. IL-1 and IL-6 have been implicated in exercise-induced muscle proteolysis and damage.

In the murine acquired immune deficiency syndrome (AIDS) vitamin E supplementation stimulates retrovirus-suppressed production of T_H1 cytokines and cell-mediated immunity, whereas it inhibits the excessive secretion of T_H2 cytokines and the hypergammaglobulinemia induced by the retrovirus. Thus, the normalization of T_H1/T_H2 cytokine secretion by vitamin E provides a mechanism for resolution of hypergammaglobulinemia and restoration of the cell-mediated immune response during murine AIDS.

In patients with human immunodeficiency virus (HIV) infection, there are high serum levels of IL-6 and tumor necrosis factor α (TNF α). Excessive amounts of these cytokines are also produced by mitogen-stimulated splenocytes or macrophages from LP-BM5 retrovirus-infected mice. Increased IL-6 and TNF α production would explain the hypergammaglobulinemia and global B cell dysfunction seen with both retrovirus infections. Dietary vitamin E significantly reduced the increased production of IL-6 and TNF α by mitogen-stimulated splenocytes, perhaps providing an explanation for the vitamin E-mediated alleviation of hypergammaglobulinemia and global B cell dysfunction in murine AIDS.

A dietary supplementation of 2–10 times higher than currently recommended levels of vitamin E significantly increased humoral and cell-mediated immune responses and phagocytic functions in laboratory and farm animals. It also increased their resistance to infectious diseases, and may counteract the immunosuppressive effect of stress in animals. Other antioxidant nutrients can interact with vitamin E in these processes.

A principal function of vitamin E is the prevention

of lipid peroxidation of cell membranes, which may form part of the mechanism of enhancing immune responses and phagocytosis. The rapidly proliferating cells of the stimulated immune and phagocytic systems are particularly prone to peroxidative damage by free radicals, peroxides and superoxides. The antioxidant effect also modulates the biosynthesis and activity of important cell regulators including prostaglandins, thromboxane and leukotrienes.

VITILIGO

David A Norris, Department of Dermatology, University of Colorado School of Medicine and Denver Department of Veterans Affairs Hospital, Denver, Colorado, USA

Vitiligo is a syndrome of depigmentation of the skin caused by damage to epidermal melanocytes. This may occur as a component of autoimmune syndromes, as a polygenic disorder, or sporadically. Melanocyte damage in vitiligo is believed to be caused by a number of cytotoxic stimuli: specific immune reactions, accumulation of toxic products of melanization, biochemical imbalances which favor cellular destruction, or neural stimuli.

Characteristics of vitiligo

Vitiligo is a syndrome characterized by acquired loss of pigmentation in a usually symmetrical but 'spotty' distribution, commonly involving the central face and lips, genitalia, hands and extremities. Pigmentation in the skin is produced by melanin, a heteropolymer synthesized in melanocytes by a complex biochemical pathway controlled by the rate-limiting

enzyme tyrosinase. Melanin is packaged in melanosomes which are transferred to keratinocytes to provide broad-spectrum photoprotection to the skin.

Jarrett and Szabo first proposed that vitiligo was characterized by two stages that might be sequential: type I vitiligo with decreased melanocyte tyrosinase activity, and type II vitiligo in which melanocytes were destroyed. In established vitiligo, cells with ultrastructural and immunohistochemical features of melanocytes are lost from the basal layer of the epidermis. Vacuolar damage to both basal layer melanocytes and keratinocytes can be found in association with infiltrates composed of monocytes and lymphocytes. Melanocytes and keratinocytes in the active border of vitiligo lesions show increased ICAM-1 expression, suggesting local effect of cytokines and potentiation of immunologic cytotoxicity.

Proposed pathological mechanisms

Several theories have been proposed to explain the functional inhibition and melanocyte destruction in vitiligo: the autocytoxic hypothesis, the neural hypothesis and the autoimmune hypothesis. In the autocytoxic hypothesis, toxic melanin intermediates are produced in excess or imbalance, causing autocytoxicity. The neural hypothesis is based on a proposed adrenergic/cholinergic imbalance in some vitiligo patients, and was promoted as a cause for segmental vitiligo. Schallreuter and Wood have proposed a variant of this hypothesis, that vitiligo is a disease of the entire epidermis in which heightened adrenergic responses lead to biochemical imbalances which inhibit melanization, but do not necessarily destroy melanocytes. They have demonstrated a number of biochemical abnormalities which induce decreases in antioxidant defenses and increases in tetrahydrobiopterin, which are proposed to inhibit melanization or to bleach melanin. The autoimmune hypothesis is based on the association of vitiligo with numerous autoimmune syndromes. Melanocyte-specific autoantibodies have been consistently found in modern studies of vitiligo, and these antibodies have been proven to induce cytotoxic damage of melanocytes.

Melanocytes are abnormally susceptible to immunologic cytotoxicity and to cytotoxicity induced by reactive oxygen species, in part because of defective antioxidant defenses. Abnormalities observed in cultured melanocytes from the margins of vitiligo lesions have led to the proposal that there are intrinsic melanocyte defects in vitiligo. It is accepted that multiple factors may influence melanocyte destruction in vitiligo, leading to a common

endpoint of melanocyte inhibition, then cytotoxic destruction. However, immunologic damage to melanocytes in vitiligo is still the most convincing mechanism of melanocyte damage, supported by extensive immunopathology and immunocytotoxicity experiments.

Autoimmune features of vitiligo

Vitiligo can be found in autoimmune families in association with Addison disease, alopecia areata, pernicious anemia, or mucocutaneous candidiasis, with an incidence 10–15 times higher than in the general population. Antibodies to thyroid, adrenal gland and gastric parietal cells can be demonstrated in vitiligo patients; using modern techniques, antibodies reactive with melanocytes have been consistently found in vitiligo patients' sera. The levels of these antibodies are greatest in patients with actively progressing disease and in vitiligo patients with other autoimmune disease. Both melanocyte-specific antibodies and antibodies reactive to other cells in addition to melanocytes have been identified. Some of these antibodies are specific for proteins involved in melanization such as tyrosinase and tyrosinase-related protein 1. Antibodies to a melanocyte-specific 85 kDa antigen have been described in dogs, cats and horses with vitiligo. Similar antibodies are found in a chicken model of vitiligo; bursectomy in these animals delays onset of vitiligo.

The functional significance of these autoantibodies was demonstrated when Norris and colleagues showed that cytotoxicity of cultured human melanocyte targets could be induced by antibodies in vitiligo patients' sera by either complement-mediated lysis or antibody-dependent cellular cytotoxicity (ADCC). Other investigators have subsequently verified that autoantibodies in vitiligo patients' sera can induce cytotoxic damage of melanocytes by multiple antibody-dependent mechanisms. In a nude mouse model, injection of sera from vitiligo patients induced depigmentation of human skin grafted onto the nude mouse. Cytotoxicity induced by autoantibodies is the only proposed mechanism in vitiligo in which a specific factor isolated from vitiligo patients has been directly demonstrated to induce melanocyte destruction both *in vitro* and *in vivo*.

The factors inducing melanocyte destruction may differ in individual vitiligo patients. Members of autoimmune families are predisposed to produce autoantibodies, and melanocyte-specific autoantibodies are likely to be the major determinant of melanocyte cytotoxicity in these families. In other vitiligo patients it is possible that autoimmune melanocyte destruction may represent a later stage of

disease, following melanocyte destruction by auto-cytotoxicity or other factors. However, once melanocyte-specific antibodies are produced, it is likely that these produce additional melanocyte damage and the depletion of melanocytes in the basal layer of the epidermis.

W

WESTERN BLOTTING

Harry Towbin, Novartis Pharma Inc., Basel, Switzerland

Western blotting (immunoblotting, protein blotting) is a sensitive immunological method for detecting electrophoretically separated proteins. The technique was developed independently by several groups in 1979 and was later termed 'western blotting' because of its analogy to Southern and northern blotting. Its characteristic feature is the transfer of a complex protein pattern resolved by slab gel electrophoresis to a membrane which serves as a carrier for all subsequent immunochemical reactions. Major fields of application in basic research are determination of molecular weights of protein antigens, detection of antigens in crude mixtures of proteins, and assessment of the quality of animal antisera. Western blotting has found important clinical applications in autoimmune disease, allergy, infectious diseases and others.

Steps of western blotting experiments

Basically, western blotting experiments consist of five steps (cf Figures 1 and 2 and Table 1):

1. Sample preparation and electrophoretic separation in a slab gel.
2. Transfer to a membrane with high protein binding capacity.
3. Blocking (quenching) of the residual binding capacity of the membrane.
4. Incubation with antibody.
5. Detection of bound antibody with secondary reagents.

The procedure combines elements of immunoelectrophoresis, enzyme-linked immunoassay, and – with respect to the localized dye formation – immunohistochemistry. The deposition and immobilization

Figure 1 Common methods of transferring proteins from a slab gel to an immobilizing membrane. Two methods rely on transverse electrophoresis either by a buffer tank device (buffer tank, plastic pads and supports not shown) or by a semidry blotting apparatus where transfer is mediated by filter paper soaked in buffer. The third method, transfer by diffusion, is particularly useful for thin plastic supported gels. The arrows indicate the direction of the movement of the proteins from the gel towards the immobilizing membrane.

of the proteins on a membrane greatly facilitates access of large molecules (antibodies) to the antigen as well as all washing and any further incubation steps. Western blotting is particularly valuable for characterizing protein antigens which are difficult to analyze by immune precipitation, e.g. antigens not soluble in buffers compatible with immunological reactions or antigens that cannot be radioactively labeled (e.g. complex allergens, protozoa, food components, etc.).

Electrophoretic separation

The numerous variations possible at each step render western blotting a versatile analytical tool. For separation, electrophoresis in polyacrylamide gels containing sodium dodecyl sulfate (SDS) is usually preferred because this detergent solubilizes virtually all proteins and because the system yields information on the molecular weight of the proteins. Western blot-

ting is also easily adapted to agarose gels (e.g. isoelectric focusing) or to electrophoresis in buffer systems containing urea or physiological buffers.

Transfer

Several methods have been devised to transfer the resolved proteins to membranes. Replicas may be produced by letting the proteins diffuse to a membrane placed on one – or both sides – of the gel. However, diffusion from thick polyacrylamide gels is slow and inefficient. To speed up elution transverse electrophoresis is usually employed (Figure 1). An electric field is applied perpendicularly to the gel surface. The immobilizing membrane and the gel are held in place by plastic sponges and plastic grids to form a rigid sandwich assembly which is placed into a chamber containing buffer and plate electrodes. Alternatively, a horizontal setup is used where gel and membrane are sandwiched between several

Figure 2 Scheme of a typical immunological detection procedure for protein antigens transferred by western blotting. Microscopic views of the membrane are shown on the right.

Table 1 Commonly used components in western blotting

Transfer methods	Transverse electrophoresis Tank system Semidry system Diffusion Vacuum induced flow
Membranes	Nitrocellulose (NC) Polyvinyl difluoride (PVDF) Nylon derivatives

Primary ligands	Animal or human serum Affinity purified antibodies Monoclonal antibodies
Secondary reagents	Antibodies Protein A or protein G [as enzyme conjugated reagents (alkaline phosphatase, peroxidase) or as iodinated reagents]
Detection principles	Color formation Radioactivity Chemiluminescence Fluorescence

layers of filter paper imbibed with buffer (semidry blotting). The buffer for electrophoretic elution has to be chosen in such a way that all proteins move into the same direction. In order to retain the negative charges as well as to keep the proteins soluble, electroelution from SDS-gels is done in the presence of a low concentration (0.01%) of SDS. An excess of the detergent prevents adsorption to the membrane.

Membranes

Immobilizing membranes are extremely porous and provide a large internal surface. The binding capacity of a membrane is in the range of 100-fold higher than a flat surface. Nitrocellulose is one of the earliest types of membrane used for western blotting and still enjoys wide popularity. The forces retaining proteins on nitrocellulose are believed to be hydrophobic, mainly. This view is supported by the observation that nonionic detergents may release adsorbed proteins. Novel, sturdier membranes, for example based on nylon or other synthetic polymers, have been developed to suit the needs of blotting techniques. In particular, polyvinyl difluoride (PVDF) membranes have found extensive use. Substitution with strongly positively charged groups has further improved the binding capacity of membranes, presumably by adding ionic binding forces to the hydrophobic interaction. Furthermore, several types of chemically activated membranes are in use which allow covalent binding of the transferred protein.

Visualization of total protein pattern

In order to assure that the proteins are transferred and retained on the membrane the protein pattern can be visualized by a range of protein-staining methods. Several dyes (e.g. Ponceau S) allow reversible staining and for these antigenicity is usually not impaired. Molecular weight standards covalently derivatized with a dye are also useful for monitoring the efficiency of the transfer and, in addition, later serve to position immunostained bands relative to marker proteins on the membrane.

Blocking

The high capacity to absorb proteins nonspecifically interferes with ensuing steps which rely on specific binding interactions. In order to avoid nonspecific sticking of the antibody probe, the excess binding capacity of the chosen membrane has to be saturated. Blocking can be achieved by concentrated solutions of cheap proteins (bovine serum albumin, an irrelevant serum, milk proteins, etc.). As nonionic detergents do not usually interfere with antibody binding, they can be used alone or as additions to protein-based blocking solutions. Blocking with detergents allows staining of the total protein pattern after visualization of immunologically stained bands, an aspect particularly important for two-dimensional separations.

Probing with specific antibodies

Western blotting may be performed with both polyclonal and monoclonal antibodies. In most respects, considerations given to solid phase immunoassays in microtiter plates also apply to western blotting. Hence, the signal ultimately generated will depend on the interplay of numerous factors such as affinity, concentration, duration of incubation, nonspecific binding, etc. As a rule of thumb, solutions of $1 \mu\text{g ml}^{-1}$ specific antibody incubated for several hours is a good starting point for optimizations. Only a small fraction of the antibody in the incubation mixture will be bound to the immobilized antigen, even if monospecific antibodies are used. Due to the thickness of the membranes, incubations and washing steps are often longer than for solid phase immunoassays on nonporous surfaces such as microtiter plates. Before the next step (detection of bound antibody), nonbound primary antibody has to be washed out thoroughly.

Detection of bound antibody

It is possible to directly label the primary antibody, for example by radioiodination. However, it is the large choice of secondary reagents which accounts

for the flexibility of western blotting and the large signal amplification that often is needed. There is virtually no limitation to the variations at this step and any of the labels (radioactivity, enzymes, fluorescence, colloidal gold or dyes) may be combined with antibody-binding reagents (antibodies directed against the primary antibody, protein A, protein G). The avidin-biotin system with all of its variations has also been introduced for blotting applications. Some of the staining protocols have in part been adapted from immunohistochemistry where localized enzymatic color formation is the final readout, as in western blotting. When monitoring patient sera it is often important to assess the class of the reactive immunoglobulins (IgE in allergy, IgM/IgG in infectious diseases, etc.). With commercially available specific reagents this can be readily achieved on western blots. Sensitive detection in the range of picograms of antigen is accomplished with chemiluminescent enzyme substrates where the products decay under light emission. Bands are made visible by exposing the blot to photographic films or sensitive cameras for a few seconds up to several minutes.

Quantification

Blots may be quantitatively analyzed by reflectance densitometry of enzymatically stained blots of autoradiographs as well as by directly counting excised areas of a radiolabelled blot. Usually by comparing with appropriate standards, the amount of antigen or the potency of an antiserum can be measured.

Antigenicity of blotted proteins

The sample treatment before electrophoresis usually affects the conformation of proteins and influences their antigenicity. Even mere adsorption to solid phases may lead to loss or gain of antigenicity, be it due to interactions between the solid phase and the antigenic region of the protein or due to conformational changes associated with adsorption. If polyclonal antibodies are used as probes on western blots, sample treatment is often less critical than for monoclonal antibodies. The phenomenon may be explained by considering that various types of antibody may be present in a polyclonal serum: 1) antibodies recognizing the native molecule exclusively, 2) antibodies recognizing native as well as denatured proteins, and 3) antibodies reacting with denatured proteins, exclusively. The antibody spectrum present in the serum is, of course, dependent on the immunization schedule as well as on the properties of the protein of interest. Many examples are known where sera raised against peptides of a protein react much better with a blotted protein than with the native protein. In the case of monoclonal antibodies, the

range of antigenic conformations tolerated is often much narrower and an antibody selected for binding the native molecule may completely fail to react on western blots.

However, even after boiling in SDS and blotting, proteins may refold to some extent. Refolding can be promoted by certain detergents or heating during the blocking step, or be initiated during the transfer step.

Special techniques

Affinity purification of antibodies from blots

Small amounts of specific antibodies can be recovered from excised bands of a blot. The antibodies can serve as reagents in immunohistochemistry or for clarifying suspected cross-reactions between protein mixtures. In order to deposit a large amount of antigen on the blot the sample is applied across the whole width of a slab gel.

Protein sequencing

In this technique proteins are transferred from SDS-gels to glass fiber filters or membranes resisting the organic solvents and reagents used for sequencing. Proteins, visualized by a general protein stain, are excised and directly inserted into an automatic sequencer. The technique is used for small amounts of protein which are difficult to purify by other methods.

Ligand blotting

Many solubilized receptor proteins will specifically bind their ligands and do so even after western blotting if harsh treatments (heating in SDS, reduction of disulfide bonds) are avoided at all steps. The ligand-receptor pairs analyzed by this procedure encompass a wide variety of molecules (steroids, peptide hormones, toxins, adhesion molecules). Even live cells (bacteria, eukaryotic cells) have been found to interact specifically with immobilized blotted adhesion proteins.

Fingerprinting of pathogens

This is useful for epidemiological studies of bacteria and viruses. Pathogens are cultured by usual microbiological techniques and isolates are subjected to SDS-gel electrophoresis and blotting. The strips are incubated with a standard antiserum and developed with suitable secondary reagents. The banding pattern characterizes the strain and distinguishes it from other strains.

Immunization

Proteins attainable only in small amounts are difficult to purify by liquid chromatography but may be separated by gel electrophoresis. The small amounts of pure proteins in a resolved band often suffice to immunize experimental animals. As an alternative to homogenizing the relevant slices of polyacrylamide (which leads to quite voluminous slurries) the blotted protein band may be implanted or injected into an animal.

Dot immunobinding

Other names for dot immunobinding are dot blotting and dot assay. The high binding capacity of blotting membranes can also be utilized for immunoassays where the electrophoretic separation of western blotting is not required. The antigen solution is spotted on to the membrane as a drop of 1 µl volume or smaller, resulting in a dot of a few millimeters diameter. Larger volumes may be deposited in a filtration manifold where proteins adsorb to the membrane. The technique is useful for adsorbing relatively impure antigens where the reactive components only constitute a small fraction of the total protein. The investigator is free to deposit different antigen and control preparations on the same piece of membrane. Further processing for antigen detection is analogous to western blotting.

HIV-1

A diagnostic test based on blotted viral proteins is commercially produced to confirm presence of antibodies against human immunodeficiency virus 1 (HIV-1). To perform the test the prefabricated strip has only to be incubated with test serum and developing reagents. About nine viral proteins are discernible on blots. Certain empirically found constellations of banding patterns confirm the primary test.

XENOTRANSPLANTATION

Amelia Bartholomew, University of Illinois, Chicago, Illinois, USA

Hugh Auchincloss, Harvard Medical School, Massachusetts
General Hospital, Boston, Massachusetts, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Xenotransplantation is the transplantation of tissues between members of different species. The term 'heterotransplantation' appeared in earlier literature before the words autologous, syngeneic, allogeneic and xenogeneic were commonly accepted to describe the genetic differences between donors and recipients. Xenogeneic transplantation can involve 'concordant' or 'discordant' donors, roughly according to the phylogenetic distance between the species involved. Discordant species combinations are those in which the recipient has natural preformed antibodies against donor endothelial antigens which cause hyperacute rejection of most vascularized organ transplants.

Xenogeneic transplantation elicits an immune response which is fundamentally similar to that which occurs in allotransplantation. Unique features of xenotransplantation stem partly from the greater antigenic disparities involved and partly from the physiologic incompatibilities which occur when mixing tissues from different species.

Brief clinical history

Clinical interest in xenogeneic transplantation has stemmed from the shortage of organs available for human transplantation, originally because cadaver donors were not often available before the concept of brain death was accepted in the 1960s, and more recently because the extraordinary success of clinical allotransplantation has again created a demand which exceeds the supply of organs.

Reemtsma was the first to report a technically successful xenotransplant to a human patient in 1963. He performed a series of kidney transplants from chimpanzees, one of which survived for 9 months with good renal function before the patient died from complications of immunosuppression. Over the next several years, Starzl and several others performed kidney, liver and heart transplants from

baboons, chimpanzees and pigs to human recipients without long-term success.

Clinical xenotransplantation began again with a heart transplant from a baboon to 'Baby Fac' in 1985. Since then there have been two baboon-to-human liver transplants, a series of islet transplants from fetal pigs to humans, transplantation of fetal pig neural cells to patients with Parkinson disease, and at least one bone marrow transplant from a baboon to a patient with the acquired immune deficiency syndrome (AIDS). In addition, livers from pigs and other species have been used to maintain patients with fulminant hepatic failure by intermittent *ex vivo* perfusion of an animal organ, and there has been at least one effort at 'bridge' transplantation in which a pig liver was transplanted to a critically ill human patient as a first step toward subsequent replacement by an allogeneic organ. At this point, however, no clinically successful xenotransplant has been reported in the sense of achieving patient survival for one year based on the ongoing physiologic function of the transplanted tissue.

Choice of donor species

Clinical efforts at xenografting have used both concordant (chimpanzee and baboon) and discordant (pig) donors. Although there are clear immunologic advantages to the use of concordant donors, practical issues will prevent the large-scale use of non-human primates for human transplantation. Chimpanzees are an endangered species. Baboons, while available in larger numbers, are too small for many types of transplantation. In addition, the need to exclude many potential pathogens in baboons, their long gestation time, and their slow maturation make it unlikely that large numbers of transplants from baboons to humans will ever be performed. Thus, concordant clinical xenotransplantation will prob-

ably occur only as a step toward more clinically useful discordant transplantation.

While many discordant species are available for humans, research efforts have focused almost exclusively on pigs. They are abundantly available, of appropriate size, demonstrate some important physiologic similarities to humans, and have short gestation times and large litters. These last features make it possible to accomplish genetic modifications of pigs over reasonable periods of time.

Immunologic barriers and types of rejection

Hyperacute rejection

Hyperacute rejection of primarily vascularized organ transplants is characterized by vascular disruption leading to hemorrhage and thrombosis within minutes of transplantation. The essential elements leading to hyperacute rejection include the expression of foreign determinants on donor vascular endothelium, the presence of preformed antibodies in the recipient which bind to these determinants, the activation of complement, and the subsequent activation of donor endothelium.

The primary pig endothelial determinant recognized by human recipients is a galactose- α 1,3-galactose sugar linkage formed by the action of a galactosyltransferase enzyme expressed by pigs but not by higher order primates. This determinant is present on many cell surface glycoproteins, especially endothelial adhesion molecules. There are undoubtedly other novel determinants on pig endothelium which are not expressed at sufficient density to cause hyperacute rejection consistently.

The human preformed antibodies which bind the pig α -Gal determinant are similar to blood group antibodies within a species. They are thought to arise from cross-reactions with bacterial carbohydrate antigens which are common in the environment. Thus, although they are called 'natural' antibodies, their presence actually reflects previous exposure. Although both immunoglobulin M (IgM) and IgG natural antibodies exist, only IgM antibodies cause hyperacute rejection of pig organs by primates. This reflects the low binding affinity of natural antibodies with their antigens such that hyperacute rejection is only triggered when the foreign determinant is expressed at high density and polyvalent antibodies are involved.

Sufficient binding of natural antibodies to pig endothelium activates complement by the classical pathway. Complement then becomes the principal mediator of hyperacute rejection. In some species combinations, complement activation can also occur

by the alternative pathway leading to hyperacute rejection even when natural antibodies have been removed. However, this does not occur in the pig-to-human combination.

Complement activation is normally controlled by a series of complement regulatory proteins including decay-accelerating factor (DAF), CD59 and membrane cofactor protein (MCP). Despite the function of these proteins, hyperacute rejection can occur in allogeneic transplantation when preformed antibodies are present. In xenogeneic transplantation, however, the process is magnified considerably because some of the complement regulatory proteins show species-restricted function. For example, the pig DAF protein does not interact with molecules of the human complement system, allowing complement activation to occur without its ordinary feedback inhibition.

The target of complement activation in hyperacute rejection is the donor endothelium. Evidence suggests that it is not the death of endothelial cells which is important, but rather their activation triggered by binding of the complement membrane attack complex. Endothelial activation causes changes in the shape of endothelial cells, creating intercellular gaps, and the loss of heparan sulfate, which normally enhances antithrombin III activity and inhibits coagulation and complement activation. The outcome of endothelial activation is the escape of blood components, exposure of thrombogenic surfaces and, therefore, interstitial edema, hemorrhage and thrombosis in the graft.

Acute vascular or delayed xenograft rejection

Concordant xenografts do not suffer hyperacute rejection. In addition, this form of rejection can be prevented in discordant combinations by inhibition of complement activation or by depletion of preformed natural antibodies. In both cases, however, xenografts are still rejected more rapidly than allografts by a process which has been termed 'acute vascular rejection' or 'delayed xenograft rejection' by different investigators. This rejection appears to be independent of complement, but is associated with the early appearance of antibodies directed primarily at donor endothelial glycoproteins. Thus, this early antibody response may reflect pre-existing 'natural' antibodies which were not detectable prior to transplantation or which were only transiently removed to avoid hyperacute rejection. Although this accelerated form of xenograft rejection can sometimes be prevented by immunosuppressive agents directed at B cells, it is not clear that the process is entirely dependent on antibodies.

'Acute vascular' or 'delayed xenograft' rejection

involves endothelial activation, but the process is slower than in hyperacute rejection and requires the synthesis of new endothelial proteins. Thus, this has been referred to as type II endothelial activation. Changes in the endothelium include the upregulation of adhesion molecules (including P- and E-selectin and VCAM-1), loss of fibrinolytic and anticoagulant activity, and the release of cytokines such as interleukin 1 (IL-1) and IL-8 which promote inflammation. In some cases, species-restricted function of some of the molecular interactions which regulate inflammatory responses may augment the consequences of this endothelial activation, just as the failure of complement regulatory proteins enhances hyperacute rejection.

Cell-mediated xenograft rejection

Because the humoral rejection of xenografts is so powerful, it has been difficult to study the cell-mediated rejection which would play a role if both hyperacute and delayed xenograft rejection were adequately controlled. However, cellular xenografts, including cultured pancreatic islets, do not express donor endothelium and are revascularized by recipient vessels. Thus, these types of xenotransplants may not undergo hyperacute rejection and acute vascular rejection, both of which depend on endothelial activation. The difficulty in achieving prolonged survival of xenogeneic cellular transplants and the rapid rejection of all types of xenografts by B cell-deficient mice indicate that cellular immunity causes powerful xenograft rejection.

In vitro studies of xenogeneic cellular immunity show different results from allogeneic responses depending on the species combination. In some cases, primary *in vitro* responses are weak or absent, while in others (including the pig-to-human combination) they are intact and include an additional natural killer (NK) response which is not seen in allogeneic cultures. Molecular incompatibilities between species again appear to be responsible for these unusual results. In some cases, incompatibilities between the accessory molecules involved in T cell activation and their ligands on xenogeneic stimulating cells weaken the T cell response. In others, the inability of NK cell inhibitory receptors to recognize xenogeneic class I molecules may increase this form of cellular immunity. After xenograft rejection, *in vitro* assays show strong responses which often depend on the indirect pathway by which T cells are stimulated by self antigen-presenting cells (APCs) presenting peptides of the xenoantigens.

In vivo studies of cell-mediated xenograft rejection have suggested that CD4⁺ T cells are especially important in initiating rejection. The cytokines pro-

duced by these T cells are probably required to activate macrophages, eosinophils or NK cells, but the actual effector mechanisms of cell-mediated xenograft rejection are poorly understood.

Chronic rejection

Few xenografts have survived long enough *in vivo* to determine their susceptibility to chronic rejection. However, their greater antigenic disparity and the importance of their vascular endothelium as a target for other types of rejection suggest that xenografts will be even more susceptible to chronic rejection than allografts.

Achieving prolonged survival to xenografts

The immunologic barriers to xenografts are stronger than for allografts. Strategies to overcome these barriers include efforts to reduce the recipient's immune response, to modify the donor animals, and to induce tolerance to xenogeneic antigens.

Suppression of the recipient's response

To avoid hyperacute rejection, natural antibodies have been removed from recipients by plasmapheresis, by pretransplant organ perfusion, and by column absorption of the critical $\alpha 1,3$ -Gal-binding antibodies. Complement inhibition has been achieved using cobra venom factor and by treatment with soluble complement receptor 1 (sCR1). To avoid the subsequent vigorous antibody response to xenografts, recipients have been treated with B cell-targeted immunosuppression, including drugs (such as cyclophosphamide, methotrexate, or 1,5-deoxyspergualin), IgM-specific antibodies to deplete B cells, and splenectomy. Additional immunosuppressive agents such as cyclosporine or tacrolimus have been used to suppress T cell immunity.

Accommodation

While it would seem unlikely that recipient antibody responses could be permanently eliminated by immunosuppression, some evidence suggests that this may be unnecessary. Human renal allografts transplanted between ABO incompatible individuals have been shown to survive even if recipient blood group antibodies are allowed to return several weeks after transplantation. The term 'accommodation' has been used to describe the changes in donor endothelium which prevent hyperacute rejection despite the expression of antigens and the presence of recipient antibodies reactive with them. Several examples of apparent accommodation have been demonstrated in xenogeneic transplantation.

Modifications of donor animals

One of the advantages of xenogeneic transplantation is that donor animals can be genetically modified to diminish the rejection of their organs. For pigs, it is not yet possible to eliminate gene expression by targeted gene disruption, but it is possible to generate transgenic animals. Efforts are therefore underway to diminish the antigenicity of pigs, to eliminate the physiologic incompatibilities which promote xenograft rejection, and to generate animals which actually suppress the immune response.

The α 1,3-galactosyltransferase gene has been knocked out in mice. While this is not yet possible in pigs, overexpression of the gene for α 1,2-fucosyltransferase has been found to compete during glycosylation, leading to greatly diminished expression of the α -Gal determinant in favor of a nonantigenic one. Transgenic pigs have also been generated which express genes encoding human DAF or CD59. High-level expression of these complement regulatory proteins not only corrects the physiologic incompatibilities of the xenogeneic molecules, but also appears to provide supraphysiologic protection against hyperacute rejection. Further efforts are underway to generate transgenic pigs which might prevent T cell activation or induce peripheral tolerance by the elimination of donor-reactive lymphocytes.

Tolerance induction

Because of the greater antigenic disparities and the additional immunologic barriers associated with xenografting, more immunosuppression has been required to achieve survival of xenografts comparable to that of allografts. The induction of tolerance would eliminate this serious disadvantage of xenografts for clinical transplantation. Genetic modifications of donor animals may help to achieve tolerance by peripheral mechanisms. In addition, efforts are underway to achieve deletional tolerance by generating mixed bone marrow chimeras. Small animal models have shown that xenogeneic mixed bone marrow chimeras can be generated in closely related species combinations. However, achieving engraftment of xenogeneic marrow requires more vigorous conditioning of the recipient than for allogeneic marrow and also appears to require the provision of species-specific growth factors in more distantly related species combinations. Thus, physiologic incompatibilities again play a role in the induction of tolerance for xenografts.

Limitations of physiologic organ function in xenografting

Physiologic incompatibilities are an important aspect of the immune response to xenografts. It is likely that physiologic incompatibilities of organ function will also become important in xenografting, although at present too few functioning xenografts have survived long enough to examine this issue. It does appear that pancreatic islets from one species can regulate glucose levels satisfactorily in another species. In addition, humans have survived for many months with renal function provided by a chimpanzee kidney. On the other hand, patients with baboon livers were found to have vastly reduced blood levels of uric acid and cholesterol because of differences in hepatic physiology. Thus, it is almost certain that important physiologic incompatibilities will become apparent when it is possible to transplant complex organs across wide species differences.

Xenozoonoses

The possibility that animal organs could be used for human transplantation has raised concern that infections from animals might be transmitted to human recipients. The term 'xenozoonoses' has been developed to describe this possibility. While many potential human pathogens have been identified in animals, screening of potential animal donors and their breeding in specific-pathogen-free facilities can reduce the likelihood of disease transmission. Indeed, from the point of view of the individual recipient, the infectious risk of xenotransplantation is likely to be less than for cadaveric allotransplantation, where donor screening must be done rapidly, focusing only on the most serious pathogens. On the other hand, cross-species transplantation raises the possibility that endogenous retroviruses of the donor might recombine in human recipients to generate as yet unknown pathogens.

While the risk of such an event is small for an individual recipient, the possibility raises a public health concern for society as a whole. This fear is heightened by the belief that AIDS in humans developed as a result of cross-species transmission of a retrovirus from nonhuman primates. Despite these theoretical concerns, national agencies responsible for public health safety have determined that it is reasonable to proceed with clinical attempts at xenotransplantation as long as donor animals are suitably screened and recipients monitored for evidence of disease transmission.

Y

YERSINIA, INFECTION AND IMMUNITY

Risto Tertti, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland

Auli Toivanen, Department of Medicine, Turku University, Turku, Finland

Yersinias are gram-negative rods and belong to the family Enterobacteriaceae. The three *Yersinia* species virulent for humans and rodents are *Y. pestis*, *Y. pseudotuberculosis* and certain serotypes of *Y. enterocolitica*. They all show tropism for lymphoid

tissue. However, yersiniosis, the disease caused by *Y. pseudotuberculosis* and *Y. enterocolitica* is very different from bubonic plague or 'black death' caused by *Y. pestis*. Yersiniosis is characterized in the acute phase by gastroenteritis with inflammation of the ter-

minal ileum and mesenteric lymph nodes, and it is sometimes followed by postinfection complications, but life-threatening infections are exceptional. In contrast, as recently as in 1988, 13 of 1363 reported cases of bubonic plague were fatal. Interestingly enough, *Y. pestis* and *Y. pseudotuberculosis* show an extremely high degree of homology at the DNA level.

The virulence of *Yersinia* species depends on a 70–80 kb virulence plasmid, but chromosomal genes also contribute to virulence. Serotyping of *Yersinia* species is based on lipopolysaccharide. At least 57 serotypes of *Y. enterocolitica* and 13 serotypes of *Y. pseudotuberculosis* have been determined, and certain serotypes are clearly more virulent than others. Nevertheless, the role of lipopolysaccharide in the virulence of *Yersinia* has not been established.

Immune responses of the host

Yersiniosis elicits both humoral and cell-mediated immune responses in the host. It appears that most of the antibody response is directed toward the lipopolysaccharide. Follow-up studies have, however, demonstrated that patients with *Yersinia* infection produce antibodies directed towards a multitude of antigenic determinants, both plasmid and chromosomally encoded ones. The antibodies often persist for several months and in the case of postinfection complications even years. As yersiniosis is fairly common in some parts of the world it is thus not surprising that, for example in northern Europe, the sera of 10–30% of healthy blood donors indicate previous *Y. enterocolitica* or *Y. pseudotuberculosis* infection. A remarkable feature of *Yersinia* infection is that it may pass quite unnoticed. This is illustrated by occasional severe reactions upon transfusion of blood, the donor of which, unaware of it, has carried *Yersinia* in the blood. During preservation at refrigerator temperature the psychrophilic yersinias multiply. Furthermore, epidemiologic studies have demonstrated that many individuals with verifiable infection remain symptomless.

Reactive arthritis, a common postinfection complication of yersiniosis, belongs to the seronegative spondyloarthropathies strongly associated with possession of the class I major histocompatibility complex (MHC) antigen HLA-B27. Approximately 80% of patients with *Yersinia*-triggered reactive arthritis are B27-positive. *Yersinia*-triggered uveitis and urethritis are also associated with B27 antigens but erythema nodosum is not. Of the seronegative spondyloarthropathies, ankylosing spondylitis shows the strongest association to HLA-B27 (95%), and hypotheses regarding the pathogenesis of *Yersinia*-triggered reactive arthritis and ankylosing spondylitis

go along similar lines. It has been suggested but not proven that molecular mimicry between antigens of the *Yersinia* microorganism and the B27 antigen leads to the development of reactive arthritis. Molecular mimicry might either cause ineffective elimination of the microorganism due to tolerance or, on the other hand, trigger autoimmunity. Extensive studies regarding the peptide-binding groove of the HLA-B27 molecule and of the bound peptides have not led to an explanation of this disease association. However, a surface component of *Y. enterocolitica* shares certain structural similarity with the human thyrotropin receptor.

There is evidence that patients with *Yersinia*-triggered reactive arthritis differ in their immune functions from yersiniosis patients with uncomplicated disease. The former tend to have a weaker *Yersinia*-specific cell-mediated immune response but a stronger and more persistent immunoglobulin A (IgA) antibody response against the microbe. At the early phase of infection those with reactive arthritis show more *Yersinia*-specific opsonic antibodies, and they have more *Yersinia*-specific immune complexes. In addition, B27-positive individuals may have exaggerated inflammatory responsiveness, such as stronger chemotactic function and production of some inflammatory mediators. It is probable that the immune response against the causative microorganism has an important role in the pathogenesis of *Yersinia*-triggered reactive arthritis. *Yersinia* antigens have been detected in synovial membrane and in synovial fluid cells in patients with reactive arthritis, and the longstanding antibody response may be a reflection of the continuous stimulation by the microbes hiding in, for example, gut-associated lymphoid tissues.

Evasive strategies by the organism

Yersinias are regarded as facultatively intracellular microorganisms, but this notion is currently questioned, especially regarding *Y. enterocolitica* and *Y. pseudotuberculosis*. Yersinias can obviously stay viable and even multiply in macrophages. In calcium-deficient conditions at 37°C, the growth of virulence plasmid-positive yersinias is greatly retarded and they express several outer membrane proteins, which are also released to the culture medium. This phenomenon is called calcium dependency or low calcium response. It is currently believed that low calcium content and the temperature of 37°C signal to the microbe that it is in an intracellular compartment.

Y. pestis has, in addition to the virulence plasmid coding for low calcium response, other plasmids

coding for the plague murine toxin, pesticin, plasminogen activator and coagulase. In addition to plasmid-encoded genes, chromosomal genes are needed for full virulence. For example, some invasion and iron metabolism-associated structures necessary for virulence are chromosomally encoded. This is also illustrated by the fact that the avirulent *Yersinia* species do not gain virulence even if they are provided with the plasmid. The role of iron is also indicated in the clinical setting, as iron overload predisposes to severe septic forms of yersiniosis.

Virulence-determining *Yersinia* plasmid-encoded outer membrane proteins (YOPs) of *Y. enterocolitica* and *Y. pseudotuberculosis* mediate attachment of the bacteria to epithelial cells, cytotoxicity *in vitro* for mouse macrophage cell lines and resident mouse peritoneal macrophages, resistance to the complement-mediated bactericidal activity of serum and resistance to opsonization and phagocytosis. A few of these virulence-associated functions have already been attributed to specific YOPs. Invasiveness, a chromosomally encoded factor, is understood to some extent at the molecular level and involves a molecule termed 'invasin'. The entry of yersinias into mammalian cells is initiated by specific binding of bacteria to cell receptors belonging to the integrin family of cell adhesion molecules. A *Yersinia* adhesin (YadA) has been demonstrated to bind specifically to joint collagens and other extracellular matrix molecules and it has also been found to contribute to the arthritogenicity of *Y. enterocolitica* 0:8 in a rat experimental model. Furthermore, yersinias produce interesting superantigens, stimulating and expanding T cells.

Vaccines

Effective vaccines against yersiniosis have yet to be developed. An effective plague vaccine would naturally be valuable. *Yersinia* gastroenteritis as such is rarely a problem for patients, but the postinfection complications may cause a great amount of pain and inconvenience. A vaccine against yersiniosis might be useful for individuals prone to reactive arthritis. Relatively little is known about the role of immune responses in protection against *Yersinia* infections. Some studies have indicated that cell-mediated reactions are associated with long-term immunity to plague. This is compatible with the fact that *Y. pestis* is a pathogen capable of intracellular growth. That cell-mediated immune responses are elicited during yersiniosis is quite clear, but their role in protection against infection remains unclear. Most of the evidence supports the role of humoral immunity in protection against yersiniosis.

To obtain protection against the many serotypes of pathogenic *Yersinia* species the putative vaccine should be directed against a determinant found in all of them. Such a determinant could be one of the YOPs or invasin. However, more information regarding the pathogenesis of *Yersinia* infections is needed if effective vaccines are to be developed.

ZINC AND THE IMMUNE SYSTEM

William R Beisel, Department of Molecular Microbiology and Immunology, The Johns Hopkins School of Hygiene and Public Health, Baltimore, Maryland, USA
 Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Zinc, an essential nutrient, is an element of profound importance in many functions of the immune system and other host defense mechanisms. And uniquely, through the action of proinflammatory cytokines, immunological responses can acutely alter the body distribution of zinc.

Since zinc is in the active site of more than 200 metalloenzymes, it is not surprising that it is of widespread metabolic importance, contributing to the proper functioning of all body cells, including those of the immune system. Zinc is an essential nutrient during cell replication, because zinc metalloenzymes are required for nucleic acid synthesis, with DNA and RNA polymerases, reverse transcriptase and nucleoside phosphorylase serving as examples.

But molecular mechanisms by which zinc influences the immune system are not limited to enzymatic functions. Zinc may also influence nucleic acid metabolism by altering the binding of F1 and F3 histones to DNA, so as to affect RNA synthesis. Zinc appears to modify and stabilize cell membranes, forming mercaptides with thiol groups of proteins, and interacting with phosphate groups of phospholipids and with carboxyl groups of sialic acid. Zinc may inhibit some calmodulin-stimulated functions. In another important role, zinc molecules in plasma must bind to newly synthesized thymulin and other thymic hormones in order to activate them, and allow these hormones to stimulate T lymphocytes throughout the body.

Zinc deficiency and immunity

Severe, or even marginal, deficiencies of zinc lead to reversible dysfunctions of human T lymphocytes.

Zinc deficiency is easily produced in laboratory animals, with a prompt development of numerous abnormalities in immune functions. Zinc deficiency consistently leads to atrophy of the thymus and other lymphoid organs, to reduced lymphocyte numbers in tissues (especially in the T cell areas) and to lymphopenia. Zinc deficiency is accompanied by anergy, manifested predominantly by dysfunctions of cell-mediated immunity, along with some depression in the production of T cell-dependent antibodies and splenic plaque-forming cells.

Zinc deficiency initiates a selective decrease in CD4⁺ helper cell numbers. *In vitro* testing reveals a markedly reduced proliferative response by these cells to phytohemagglutinin and other mitogens. Natural killer cells also show decreased activity and T cell-mediated cytotoxicity is reduced. In zinc deficiency, lymphocytes have a reduced ability to produce interleukin 2 (IL-2) *in vitro*. These dysfunctions could be due to direct effects of zinc deficiency on individual lymphocytes and their metabolic mechanisms. But some dysfunctions, especially in T cells, could also be due to a concomitant reduction in the synthesis and zinc-dependent activation of thymic hormones. Zinc deficiency also has adverse effects on B cell functions, although not as marked as those seen in T cells.

Zinc deficiency also affects many nonspecific aspects of host defense. The production of monocytes and macrophages is reduced, and granulocytes exhibit impaired chemotaxis. Wound healing and tissue integrity become defective, with the development of extensive mucosal and dermal lesions, especially at mucocutaneous borders.

Dysfunctions in host defense mechanisms during

zinc deficiency thus include the immune system, monocyte/macrophages, granulocytes and the breakdown of anatomical surface barriers. Such combined problems make the zinc-deficient host extremely susceptible to infectious diseases, and greatly increases the severity of infections that do occur.

Effects of acute phase reactions on the distribution of body zinc

The body distribution of zinc responds in a unique and unusual manner during proinflammatory cytokine-induced acute phase reactions which accompany generalized infections, trauma or endotoxemia. Zinc concentrations in plasma show an abrupt decline, falling to about half of their normal values. This suddenly developing hypozincemia occurs because of a sequestration of zinc within hepatocytes, thymocytes and marrow cells. Zinc sequestration then persists throughout the duration of illness. The sequestration of zinc is the secondary consequence of the induced expression, caused by IL-1 and other proinflammatory cytokines, of metallothionein 1 and 2 genes within these responding cells. Newly synthesized intracellular metallothionein proteins generate binding sites for zinc, and lead to the hypozincemia which characterizes acute phase reactions. Biological reasons for this unique sequestration of zinc remain unknown, although macrophage activation may be enhanced by low plasma zinc values.

The broad spectrum of zinc deficiency

Zinc deficiency is generally present whenever protein-energy malnutrition is seen. The losses of body nitrogen that occur during the acute phase reactions to febrile illness or severe trauma, measured by negative balances, are accompanied by concomitant, comparable losses of body zinc (as well as by the previously described sequestration of zinc). Zinc deficiency can also occur as an isolated nutritional problem if zinc intakes are low, or if there is an inherited defect in intestinal zinc absorption.

Since the intestinal absorption of zinc is an active process, zinc deficiency can occur if absorption is inhibited. Phytates and some dietary fibers can bind zinc within the intestinal tract and thereby impair its absorption. The congenital disease acrodermatitis enteropathica is due to a defective intestinal absorption of zinc. Infants with this disease exhibit exten-

sive mucocutaneous lesions, immunological defects and severe infections which lead to an early death. Fortunately, an increase in oral zinc intake can usually reverse all manifestations of this disease. A similar congenital problem, seen in one variety of Friesian cattle, is also reversible with dietary zinc supplements. Zinc deficiency is also a factor in congenital epidermolysis bullosa.

Reversibility of zinc deficiency

The immunological aspects of zinc deficiency are, as a rule, easily and rapidly restored to normal by the oral administration of sufficient zinc. Excessive supplementation of diets with zinc, may, on the other hand, lead to immune system suppression. In the nutritional rehabilitation of children with severe protein-energy malnutrition (marasmus or kwashiorkor), supplementation with oral zinc may be necessary in order to restore the thymus to its normal size. Some studies in laboratory animals suggest that zinc malnutrition during fetal, and even neonatal life may result in a long-term impairments in the development and function of the immune system.
